Fig. 6.13 *ICP mass spectrum for* ^{237}*Np in environmental samples. The mean value of the concentration of* ^{237}*Np was obtained to be* 6.2×0.1 Bq kg^{-1} *based on intercomparison analysis using spectrometry by seven laboratories. Reprinted from Kim* et al. (1989), *with permission from Elsevier Sequoia S. A.*

carried out the ^{237}Np detection by RIMS and estimated the detection limit as 4×10^8 atoms (1.6×10^{-13} g) which is almost two orders of magnitude more sensitive than that by alpha spectrometry.

Accelerator mass spectrometry (AMS) was applied to the detection of ^{237}Np in environmental samples such as mud, sediment, and pore water (Fifield *et al.*, 1997). It was estimated that sensitivity by AMS approached 10^5 atoms (4×10^{-17} g) of ^{237}Np. The results obtained by such a highly sensitive method make it possible to elucidate a distribution behavior of neptunium in natural environment and therefore to conclude that neptunium is more mobile than plutonium in the environment.

6.10.6 Electrochemical methods

Electrochemical methods are feasible for the determination of the total concentration and redox speciation of neptunium ions. The reduction–oxidation processes between Np(VI) and Np(V) and between Np(IV) and Np(III) are practically reversible and of simple one-electron transfer characteristics, which enables various electroanalytical performance based on these electrode reactions. The electroanalytical data of neptunium mainly obtained by voltammetry and polarography were reviewed by Kihara *et al.* (1999).

(a) Potentiometric titration and coulometry

Titration methods based on the reduction–oxidation of neptunium ions have been widely used for the accurate and precise determination of 1–10 mg quantities of neptunium. A method proposed by Godbole and Patil (1979) consists of the oxidation of neptunium ions to Np(VI) with Ag(II), destruction of excess

Ag(II) with sulfonic acid, reduction of Np(VI) to Np(IV) by a slight excess of Fe(II) in 2 M H_2SO_4, and potentiometric titration of the excess Fe(II) with standard Ce(IV) solution. The end point was detected potentiometrically using a platinum indicator electrode. Cao *et al.* (1994) proposed an alternative amperometric titration method by the use of Cr(VI) instead of Ce(IV) to titrate Fe(II). They attained less than 0.3% relative standard deviation in the determination of 2 mg of neptunium.

Controlled-potential coulometry is the standard method based on a primary theory, which enables an accurate and precise determination of neptunium. Stromatt (1959) recommended the procedure that consists of the oxidation of neptunium ion to Np(VI) with Ce(IV), the electrolytic reduction of Np(VI) and the excess Ce(IV) to Np(V) and Ce(III), and coulometric determination of Np(V) by the oxidation of Np(V) to Np(VI).

Kasar *et al.* (1991) determined 2–5 mg of neptunium with a relative standard deviation of ±0.25% by controlled-potential coulometry consisting of oxidation to Np(VI) with Ce(IV), decomposition of the excess Ce(IV) with $NaNO_2$, and titration based on the reduction of Np(VI) to Np(IV) with internally and electrolytically generated Fe(II). Karelin *et al.* (1991) developed constant current coulometry adopting amperometric end point detection, which enabled the determination of neptunium in the solution coexisting with uranium, plutonium, cerium, chromium, iron, and manganese. Chemists at the Savannah River Plant, USA, developed an automatically controlled apparatus for coulometry that was applied to the determination of neptunium. Measurement precision within 0.1% was achieved (Holland and Cordaro, 1988). Narrow span controlled-potential coulometry, which can minimize the interference from ions of formal redox potential close to that of the ion to be determined, was developed (Kalsi *et al.*, 1994) and applied to the determination of neptunium with enough high reproducibility, e.g. with relative standard deviation of 0.2%, even in the presence of five times the concentration of plutonium. Kihara *et al.* (1999) proposed a flow-coulometry method using multi-step column electrodes of glassy carbon fibers working electrode for the determination and speciation of neptunium ions in acidic solutions. (The redox behavior of neptunium ions observed by flow-coulometry is described in detail in Section 6.8.1b.)

(b) Voltammetry and polarography

Polarography was applied to the simultaneous determination of Np(V) and U(VI) in samples from the spent nuclear fuel reprocessing process based on the fluoride vaporization (Li *et al.*, 1988). The reduction currents of Np(V) and U(VI) were recorded with the electrolyte solution of a mixture of 2 M acetic acid and 2 M ammonium acetate. Kuperman *et al.* (1988) developed potentiostatic voltammetry for the determination of 2×10^{-8} to 1×10^{-5} M of neptunium and plutonium ions. Yakovlev and Kosyakov (1991) developed anodic stripping voltammetry method for the determination of neptunium using column electrode of carbon fibers as a working electrode whose surface was modified by bis(2-ethylhexyl) phosphate. The recommended procedure consists of the electrolytic preconcentration of Np(VI) at the electrode surface and the measurement of the current peak due to the oxidation of Np(V) to Np(VI). The detection limit was ca. 10^{-7} M.

6.10.7 Mössbauer spectroscopy of ^{237}Np materials

Neptunium–237 is one of the best Mössbauer nuclei in the periodic table. ^{237}Np has the following characteristics which allow the Mössbauer spectroscopic measurement successful: (1) the lifetime of the excited state for Mössbauer transition is long enough, 68 ns, to obtain a sharp resonance line; (2) the spread range of the isomer shift is large enough to differentiate nature of chemical bonds from the shift; and (3) the radiation from a ^{237}Np absorber is low enough to record a spectrum in a standard transmission geometry. The most useful Mössbauer measurement system is the 60 keV radiation from ^{237}Np excited in the alpha decay of ^{241}Am. Nakada *et al.* (1998) developed a source assembly with small sources of ^{241}Am metal and designed the sealed holders to encapsulate the sample without the seepage of liquid helium.

Kalvius (1989) summarized basics and the power of Mössbauer spectroscopy of ^{237}Np in his review article demonstrating examples of study on 5f-electron structure of antiferromagnetic NpAs compounds and various Np(VI) and (VII) compounds. Jovè *et al.* (1991) reviewed applications of Mössbauer spectroscopy to the study of insulating neptunium compounds and discussed correlations between isomer shift, electric field gradient, and bonding or crystallographic structure of neptunium in crystallized or amorphous compounds of Np(III–VII).

Each oxidation state has a characteristic isomer shift range that is correlated with the number of 5f electrons present, and thus the isomer shift is a good indicator of the coordination number as well as the oxidation state of Np in a compound. The isomer shift increases regularly with decreasing oxidation state. Systematic trend of the isomer shift of ^{237}Np in various metal coordination complexes was studied and a linear dependence was found between the isomer shift and the mean neptunium–ligand distance in a series of Np(VI) compounds, which were summarized by Jovè *et al.* (1988a,b, 1991). Ionova and Jovè (1989) proposed a model, which correlated the population of the 5f orbital of ^{237}Np with the isomer shift, for the estimation of covalent effect in neptunium compounds based on the isomer shift. Bickel *et al.* (1987) studied the Mössbauer spectra of such oxoneptunates as $Li_5Np^{(VII)}O_6$, $Li_6Np^{(VI)}O_6$, $BaNp^{(VI)}O_4$, $Np^{(IV)}GeO_4$, $SrNp^{(IV)}O_3$, and $BaNp^{(IV)}O_3$. The isomer shifts were more negative or positive for the bond of ionic or covalent characteristics, respectively.

Sanchez *et al.* (1988) studied the electronic and magnetic properties of a novel intermetallic $NpRh_2Si_2$ by ^{237}Np Mössbauer spectroscopy. The isomer shift ranging from 5.3 (at 4.2 K) to 4.8 mm s^{-1} (at 77 K) with respect to $NpAl_2$ suggested a Np^{4+} electronic configuration in conducting materials.

Nakamoto *et al.* (1998) and Saeki *et al.* (1999) measured Mössbauer spectra of Np(v) compounds such as formate, $NpO_2OOCH \cdot H_2O$, and $NH_4NpO_2(OOCH)_2$, glycolate, $NpO_2OOCCH_2OH \cdot H_2O$, malonate $(NpO_2)_2C_3H_2O_4 \cdot 4H_2O$, and phthalate $(NpO_2)_2(OOC)_2C_6H_4 \cdot 4H_2O$, and found a good correlation between coordination numbers of Np atoms and isomer shifts in the range from –18.6 to –19.1 mm s^{-1} for the compounds with Np atoms surrounded by seven oxygen atoms, i.e. coordination number = 7. The isomer shift for Np of coordination number 8 in the compound is larger than that of coordination number 7. Isomer shifts of Np(iv) to (vii) with different coordination numbers in the compounds are summarized in Fig. 6.14 (Saeki, 2003).

Heptavalent neptunium compounds have been studied by Mössbauer spectroscopy. The characteristic isomer shift of Np(vii) has been reported to be from –64 to –75 mm s^{-1} with respect to $NpAl_2$ (Stone *et al.* 1969; Fröhlich *et al.* 1972; Ilyatov *et al.* 1975; Grigor'ev *et al.* 1979; Ananyev *et al.* 1980). Recently Nakamoto *et al.* (1999) reinvestigated the Mössbauer spectra for Np(vii) in $[Co(NH_3)_6][NpO_4(OH)_2] \cdot 2H_2O$ at 4.2 K. They pointed out that the fitting by using two quadrupole-split peaks did not give a good agreement with the previous data by Stone *et al.* (1969), although the spectrum observed by Nakamoto *et al.* (1999) consisted of two quadrupole-split peaks.

Filin *et al.* (1989, 1990) studied ^{237}Np Mössbauer emission spectra resulting from the alpha decay of ^{241}Am in various solid solutions of actinide dioxides. The oxidation state of ^{237}Np in ^{241}Am(0.6 and 11 at%) + PuO_2 was determined from the isomer shifts of –5.8 and 18.5 mm s^{-1} relative to $NpAl_2$ to be Np^{4+} and Np^{5+}, respectively. They found that the oxidation state strongly depended on the matrix stoichiometry of PuO_2 as well as on the content of the impurity in the sample.

6.10.8 Miscellaneous methods

Speciation of neptunium in samples has been a strong analytical interest and requirement, because the ions of five oxidation states from (iii) to (vii) are stable under certain conditions and the ions form complexes differently with many kinds of ligands. The methods for the speciation were evaluated recently by OECD/NEA (2001).

The redox speciation of neptunium ion of relatively high concentration can be performed by direct absorption spectrophotometry (see Section 6.10.2) or electrochemical methods (see Section 6.10.6). For the redox speciation of neptunium ion at lower concentration, e.g. in environmental samples, a method utilizing chemical separation between ions of different oxidation states followed by the determination of the ions using sensitive methods such as radiometric methods and ICP-MS is employed. Coprecipitation with such precipitates as LaF_3, followed by solvent extraction with, e.g. HTTA, can be used for the separation. It is essential that the separation method does not disturb the

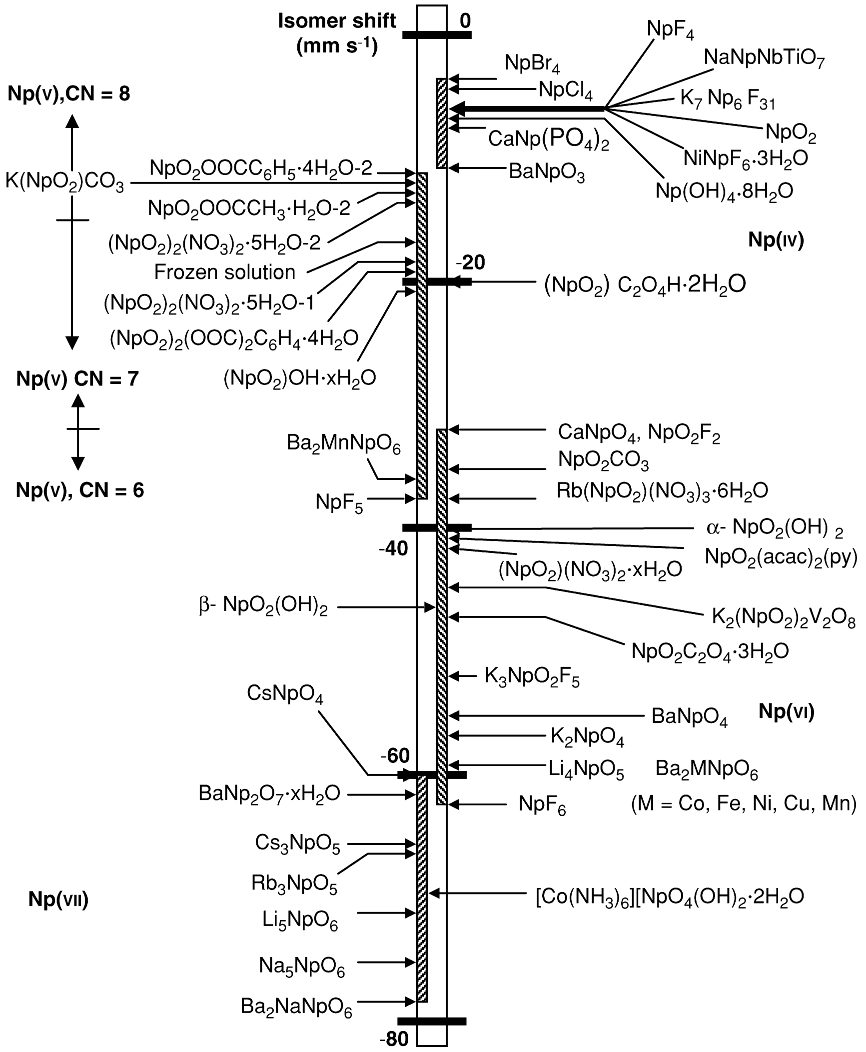

Fig. 6.14 *Isomer shifts of Np(IV), (V), (VI), and (VII) compounds.*

redox equilibrium during the treatment of the sample. Mang *et al.* (1993) investigated a continuous electrophoretic ion focusing method for the separation of Np(vi) from Np(v) at a trace concentration level, e.g. 10^{-14} M level using ^{239}Np tracer. Np(vi) was not stable enough under the recommended conditions. The Np(iv) and Np(v) species were well focused and separated with very reproducible peaks by continuous ion focusing with glycolic acid and tartaric acid.

Chen *et al.* (1992) employed traditional solvent extraction with HTTA and TOPO for the separation of Np(vi), Np(v), and Np(iv). Enokida and Suzuki (1987) employed extraction chromatography with TBP-impregnated resin for the separation of 10^{-5} M levels of neptunium ions of different oxidation states. Nagasaki *et al.* (1988) recommended a paper electrophoresis method for the redox speciation of neptunium ions.

X-ray absorption fine structure (XAFS) was applied to the speciation of Np(v) in an aqueous solution containing high concentration of chloride salt (Allen *et al.*, 1997), and adsorbed at the interface between alpha-Fe hydroxide solid and aqueous solution (Combes *et al.*, 1992).

High-resolution ultraviolet and X-ray photoelectron spectroscopy (UPS and XPS) were applied to characterize the surface of neptunium metal (Naegele *et al.*, 1987). An oxide layer of Np(iii), i.e. Np_2O_3, was found in the near surface of about 10 Å in thickness of the sample.

CHAPTER SEVEN

PLUTONIUM

David L. Clark, Siegfried S. Hecker, Gordon D. Jarvinen, and Mary P. Neu

7.1 INTRODUCTION

The element plutonium occupies a unique place in the history of chemistry, physics, technology, and international relations. After the initial discovery based on submicrogram amounts, it is now generated by transmutation of uranium in nuclear reactors on a large scale, and has been separated in ton quantities in large industrial facilities. The intense interest in plutonium resulted from the dual-use scenario of domestic power production and nuclear weapons – drawing energy from an atomic nucleus that can produce a factor of millions in energy output relative to chemical energy sources. Indeed, within 5 years of its original synthesis, the primary use of plutonium was for the release of nuclear energy in weapons of unprecedented power, and it seemed that the new element might lead the human race to the brink of self-annihilation. Instead, it has forced the human race to govern itself without resorting to nuclear war over the past 60 years. Plutonium evokes the entire gamut of human emotions, from good to evil, from hope to despair, from the salvation of humanity to its utter destruction. There is no other element in the periodic table that has had such a profound impact on the consciousness of mankind.

In 2005, approximately 2000 metric tons of plutonium exist throughout the world in the form of used nuclear fuel, nuclear weapons components, various nuclear inventories, legacy materials, and wastes (Albright and Kramer, 2004). This number grows every year by 70 to 75 metric tons through production in irradiated nuclear fuels (Albright and Kramer, 2004). It is clear that the large inventories of plutonium must be prudently managed for many centuries. A complex blend of global political, socioeconomic, and technological challenges must be dealt with to manage these inventories efficiently and safely.

From physical, chemical, and technological perspectives, plutonium is one of the most complex and fascinating elements in the periodic table. The metal exhibits six solid allotropes at ambient pressure and its phases are notoriously unstable with temperature, pressure, chemical additions, and time. With little provocation, the metal can change its density by as much as 25%. It can be as brittle as glass or as malleable as aluminum; it expands when it solidifies, and its freshly machined surface will tarnish in minutes. It is highly reactive in air, has five chemical oxidation states (six if the metal is included), and can form numerous compounds and complexes in the environment and during chemical processing. Plutonium's continuous radioactive decay causes self-irradiation damage of the metal lattice, or modification of solutions containing plutonium ions. Plutonium sits near the middle of the actinide series, which marks the emergence of 5f electrons in the valence shell. Elements to the left of plutonium have delocalized (bonding) electrons, while elements to the right of plutonium exhibit more localized (nonbonding) character. Plutonium is poised in the middle, and in the δ-phase metal, the electrons seem to be in a unique state of being neither fully bonding nor localized, a property that leads to novel electronic interactions and unusual physical and chemical behavior. This position in the periodic table challenges our understanding of relativistic electronic interactions and the nature of chemical bonding in heavy element metals, compounds, and complexes. When the unique nuclear properties are also considered, the study of plutonium is inherently multidisciplinary in nature. The present discussion will be confined to the most recent aspects of the subject. Reviews describing aspects of the chemistry and physics of plutonium can be found by Keller (1971), Cleveland (1979), Wick (1980), Cooper and Schecker (2000), Hecker (2003), Hecker *et al.* (2004), and in the *Gmelin Handbook of Inorganic Chemistry* (Koch, 1972, 1976a,b).

7.2 HISTORICAL

When the first of the transuranium elements, neptunium (Chapter 6) was discovered, it was realized that the radioactive β decay of $^{239}_{93}\mathrm{Np}$ should lead to the formation of element 94. The scale of the experiments at that time, however, precluded its identification. Plutonium was first produced late in 1940 by Seaborg, McMillan, Kennedy, and Wahl (Seaborg *et al.*, 1946, 1949a) by bombarding uranium with deuterons to produce the isotope $^{238}\mathrm{Pu}$:

$$^{238}_{92}\mathrm{U} + ^{2}_{1}\mathrm{H} \rightarrow ^{238}_{93}\mathrm{Np} + 2\,^{1}_{0}\mathrm{n} \qquad (7.1)$$

$$^{238}_{93}\mathrm{Np} \xrightarrow[2.1\mathrm{d}]{\beta^-} {}^{238}_{94}\mathrm{Pu}\ (t_{1/2} = 87.7\,\text{years}) \tag{7.2}$$

The short half-life of ^{238}Pu was conducive to tracer studies, and allowed Seaborg, Wahl, and Kennedy to obtain enough chemical information for subsequent separation and isolation of other plutonium isotopes. The isotope of major importance, ^{239}Pu, was discovered in 1941. Bombardment of $^{238}_{92}$U by neutrons produced $^{239}_{92}$U, which decayed to $^{239}_{93}$Np, and ultimately to $^{239}_{94}$Pu:

$$^{238}_{92}\mathrm{U} + {}^{1}_{0}\mathrm{n} \rightarrow {}^{239}_{92}\mathrm{U} + \gamma \tag{7.3}$$

$$^{239}_{92}\mathrm{U} \xrightarrow[23.5\ \mathrm{min}]{\beta^-} {}^{239}_{93}\mathrm{Np} \xrightarrow[2.36\,\mathrm{days}]{\beta^-} {}^{239}_{94}\mathrm{Pu}\,(t_{1/2} = 24,110\ \text{years}) \tag{7.4}$$

In 1941 Kennedy, Seaborg, Segré, and Wahl established the fissionability of ^{239}Pu with slow neutrons (Kennedy *et al.*, 1941). This crucial experiment revealed the potential of ^{239}Pu as a nuclear energy source. In March 1942, element 94 was christened 'plutonium' with the chemical symbol 'Pu' (Seaborg and Wahl, 1948a). Plutonium was named after the planet Pluto, following the pattern used in naming neptunium.

In August 1942, Cunningham and Werner, working at the wartime Metallurgical Laboratory at the University of Chicago, succeeded in isolating about 1 μg of $^{239}_{94}$Pu, which was prepared by cyclotron irradiation of 90 kg of uranyl nitrate (Cunningham and Werner, 1949a). This experiment made plutonium the first man-made element to be obtained (as Pu(IV) iodate) in a visible quantity. These same investigators carried out the first weighing of this man-made element using a larger sample size of 2.77 μg, on September 10, 1942.

Plutonium is now produced in much larger quantities than any other synthetic element. The large wartime chemical separation plant at Hanford, Washington, was constructed on the basis of investigations performed on the ultramicro chemical scale of investigation. The scale-up between ultramicro chemical experiments and the final Hanford plant corresponds to a factor of about 10^{10} (Seaborg, 1958). Seaborg and Cunningham give detailed first-hand accounts of the early history of plutonium in the *Proceedings of the 1963 Plutonium Chemistry Symposium* (1963). More recent descriptions of this fascinating history have been given by Seaborg (1977, 1978, 1979, 1980, 1983, 1992, 1995), Seaborg and Katz (1990), Seaborg and Loveland (1990), and by Hoffman *et al.* (2000).

7.3 NUCLEAR PROPERTIES

Numerous isotopes of plutonium have been synthesized, all of which are radioactive. These are listed in Table 7.1. The most recent isotope to be discovered is ^{231}Pu, which was reported in 1999 (Laue *et al.*, 1999). For data on nuclear masses the reader is referred to the compilation by Audi and Wapstra (1995),

Table 7.1 *Radioactive decay properties of plutonium isotopes*[a].

and the update by Audi *et al.* (1997). A more detailed description of the nuclear properties of the individual plutonium isotopes may be found in the book by Hyde *et al.* (1964), in the *Table of Isotopes* (Firestone *et al.*, 1996, 1998), and in *Nuclear Data Sheets* (Tuli, 2004). As mentioned above, ^{238}Pu was the first of the plutonium isotopes discovered. Because of its relatively short half-life, it is a particularly useful tracer for plutonium. ^{238}Pu is readily obtained by neutron bombardment of ^{237}Np in the reaction:

$$^{237}\mathrm{Np}(\mathrm{n},\gamma)^{238}\mathrm{Np} \xrightarrow{\beta^-} {}^{238}\mathrm{Pu} \tag{7.5}$$

The ^{238}Pu is chemically separated from unreacted ^{237}Np by ion-exchange techniques (Burney, 1962; Tetzlaff, 1962; Coogler *et al.*, 1963; Burney and Thompson, 1972, 1974). ^{238}Pu may also be obtained from the α decay of ^{242}Cm and subsequent chemical separation from undecayed curium (Thompson, 1972). Because of its power density of 6.8–7.3 W cm^{-3} (specific power 0.57 W g^{-1}), ^{238}Pu has found important applications in radioisotope power systems – nuclear power systems that derive their energy from the spontaneous decay of radionuclides as distinguished from nuclear fission energy created in a nuclear reactor. Most radioisotope power systems utilize ^{238}Pu as an isotope heat source and an energy conversion system to partially transform the heat produced from ^{238}Pu radioactive decay into electricity (Lange and Mastal, 1994).

In the late 1960s, cardiac pacemakers suffered from early battery exhaustion, and the use of nuclear pacemakers whose battery life could outlive the patient was examined (Boucher and Quere, 1981; Pustovalov *et al.*, 1986). The first implantation of a ^{238}Pu-powered nuclear pacemaker was performed in France on April 27, 1970. Since that time, nuclear pacemakers powered by ^{238}Pu were implanted in patients in a number of countries. The overall results of these studies indicated that nuclear pacemakers required fewer follow-up operations and less maintenance, and were found to be safe and reliable. Subsequent advances in electronics in the intervening years rendered the plutonium-powered devices obsolete, and their use was discontinued. In 2004, there were still a number of living patients with ^{238}Pu pacemakers that had been functioning for over 30 years (Parsonnet *et al.*, 1990; Freedberg *et al.*, 1992; Parsonnet, 2004).

The most prevalent application for ^{238}Pu is as an important fuel for heat and power sources for space exploration (Lange and Mastal, 1994; Rinehart, 2001). For space exploration, heat source fuel is normally enriched to 83.5% in the ^{238}Pu isotope, and the oxygen atoms in ^{238}PuO$_2$ are enriched in ^{16}O to reduce the neutron emission rate to as low as 6000 n s^{-1} g^{-1} ^{238}Pu. In freshly prepared fuel, the specific power is 0.4743 W g^{-1} Pu or 0.4181 W g^{-1} PuO$_2$. The ^{238}Pu isotope provides 99.9% of the thermal power in heat source fuel. Radioisotope thermoelectric generators (RTGs) have been used in the United States to provide electrical power for spacecraft since 1961 (Angelo and Buden, 1985). Early ^{238}Pu-fueled power sources employed Space Nuclear Auxiliary Power (SNAP) units to power satellites and remote instrument packages (DOE, 1987;

Lange and Mastal, 1994). SNAP units served as power sources for instrument packages on the five Apollo missions to the Moon, the Viking unmanned Mars Lander, and the Pioneer and Voyager probes to the outer planets (Jupiter, Saturn, Uranus, Neptune and beyond). The SNAP-3B and SNAP-9A systems were fueled with plutonium metal, the SNAP-19 and Transit systems were fueled with $^{238}PuO_2$–molybdenum cermets, and the SNAP-27 unit was fueled with $^{238}PuO_2$ microspheres (Rinehart, 2001). Voyager missions employed Multihundred Watt Radioisotope Thermoelectric Generators (MHW-RTGs) that consisted of 24 100-W heat sources of $^{238}PuO_2$ (Fig. 7.1) each enclosed in an iridium shell, a graphitic impact material, an ablative heat shield, and a thermoelectric material to convert the decay heat to electrical power at a design voltage of 30 V (Kelly, 1975; De Winter *et al.*, 1999).

The current systems employ General Purpose Heat Source-Radioisotope Thermoelectric Generators (GPHS-RTGs) fueled by $^{238}PuO_2$ pellets. Each GPHS consists of a hot-pressed 150 g pellet of $^{238}PuO_2$ encapsulated in an iridium alloy (iridium-0.3% tungsten) container or clad (Fig. 7.2). Each iridium

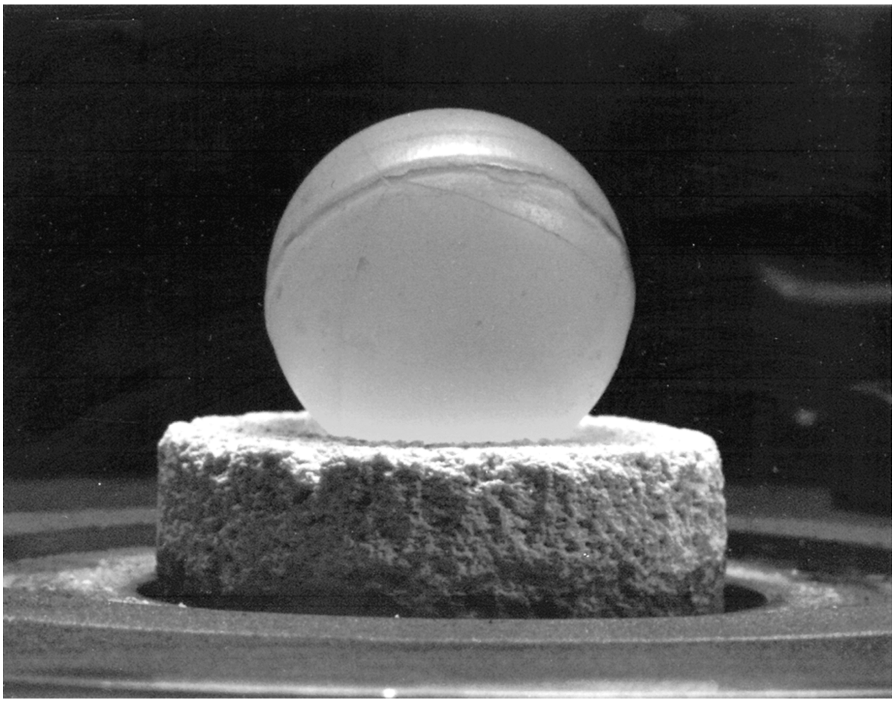

Fig. 7.1 *A* 100 W ^{238}*Pu heat source used in multihundred watt radioisotope thermoelectric generators* (*MHW-RTGs*) *employed in the Voyager space missions. clad contains a sintered iridium powder frit vent designed to release the helium generated by the α-particle decay of the $^{238}PuO_2$. The heat sources are packed in a tightly woven pierced fabric™ graphite aeroshell assembly that protects the fuel from impact, fire, or atmospheric reentry. The RTG consists of 72 GPHS pellets and a thermoelectric converter. The GPHS-RTGs flown on the Galileo, Ulysses, and Cassini spacecraft (3 RTGs per spacecraft) had a mass of 54 kg of PuO_2 and supplied 285 W of electrical power at the beginning of the mission from 4300 W of ^{238}Pu decay heat (Rinehart, 2001). These plutonium power sources have enabled huge advances in our scientific understanding of the solar system. The Cassini–Huygens spacecraft arrived at Saturn on June 30, 2004, and will provide vast amounts of new scientific data on the Saturnian system in the years to come.

Smaller Light Weight Radioisotope Heater Units (LWRHUs) are also used to maintain spacecraft equipment within their normal operating temperature range (Rinehart, 1992). The LWRHUs are cylindrical fueled clads consisting of a hot-pressed, 2.67 g pellet of $^{238}PuO_2$ encapsulated in a Pt-30%Rh container with a sintered platinum powder frit vent to release helium as shown in Fig. 7.3. As in the GPHS, the capsules are contained in a pyrolytic graphite insulator and aeroshell assembly (Rinehart, 2001). These smaller heater units have been employed on the Pioneer 10 and 11, Galileo, Mars Pathfinder, Mars Exploration Rovers (Spirit and Opportunity), and Cassini spacecraft, and are planned for use in many future missions.

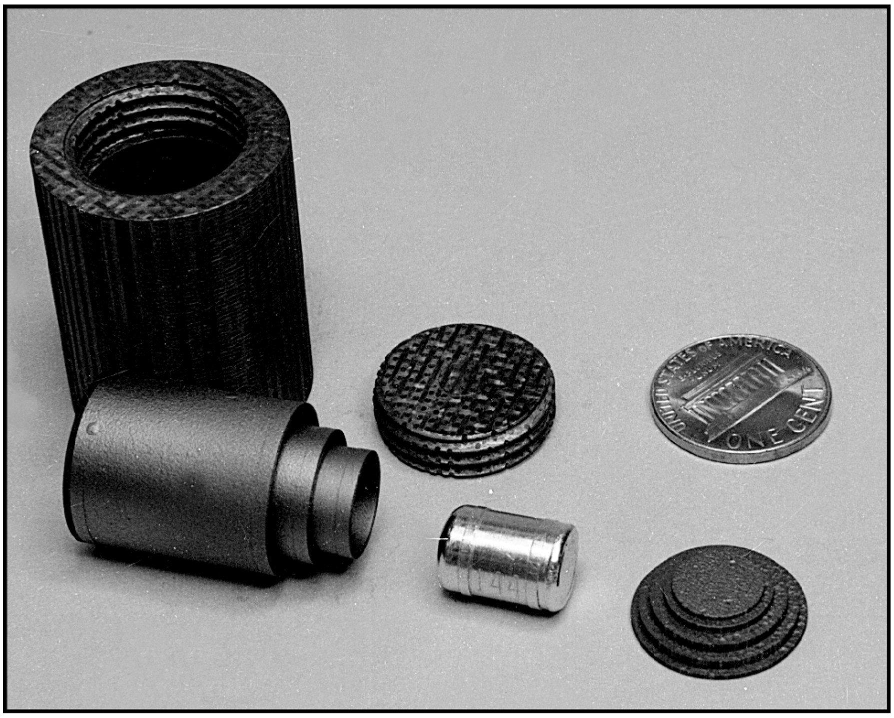

Fig. 7.3 *A* ^{238}*Pu lightweight radioisotope heater unit* (*LWRHU*) *before final assembly. The heat source consists of a fine weave pierced fabric graphite aeroshell, three inner layers of pyrolytic graphite thermal insulators, and a Pt-*30% *Rh-fueled clad containing a hot pressed* 2.67 g *pellet of* $^{238}PuO_2$ *that produces* 1 *thermal watt. The aeroshell serves as the primary heat shield to protect the interior components from aerodynamic forces and thermal heating during accidental atmospheric reentry as well as protecting the fueled clad from mechanical loads during ground impact. The pyrolytic graphite sleeves and plugs serve as thermal shields to keep the fueled clad from melting during an accidental reentry in the atmosphere* (*photograph courtesy of Los Alamos National Laboratory*).

Plutonium-239 is the most important isotope of plutonium. Its half-life (24,110 years) is sufficiently long to permit the preparation of this isotope in large-scale amounts, and to make it feasible to carry out conventional scientific studies. ^{239}Pu has a high cross-section for fission with slow neutrons, and is the isotope that serves as nuclear fuel for both nuclear power and nuclear weapons. By far the greatest portion of the knowledge of the chemical and physical properties of plutonium has been acquired by the use of ^{239}Pu. While its half-life is long enough to permit chemical studies, it is still short enough to present serious problems in handling. These difficulties are discussed in some detail below (Section 7.6). ^{239}Pu has a specific power of 2.2×10^{-3} W g^{-1}. In handling large quantities of ^{239}Pu, the criticality hazard caused by its fissionability becomes an additional problem. Amounts as small as 500 g may become critical

under certain conditions. In Table 7.2 some minimum critical parameters for pure ^{239}Pu obtained in various configurations have been summarized (Clark, 1981). Additional safety and criticality data are available in the compilations by Paxton (1975), Clark (1981), Knief (1985), and Paxton and Pruvost (1987).

The higher plutonium isotopes are formed as a result of successive neutron capture by the various plutonium isotopes:

$$^{239}\mathrm{Pu}(n,\gamma)^{240}\mathrm{Pu}(n,\gamma)^{241}\mathrm{Pu}(n,\gamma)\ \text{etc.} \tag{7.6}$$

The isotopic composition of plutonium produced in a nuclear reactor will therefore vary according to the length of time the plutonium formed is allowed to remain in the neutron flux. From this perspective it is noteworthy that the heavier isotopes ^{244}Pu, ^{245}Pu, and ^{246}Pu were originally discovered in the coral debris of the Mike thermonuclear test conducted in 1952, due to the extremely high neutron fluxes of the event. Hoffman, Ghiorso, and Seaborg described the events that led to the discoveries of these isotopes (Hoffman *et al.*, 2000). When ^{239}Pu targets were irradiated in a high-flux reactor to more than 90% burn-up, the residual plutonium was found to consist mainly of the higher isotopes ^{242}Pu and some ^{244}Pu. Many of the complications arising from the use of the relatively short-lived ^{239}Pu can be greatly ameliorated by the use of these long-lived isotopes of plutonium for fundamental scientific study.

Isotopically pure ^{240}Pu, ^{241}Pu, ^{242}Pu, and ^{244}Pu have become available from various sources. ^{240}Pu may readily be obtained by chemical separation from old ^{244}Cm samples. All the heavier plutonium isotopes have also been isotopically separated by electromagnetic separation in the Y-12 calutron plant in Oak Ridge (Love *et al.*, 1961; Love, 1973), but presently these calutrons have been placed in a standby condition. Gram quantities of these isotopes with isotopic purity above 99% were available from such separations. Russian scientists have also been very successful in producing research quantities of higher plutonium isotopes using electromagnetic mass separation. Ultrapure ^{236}Pu and ^{237}Pu have been produced by Dmitriev and coworkers at the Joint Institute for Nuclear Research in Moscow (Dmitriev *et al.*, 1993, 1995, 1997), and Vesnovskii and Polynov at the Institute of Experimental Physics in Arzamas have been able to produce milligram to gram quantities of ^{240}Pu, ^{241}Pu, ^{242}Pu, and ^{244}Pu at greater than 99% isotopic purity (Vesnovskii and Polynov, 1992a,b). Milligram quantities of ^{244}Pu have been prepared at the IAEA Safeguards Analytical Laboratory in Austria using electromagnetic separation (Deron and Vesnovskii, 1999) and by selective ionization using a pulsed laser beam in Japan (Sasao and Yamaguchi, 1991).

The higher isotopes of plutonium possess interesting nuclear properties, which cannot be discussed in detail here. For further information see Hyde *et al.* (1964).

7.4 PLUTONIUM IN NATURE

Traces of plutonium are found all over the world, predominantly due to 'man-made' plutonium. In addition, two isotopes of plutonium (^{239}Pu and ^{244}Pu) can be found that are 'natural' in origin. Natural ^{239}Pu is produced in nature by nuclear processes occurring in uranium ore bodies, and minute traces of ^{244}Pu exist in nature as remnants of primordial stellar nucleosynthesis.

The presence of small amounts of plutonium in uranium of natural origin was first established in 1942 by Seaborg and Perlman (1948) and by Garner *et al.* (1948). These researchers were able to show that Canadian pitchblende and Colorado carnotite both contain a small amount of alpha activity due to a plutonium isotope, presumed to be ^{239}Pu at the time. Peppard *et al.* (1951) and Levine and Seaborg (1951) conclusively demonstrated the existence of ^{239}Pu in nature. Levine and Seaborg determined the plutonium content of a number of uranium ores, and Peppard and coworkers isolated microgram amounts of ^{239}Pu from uranium process wastes. Recent high-resolution thermal ionization mass spectrometry analyses of plutonium in uranium ore bodies have been described by Curtis *et al.* (1999) and by Dixon *et al.* (1997). The concentrations of plutonium in uranium ore bodies are collected in Table 7.3. No plutonium isotopes other than ^{239}Pu have been conclusively found in any of these experiments. More recently, ^{239}Pu has also been detected in granites from deep boreholes in Germany, and in salt brines from deep boreholes in the United States (Ganz *et al.*, 1991). Alpha pulse analysis and high-resolution mass spectrometry have been the experimental methods of choice for characterization of the isotopic composition of plutonium isolated from natural sources.

With the exception of the very long-lived ^{244}Pu, the half-lives of plutonium isotopes are so short that it is most unlikely that any plutonium except ^{244}Pu

Table 7.3 *Content of plutonium in natural uranium ore deposits.*

Colorado carnotite	10	<0.4	Levine and Seaborg (1951)

could have survived in nature from primordial times. It is overwhelmingly likely that ^{239}Pu arises in nature by nuclear reactions with ^{238}U and represents a steady-state concentration:

$$^{238}\mathrm{U}(\mathrm{n},\gamma)^{239}\mathrm{U} \xrightarrow{\beta^-} {}^{239}\mathrm{Np} \xrightarrow{\beta^-} {}^{239}\mathrm{Pu} \tag{7.7}$$

Neutrons necessary for the formation of ^{239}Pu from ^{238}U may arise from spontaneous fission of ^{238}U; by neutron multiplication in ^{235}U; from (α,n) reactions caused by the action of α particles (from the radioactive decay of uranium and daughters) on the nuclei of light elements in the ore (Li, B, Be, F, O, Si, Mg); and neutrons produced by cosmic rays. The neutrons from cosmic rays appear to be of negligible importance, since the neutron production from uranium by the capture of μ mesons is considerably less than 0.1% of the neutrons arising from spontaneous fission (Littler, 1952). Spontaneous fission in uranium occurs at the rate of (24.2 ± 0.5) fissions per gram per hour, which produces a neutron flux insufficient to account for the observed plutonium concentration. Neutron multiplication by capture of thermalized neutrons in ^{235}U and the production of fission neutrons will contribute to overcoming the deficiency. The contribution from this source will clearly depend on the uranium concentration, on the composition of the ore, and on the probability that a fission neutron will be slowed down to thermal energies. In all probability, the neutrons produced in (α,n) reactions account for a major portion of the neutrons required for ^{239}Pu formation. Fleming and Thode (1953a,b) found evidence that (α,n) and (α,p) reactions occur to a considerable extent in uranium minerals. This conclusion was reached from a study of the isotopic composition of argon obtained from uranium minerals. In thorium ores containing small amounts of uranium, the neutrons from (α,n) reactions predominate. The amount of plutonium created depends not only on the number of neutrons produced but also on their subsequent fate. Elements with high neutron-capture cross-sections will compete for neutrons and decrease plutonium formation. In carnotite, potassium and vanadium atoms, and in fergusonite, tantalum atoms capture most of the available neutrons, thus accounting for the unusually low plutonium content found in these minerals (Table 7.3).

A fascinating example of the formation of ^{239}Pu by neutron multiplication in ^{235}U was found by French scientists in the uranium deposit at Oklo in the Gabon, Africa. From anomalies in the isotopic composition of rare earths (especially neodymium) and anomalies in the ^{235}U content, it was concluded that, in at least six different locations of this deposit, a self-sustaining nuclear chain reaction must have occurred (Bodu *et al.*, 1972; Neuilly *et al.*, 1972). It was found that, in these locations, a burn-up of part of the original ^{235}U had occurred, but the depletion found was not as great as one would have expected from the observed anomalies in the isotope composition of other elements. It is generally agreed that ^{239}Pu is formed through resonant capture of epithermal neutrons by the ^{238}U present in the matrix, and that subsequent radioactive decay of the ^{239}Pu again regenerates a fraction of the ^{235}U (Holliger and Devillers, 1981; Hidaka and Holliger, 1998; Hidaka, 1999). Since no plutonium has been found in the Oklo deposit, one may conclude that the self-sustaining chain reaction must have taken place around 1.9×10^9 years ago (Cowan, 1976).

A different situation exists with regard to ^{244}Pu, which is sufficiently long-lived to have survived from primordial times. In 1960, Kuroda postulated the existence of ^{244}Pu in the early solar system based on the Xe isotope ratios found in chondritic meteorites (Kuroda, 1960). In 1971, Alexander and coworkers measured the ratios of the Xe isotopes formed by spontaneous fission (SF) of ^{244}Pu and found they agreed with those found in chondritic meteorites, thus strongly supporting this hypothesis and SF decay of ^{244}Pu (Alexander *et al.*, 1971). The discovery of ^{244}Pu fission xenon in extraterrestrial samples such as the Moon (Kuroda and Myers, 1998), Martian (Marty and Marti, 2002), and other meteorites demonstrated that the transuranium elements were synthesized in exploding (supernovae) stars (Kuroda and Myers, 1998).

Conclusive proof for the occurrence of natural ^{244}Pu in a pre-Cambrian bastnasite ore was provided by Hoffman and coworkers (Hoffman *et al.*, 1971). Starting from approximately 85 kg of ore containing 10% bastnasite, these workers isolated 2×10^7 atoms (8×10^{-15} g) of ^{244}Pu corresponding to about 10^{-18} g of ^{244}Pu per gram of pure bastnasite. The presence of ^{244}Pu was conclusively identified using high-resolution mass spectrometry. Thus it seems most probable that this ^{244}Pu sample is a remnant of the stellar debris that coalesced to form the solar system.

That even the richest uranium deposits are not likely to supersede synthetic methods as a source of plutonium can be appreciated from the fact that the microgram amounts of plutonium isolated by Peppard and coworkers (Peppard *et al.*, 1951) required the residues of 100 metric tons of ore concentrate for each microgram of plutonium recovered.

7.5 SEPARATION AND PURIFICATION

7.5.1 Introduction

At the end of 2003, a little more than 60 years after the discovery of the first plutonium isotope in 1940, about 1855 metric tons of plutonium existed, principally within irradiated fuel from nuclear power plants (Albright and Kramer, 2004). About 225 metric tons of plutonium that had been separated and purified for recycling in commercial nuclear fuel cycles was in the unirradiated form. Roughly 260 metric tons of plutonium with a high ^{239}Pu content has been separated for use in nuclear weapons programs worldwide. Some of this weapons plutonium has been declared excess to military needs and will be incorporated into the commercial nuclear power system. Production of plutonium for military use had greatly decreased by early in the 21st century, but the total plutonium inventory will continue to increase as a consequence of nuclear power production for the foreseeable future. The rate of plutonium production in fuel of operating reactors was estimated at 70–75 metric tons per year at the end of 2003. Clearly, the separation of plutonium has been carried out on a large scale. The management of the separated plutonium and the large quantities of highly radioactive by-products of this production will continue to be a challenge in the decades to come.

Plutonium isotopes are produced mainly from neutron absorption by ^{238}U and the subsequent product nuclei as shown in the simplified scheme in Fig. 7.4. The major pathway to plutonium proceeds through absorption of a neutron to give ^{239}U followed by two successive β^- decays to give ^{239}Np and then ^{239}Pu. Neutron absorption by ^{239}Pu produces higher isotopes of plutonium and other transuranic elements, in competition with neutron-induced fission. Beta decay by ^{241}Pu and ^{243}Pu and further neutron absorption leads to the production of higher actinides, americium, curium, etc., but these steps are not shown in the diagram for the sake of clarity. As the scheme for the production of plutonium isotopes suggests, the isotopic composition of plutonium produced in a

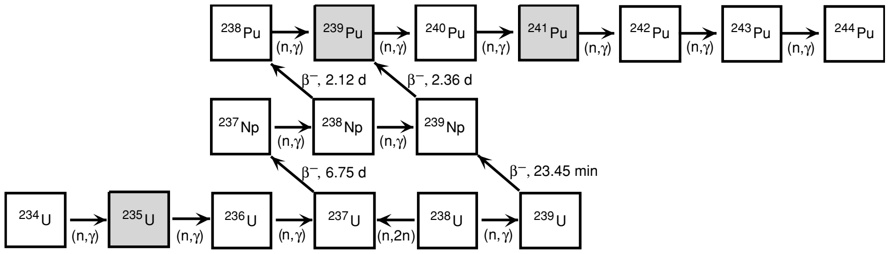

Fig. 7.4 *Major pathways for formation of plutonium isotopes by neutron absorption* (*n, γ*) *and beta decay* (β^-) *in uranium fuels or targets. Shaded boxes indicate most important isotopes undergoing neutron-induced fission in competition with neutron absorption.*

particular portion of the reactor fuel will be a complex function of the total flux and energy distribution of the neutrons that irradiate that fuel segment. The neutron flux and energy distribution will vary with irradiation time and the location of the fuel in the reactor.

The majority of nuclear power reactors around the world use low-enrichment uranium oxide fuels (^{235}U content of 3–5%) and light water (H_2O) to moderate the neutrons and act as the coolant for the system (Neeb, 1997). The uranium oxide fuel is fabricated into cylindrical pellets that are stacked inside a sealed container made of a cladding material such as a zirconium alloy to make a fuel pin. The plutonium content after 'burning' of these fuels amounts to about 1% of the mass of heavy metal content of the used fuel from a 'typical' light water reactor (LWR). Neutron-induced fission of the plutonium generated from neutron absorption by ^{238}U adds substantially to the total power production in commercial nuclear power plants ($\sim$40% of the total). The remaining mass of the used fuel consists of about 95% uranium, 4% fission products, and 0.1% all other transuranic actinides. It is the plutonium content in these 'spent' reactor fuels that provides most of the global plutonium inventory.

The build-up of the plutonium isotopes is accompanied by the production of a great variety of fission product elements. The fission process leads mostly to two product nuclei (only 0.2 to 0.3% of the fission events yield three fragments) that have an asymmetric statistical mass distribution with peaks at mass numbers of 95 and 138 for ^{235}U thermal (low energy) neutron-induced fission. The fission product nuclei commonly have excess neutrons relative to stable nuclei with the same atomic number and thus most are radioactive. The fission products decay primarily by beta/gamma chains to more stable nuclei. A calculation of the principal actinide and fission product isotopes present at the end of irradiation followed by 10 years of storage of a commercial reactor-type fuel is shown in Table 7.4. The burn-up of this fuel is higher than that used in most commercial plants to date, but the nuclear power industry trend is toward such higher burn-ups in the future. The list of fission product masses in Table 7.4 illustrates the two peaks in the fission product yield among the elements Zr through Pd and Xe through Nd. While the fission product masses do not change dramatically for most of the elements in the used fuel after 10 years of storage, the radioactivity has dropped more than two orders of magnitude and the ^{90}Sr and ^{137}Cs decay chains dominate the radioactivity of the used fuel from 10 years out to a few hundred years.

Inspection of Table 7.4 also illustrates that the fission products include elements from all the families of the periodic table. This considerably complicates the chemical problem of separation and purification of plutonium from the irradiated fuel. Additionally, the intense radioactivity requires facilities that use heavy shielding and remotely operated equipment to perform the separation processes. The mixture of plutonium isotopes present in the spent fuel is not so intensely radioactive and can be handled in a gloved box system once the fission products are removed. The term 'decontamination' is often applied to the

Table 7.4 *Actinide and fission product content of neutron-irradiated UO_2 fuel calculated using ORIGEN* 2 *code* (*Croff*, 1980, 1983)[a].

[a] Based on an initial uranium loading of 4.25% ^{235}U enrichment (957.5 kg ^{238}U, 42.5 kg ^{235}U, 0.293 kg ^{234}U), burn-up of 50 000 MW-days (metric ton)$^{-1}$ (Hill, 2005).

process of removing the fission products from the plutonium, uranium, or other actinides of interest in the irradiated fuel or target material. The decontamination factor measures the extent to which the concentration of fission products has been removed relative to the original level in the spent fuel at the time processing begins. To allow the product plutonium to be handled by personnel using a gloved box without undue exposure to fission product radioactivity, the decontamination factor required for some fission products is on the order of 10^8. Clearly, the required decontamination factors will vary with the cooling time of the fuel before processing begins.

The fission products and actinides produced from the irradiated uranium fuel are dispersed intimately in the fuel matrix (Neeb, 1997). The fission product nuclei dissipate their kinetic energy after traveling on average 5–10 μm through the uranium oxide matrix, leaving an ionization track and displacement cascade that ultimately generates most of the heat that is used to generate electricity. Atomic mixing occurs from both radiation-induced and thermal mass transport processes. In a typical LWR fuel each atom of the fuel is displaced from its lattice site an average of once a day. Some segregation of the fission product elements occurs under reactor conditions (Neeb, 1997). For example, inert gases such as xenon and krypton can form bubbles in the fuel matrix and even escape into the gas space inside a fuel pin, and some transition elements (Mo, Ru, Rh, Pd, Tc) form small metal inclusions in the uranium oxide. However, the bulk of the fission products and transuranic elements are dispersed fairly homogeneously within the uranium fuel. The uranium matrix must be dissolved into a suitable solution or converted into a volatile compound to allow the fission product and actinide 'impurities' to be separated from the uranium.

The methods used to recover plutonium (and other actinides) from irradiated fuels or targets can be divided into two major groups, aqueous and nonaqueous processes, depending on the primary phase used for the separation process. The major classes of aqueous processes are liquid–liquid extraction (solvent extraction), ion exchange, and precipitation. Examples of nonaqueous processes are electrorefining (ER) in molten salts and fluoride volatility. The separation methods use differences in the chemical properties of the various elements present to segregate some components preferentially between the primary phase and a secondary phase that can be a solid, liquid, or gas. Separation of the two phases partitions the components of the original single phase for further processing steps. These next steps can be additional stages of the same separation method (e.g., a bank of centrifugal contactors for extraction) or a different method (e.g., ion exchange followed by precipitation).

Nearly all of the separation methods take advantage of the multiple oxidation states that plutonium can adopt in its various chemical forms. The chemical properties of plutonium (and other metal ions) change to a large extent depending on the oxidation state. If conditions can be adjusted to obtain various metal ions in a mixture in different oxidation states, the separation of these metals is often straightforward. For example, in aqueous acid solutions it is possible to have uranium in the hexavalent oxidation state (as UO_2^{2+}), neptunium in the pentavalent state (as NpO_2^+), plutonium in the tetravalent state, and americium in the trivalent state. The complexes formed by ions in these different oxidation states in solution are quite different, so that separation by a number of methods is possible. In the case of an irradiated fuel with fission products present, if the chemical behavior of a fission product resembles that of plutonium in one oxidation state, it can be quite different when the plutonium oxidation state or the fission product element oxidation state is changed. The use of oxidation state changes to improve separations will be illustrated in the discussion of specific separation methods below.

The large-scale separation and purification of plutonium has been primarily accomplished using the Plutonium, Uranium, Reduction, EXtraction (PUREX) liquid–liquid extraction process. This process was first developed for separating plutonium from metallic uranium fuels irradiated to produce plutonium for nuclear weapons applications, but has since been adapted to separate uranium and plutonium from many kinds of fuels and targets, including commercial power reactor fuels. While a variety of other processes have been used to separate and purify plutonium from irradiated fuels, many of these are now of only historical interest. More detailed information on the separation technology for plutonium and the other actinides can be found in Chapter 24 of this work, *Actinide Separation Science and Technology*, including extensive documentation of the separation literature. The goal in this chapter is to present the main features of selected separation methods of particular importance to plutonium and to illustrate major factors guiding development of plutonium separation processes. Only brief references to the history of plutonium separations will be made here.

Processes for separation of plutonium from neutron-irradiated uranium metal, uranium oxide, or other irradiated target materials are one important group of plutonium separation and purification methods, but there are additional separation needs. Separated plutonium must be converted into the forms required for various applications, for example, purification of PuO_2 to meet all the specifications for mixed oxide (MOX) fuel fabrication. Recovery and recycle of plutonium from the process and waste streams of these conversion operations constitute another important group of separation processes. A wider variety of separation methods can be employed to accomplish these separations because the high radiation levels of the fission products are not present and the amount of material to be processed is typically much smaller. There is also a need for separation processes to remove plutonium from items that have been contaminated by plutonium-containing materials resulting from normal operations or accidental release to the environment, e.g. equipment, concrete, soils, etc. These types of operations are commonly referred to as decontamination methods; the radioactive contaminant is plutonium in this case rather than a fission product. Finally, a large number of separation methods and reagents have been used to preconcentrate or remove interfering components in analytical procedures for plutonium-containing samples to improve detection limits and accuracy of the results.

As the above discussion indicates, many processes have been developed for separating plutonium from a variety of matrices. There are often variations for a particular method and many combinations of methods possible for accomplishing a specific separation goal. The chosen process can be a result of many factors at a particular facility including available equipment and expertise, safety and operational limits, product specifications, national regulatory requirements, waste management, cost, and schedule. It is possible in some processes to vary operating conditions over a wide range and still obtain a desired result. In the discussion of separation methods that follow, variations in process conditions are common. Defining an 'optimum' process depends on factors like those mentioned above, which can vary even at a single facility over its lifetime. Operational details of this kind are beyond the scope of this chapter.

7.5.2 Introduction to aqueous-based separation methods

Before discussing aqueous separation processes for plutonium in more detail, a brief overview of actinide chemistry in aqueous solution is useful because most actinide separations have been performed using aqueous acid solutions.

The separation of actinides from basic aqueous solutions has been employed less often because the low solubilities of the hydroxides or oxyhydroxides of the high-valent actinide metal ions greatly limit the amount of material that can be processed in a given volume except where strongly complexing ligands, such as carbonate or peroxide, are present. More detailed information on the solution chemistry of plutonium (see Section 7.9) and the other actinide metal ions can be found in the appropriate sections of the chapters for each element and in other chapters of this work.

As noted above, the separation of plutonium and the other early actinides (Th–Am) from fission products and from each other is generally accomplished by adjusting the oxidation state of the actinide ion in aqueous solution to make the coordination chemistry of the actinide ion substantially different from the other species to be separated. The actinides are highly electropositive metals and form cationic species in aqueous solutions. These cations are 'hard' Lewis acids and form strong complexes in solution with hard anions such as hydroxide and fluoride. The oxidation states from III to VI are accessible in aqueous acid solutions of uranium, neptunium, and plutonium. After plutonium the actinides become more lanthanide-like with the coordination chemistry of the trivalent metal ion dominating. The pentavalent and hexavalent actinide ions are found in aqueous solutions as linear dioxo cations, e.g. NpO_2^+ and PuO_2^{2+}. These 'actinyl' species have no close analogs in transition metal oxo complexes and are also hard Lewis acids. Water and other ligands bind to these linear cations in a ring-shaped equatorial region around the metal ion between the two tightly bound oxoanions. The coordination numbers and geometries for the actinide ions are highly variable and reflect the largely ionic bonding in these complexes: generally, 6–12 for An(IV), 6–9 for An(III), and 4–6 in the equatorial ring of AnO_2^+ or AnO_2^{2+}. The trivalent actinides exhibit a slightly stronger bonding to ligands containing soft donor atoms (e.g. sulfur, nitrogen, chloride) than the corresponding lanthanides and this property can be used as a basis for separating these groups of elements.

For plutonium the oxidation states from III to VII are accessible in aqueous solution. The species Pu(III), Pu(IV), and Pu(VI) (PuO_2^{2+}) are most important in acidic aqueous solution. The pentavalent ion PuO_2^+ disproportionates rapidly in acidic solution at moderate plutonium concentrations and is usually a very minor species in acidic aqueous separation systems. Stabilizing Pu(VII) requires strongly complexing ligands such as hydroxide, fluoride, or carbonate in basic solution and, thus, Pu(VII) has not been used in any separation systems.

7.5.3 Precipitation and crystallization methods

As noted above, the oxidation states of the actinide ions in solution produce large differences in coordination chemistry facilitating separation by a variety of methods. An example of this is shown in Table 7.5 which lists the qualitative solubility behavior of the actinides in oxidation states III–VI with some common

Table 7.5 *Precipitation reactions characteristic of various actinide oxidation states (aqueous solution,* 1 M H^+)[a].

Anion	M^{3+}	M^{4+}	MO_2^+	MO_2^{2+}

I = insoluble, S = soluble.

[a] Unless otherwise stated (the OH^- and CO_3^{2-} precipitations occur in alkaline solution).

[b] At pH = 6, $RbPuO_2F_2$ and $NH_4PuO_2F_2$ may be precipitated by addition of RbF or NH_4F, respectively.

[c] Complex carbonates are formed.

[d] Solid $KPuO_2CO_3$ precipitates on addition of K_2CO_3 to Pu(v) solution.

[e] From solution of Pu(vi) in CH_3CO_2H, $NaPuO_2(CH_3CO_2)_3$ precipitates on addition of Na^+.

[f] Addition of $(NH_4)_2HPO_4$ to Pu(v) solution yields $(NH_4)HPuO_2PO_4$.

[g] On addition of H_3PO_4, $HPuO_2PO_4{\cdot}xH_2O$ precipitates.

anions. These precipitations are very useful for separating mixtures of the actinides and for recovery of solid products from an aqueous stream after using another separation process such as ion exchange or solvent extraction. They are generally not selective enough to be used as the primary process for separation of plutonium or other actinides from all the fission products in irradiated fuel or targets. This is illustrated by a study (Winchester and Maraman, 1958) that used precipitation of Pu(iii) oxalate, Pu(iv) oxalate, Pu(iii) fluoride, and Pu(iv) peroxide to recover plutonium directly from an irradiated plutonium-rich alloy dissolved in nitric acid. The decontamination factors reported in Table 7.6 indicate that none of the precipitation processes achieved high enough fission product or corrosion product (Fe and Co) removal for use as a primary separation process. However, as will be described below, coprecipitations with other metal ion species such as bismuth phosphate were used in the first large-scale separations of plutonium from irradiated uranium. These processes were replaced in time by more efficient solvent extraction processes.

The distinction between crystallization and precipitation is quite often based on the speed of the process and the size of the solid particles produced. The term precipitation commonly refers to a rapid crystallization that gives small crystals that may not appear crystalline to the eye, but still may give very distinct X-ray diffraction (XRD) peaks. Precipitation often involves a relatively irreversible reaction between an added reagent and other species in solution whereas

Table 7.6 *Decontamination factors for plutonium using various precipitation methods.*

crystallization products can usually be redissolved using relatively simple means such as heating or dilution. The details of the precipitation or crystallization process can be very important to produce a pure product and one that separates well from the liquid phase. Thus, the order and speed of reagent addition, the temperature, and the 'aging' time before filtration or centrifugation can all be important parameters in a precipitation or a crystallization process. The Pu(IV) oxyhydroxide 'polymer' that readily forms in relatively low acid solutions of Pu(IV) is an infamous example of a 'difficult' precipitate that can complicate the processing of plutonium aqueous solutions. The characteristics of this polymer will be described in more detail in Section 7.9.1.d.

(a) Coprecipitation methods

Coprecipitation processes were the first to be used for the recovery of plutonium. The tiny amounts of plutonium present in the first preparations were too small to be precipitated directly, so coprecipitation or 'carrier' precipitations were used to purify and deduce the chemical properties of plutonium and many other radioactive elements. In general, plutonium will coprecipitate if the anion contained in the bulk precipitate forms an insoluble salt with plutonium in the same oxidation state or states present in the solution. Useful carrier precipitation methods for plutonium have been reviewed (Sorantin, 1975). Coprecipitation methods have also been used to purify plutonium in microgram amounts and for recovery on a production scale.

(*i*) *Lanthanum fluoride*

Precipitation of lanthanum fluoride or other lanthanide fluorides from acid solutions carries trivalent and tetravalent actinides, but not the pentavalent and hexavalent ions. The lanthanide and yttrium fission products coprecipitate, but most of the other fission products remain in solution. The behavior of neptunium and plutonium in lanthanum fluoride precipitation was used to establish the existence of two oxidation states of these elements before weighable quantities were available (Seaborg and Wahl, 1948b). The lanthanum fluoride carrier precipitation was also a key step in the first isolation of a weighable plutonium compound to be described below.

Cunningham and Werner isolated a PuO_2 sample that weighed 2.77 μg, the first weighable quantity of any synthetic element, on September 10, 1942 at the Metallurgical Laboratory of the University of Chicago (Cunningham and Werner, 1949b). The plutonium had been separated from about 90 kg of uranyl nitrate hexahydrate that had been irradiated for 1 to 2 months with neutrons produced by bombarding a beryllium target with deuterons at the cyclotron facility at Washington University in St. Louis. The separation of plutonium was accomplished through oxidation state adjustments and a series of LaF_3 precipitations that carried Pu(IV) and Np(IV) but not Pu(VI) or Np(VI). The brief overview that follows provides an example of a coprecipitation separation method and also illustrates the painstaking effort required in these first explorations of plutonium chemistry.

About 90 kg of irradiated $UO_2(NO_3)_2 \cdot 6H_2O$ was mixed with 100 L of diethyl ether to yield about 120 L of ether solution containing uranyl nitrate solvate, $UO_2(NO_3)_2[O(CH_2CH_3)_2]_2$, and a small amount of fission products and 8 L of an aqueous phase that consisted of about 50 wt % uranyl nitrate hydrate with most of the fission products and transuranic elements, principally neptunium and plutonium. This was essentially a solvent extraction step that partitioned most of the U(VI) to the ether phase along with a small amount of the fission products.

The aqueous phase was diluted to 20 L, made 2 M in nitric acid and 0.014 M in La(III) and then HF was added to give a solution 4 M in HF. The resulting 40 g of LaF_3 precipitate contained the transuranium elements and about 25% of the original fission product activity (mostly the lanthanide and yttrium fission products). The separated LaF_3 precipitate was heated in concentrated sulfuric acid to distill HF and then dissolved in and diluted to 5 L with 2 M nitric acid. The Pu(IV) was oxidized to Pu(VI) by using $K_2S_2O_8$ and Ag(I) as a catalyst. The solution was then made 4 M in HF which produced about 40 g of LaF_3 precipitate that was separated by filtration. The LaF_3 precipitate contained most of the remaining fission product activity, while the solution contained the Pu(VI) and Np(VI). The addition of a 6% SO_2 solution to the filtrate and washings reduced the Pu(VI) and Np(VI) and the excess peroxydisulfate. Addition of 2 g of $La(NO_3)_3$ in solution precipitated LaF_3 that carried the tetravalent plutonium and neptunium. Repeated cycles of precipitation with progressively smaller amounts of LaF_3 were used to further decontaminate the plutonium and neptunium. For two of the LaF_3 precipitation cycles, $KBrO_3$ was employed as the oxidizer to selectively oxidize neptunium, but not plutonium. This allowed the separation of the neptunium into the filtrate solutions while plutonium was carried with the LaF_3. These additional cycles of smaller precipitations eventually yielded a 120 μL solution of 1.7 M HNO_3 and 5 M HF that was fumed in a platinum crucible and treated with 10 M ammonium hydroxide to precipitate Pu(VI) hydroxide. The washed precipitate of plutonium hydroxide contained about 40 μg of plutonium. The microliter-scale solution manipulations were performed in a specially designed glass apparatus viewed with a microscope. Additional purification steps yielded a 50 μL solution of plutonium in nitric acid. Ten μL of this solution were placed on a platinum weighing pan, dried, and heated to give the oxide. This sample provided the first weighable quantity of plutonium that is now displayed in the Lawrence Hall of Science at Berkeley, California.

(*ii*) *Bismuth phosphate process*

The bismuth phosphate process was used for the first large-scale purification of plutonium from neutron-irradiated uranium at the Hanford site during the Manhattan Project, and after the war until the 1950s when it was replaced by solvent extraction processes. More detail on the bismuth phosphate process and its replacement by solvent extraction processes can be found in Chapter 24. The precipitation of $BiPO_4$ from acid solutions carries the trivalent and tetravalent actinides, and especially Pu(IV), but not the pentavalent and hexavalent ions. Bismuth phosphate is quite insoluble in moderately concentrated nitric and sulfuric acids. This is an important property because addition of sulfuric acid to a nitric acid solution of neutron-irradiated uranium could be used to keep the relatively large quantity of U(VI) in solution as a sulfate complex while bismuth phosphate was precipitated and carried the plutonium. The $BiPO_4$ precipitate carried only small amounts of the fission products, and could be redissolved in concentrated nitric acid; thus simplifying the process relative to use of a lanthanum fluoride carrier that is difficult to redissolve. A series of oxidation state adjustments and precipitations of $BiPO_4$ from solutions of neutron-irradiated uranium in nitric acid separated the plutonium from the uranium, neptunium and fission products in a scheme that resembles the lanthanum fluoride process described above. In fact, cycles of lanthanum fluoride precipitation from nitric acid were incorporated into the bismuth phosphate process to concentrate and further purify plutonium.

Thompson and Seaborg first developed the bismuth phosphate process (Thompson and Seaborg, 1956). The scale-up of the process from the laboratory to an operating plant by a factor of 10^8 in a short time is a remarkable story (Hill and Cooper, 1958). An overall decontamination factor from the fission products of 10^7 was obtained at Hanford for the plutonium. The disadvantages of the process included discarding the uranium with the fission products, generation of large volumes of high salt wastes, and batch operation. Continuous solvent extraction processes based on extraction of uranium and plutonium from nitric acid solutions of dissolved fuel have replaced the bismuth phosphate process.

(b) Precipitation and crystallization methods for conversion chemistry of plutonium

Solvent extraction processes have displaced the original bismuth phosphate coprecipitation method for production scale plutonium separation from neutron-irradiated uranium fuels and targets. However, precipitation and crystallization from aqueous solutions have always been important processes for preparing and purifying solid compounds for the various applications of plutonium. The major products are plutonium metal for irradiation targets and fuels, weapons components, or storage and PuO_2 for MOX fuels, heat sources (when the ^{238}Pu content is high), and storage.

The bulk of the aqueous processing of plutonium takes place in nitric or hydrochloric acid solutions and most plutonium solids are precipitated from these solutions (Cleveland, 1980; Christensen *et al.*, 1988). The most common precipitations use oxalate, peroxide, hydroxide, and fluoride. The typical reasons for using these precipitations are:

- Good recovery of plutonium can be obtained in the solid in a form suitable for preparing metal or oxide.
- Relatively concentrated plutonium nitrate or chloride solutions can be largely or partially purified from many cationic impurities.
- Precipitation from relatively dilute solutions provides a very quick and convenient method for concentrating plutonium.
- Calcination at 500–800°C readily converts properly precipitated Pu(III) and Pu(IV) oxalates to PuO_2 that is suitable for direct oxide reduction (DOR) with calcium to the metal, or hydrofluorination to PuF_4 that is then reduced to metal (see Section 7.7.2).
- Precipitation of plutonium or americium hydroxides from waste solutions such as oxalate or peroxide filtrates generally provides an effective method to recycle the plutonium and americium in the separated precipitate and to dispose of the alkaline filtrate to low-level waste treatment operations.

This group of common precipitation methods will be briefly reviewed. The detailed procedures used at different facilities vary widely because of the many facility-specific factors that enter into the process design as discussed briefly in Section 7.5.1. Both batch and continuous processes have been developed for these precipitations.

(*i*) *Plutonium*(III) *oxalate precipitation*

Since the time of the Manhattan Project, researchers have found it useful to precipitate the easily filterable turquoise-blue $Pu_2(C_2O_4)_3 \cdot 10H_2O$ by reducing plutonium to the trivalent state in low acid solution and carefully adding an oxalic acid solution. Directly adding solid oxalic acid will produce a crystalline precipitate with a smaller average particle size (Christensen *et al.*, 1988). The solubility of $Pu_2(C_2O_4)_3 \cdot 10H_2O$ can be approximated by the expression

$[\mathrm{Pu}(\mathrm{mg\,L^{-1}})] = 3.24[\mathrm{H^+}]^3[\mathrm{H_2C_2O_4}]^{-3/2}$ (Harmon and Reas, 1957). However, the typical filtrate from a production run will have somewhat higher concentrations of plutonium (0.1–0.5 g L^{-1}) left in solution than that calculated from this equation. The precipitation is useful over a wide range of conditions when the Pu(iii) concentration is more than 1 g L^{-1} and with less than 4 M acid. The Pu(iii) oxalate precipitation gives good decontamination factors from such impurities as Al(iii), Fe(iii), and U(vi). There is less decontamination from sodium, potassium, and calcium and none from Am(iii). Plutonium(iii and iv) can be scavenged from very dilute solutions using Ca(ii) or Pb(ii) oxalates as carriers (Maraman *et al.*, 1954; Akatsu, 1982; Akatsu *et al.*, 1983).

(*ii*) *Plutonium*(*iv*) *oxalate precipitation*

Plutonium(iv) precipitates as the tan solid $\mathrm{Pu(C_2O_4)_2 \cdot 6H_2O}$ from low acid solutions upon addition of oxalic acid, but it is usually a very fine tacky solid at room temperature (Christensen *et al.*, 1988). Precipitation at elevated temperatures can greatly improve the filterability of the solid. Typical losses of plutonium to the filtrate in practical operations are 0.2–0.5 g L^{-1}. The precipitation is used over a wide range of conditions with Pu(iv) concentrations greater than 1 g L^{-1} and acid concentrations between 1 and 5 M. The decontamination factors for impurities such as Al(iii), Fe(iii), and U(vi) are typically higher than for the Pu(iii) oxalate method. There is no decontamination from Am(iii).

(*iii*) *Plutonium*(*iv*) *peroxide precipitation*

Plutonium(iv) peroxide is an olive-green solid formed by the addition of hydrogen peroxide solutions to acid solutions of Pu(iv). The typical range of acid concentration is 2.5–5.5 M. The solutions are often cooled to 10–15°C to reduce the decomposition of hydrogen peroxide. High levels of iron, copper, manganese, or nickel catalyze the decomposition of the H_2O_2 and interfere with precipitation. At higher acid concentrations and with careful H_2O_2 addition, a very filterable hexagonal form of plutonium(iv) peroxide precipitates. At lower acidities a gelatinous cubic form precipitates that is difficult to filter. Plutonium(iv) peroxide is not a stoichiometric compound and its O:Pu ratio may approach 3.5 (Cleveland, 1979, 1980), but does not reach 4.0 as is suggested by the formula $\mathrm{Pu(O_2)_2}$. Anions such as nitrate, chloride, and sulfate, if present in the solution, are incorporated into the solid. Indeed, sulfate is added in some processes at a concentration of 0.1–0.3 M to nitric acid solutions to improve the filterability of the peroxide precipitate.

The Pu(iv) peroxide precipitation is a powerful method for purification of plutonium from many impurity elements except those such as thorium, neptunium, and uranium that form similar peroxides under these conditions. Unlike the oxalate precipitations, Am(iii) is removed to a high degree. The excellent decontamination factors obtained for many elements and the use of one reagent that is easily decomposed to water and oxygen in subsequent operations are the major advantages of using this process. The disadvantages are greater losses of plutonium in the filtrate (typically 0.1–0.5%) and violent decomposition of H_2O_2 that can occur during precipitations in the presence of high concentrations of iron and other metal ion catalysts for the decomposition reaction.

(*iv*) *Plutonium*(*III*) *fluoride precipitation*

Addition of aqueous HF to a solution of Pu(III) in nitric or hydrochloric acid precipitates blue-violet $PuF_3 \cdot xH_2O(x \sim 0.75)$ (Christensen *et al.*, 1988). The Pu(IV) concentration should be kept low because the hydrated PuF_4 precipitate is very gelatinous and much more soluble than the trifluoride. Significant Pu(IV) content will thus increase filtering time and plutonium losses to the filtrate. Reducing agents such as hydroxylamine, sulfamic acid, or ascorbic acid are commonly used. With careful oxidation state control, losses of plutonium to the filtrate are very low (0.05–0.1%). A disadvantage of preparing any fluorine-containing compound of plutonium is increased production of neutrons from α-n reactions relative to the oxygen-, carbon-, and nitrogen-based precipitants. The trifluoride precipitation does not give decontamination factors from cationic impurities that are as high as the oxalate or especially the peroxide precipitations. It gives moderate decontamination from many impurities including iron, but not from aluminum, zirconium, and uranium. Dried PuF_3 can be roasted in oxygen to produce a mixture of PuF_4 and PuO_2 that can be directly reduced with calcium metal to give 95–97% yields of plutonium metal (See Sections 7.7.1 and 7.7.2).

(*v*) *Plutonium hydroxide precipitation*

Hydroxide precipitation is quite useful to produce a filtrate with very low levels of plutonium. Sodium or potassium hydroxide solutions are commonly added to precipitate the gelatinous green Pu(IV) hydroxide (Christensen *et al.*, 1988). If Pu(III) is present, it will slowly oxidize to Pu(IV). Many other metal ions will precipitate as hydroxides as well or be carried by the plutonium hydroxide so that this is not a useful purification procedure. The hydroxide is generally difficult to filter. If large amounts of magnesium or calcium are present, the voluminous hydroxide precipitates of these metal ions make filtration especially difficult, unless they are avoided by carefully controlling the pH. The dried hydroxide cake can be recycled for plutonium recovery by dissolving it in acid. The formation of the Pu(IV) oxyhydroxide polymer should be avoided because this material behaves quite differently from the hydroxide precipitate and can be quite difficult to redissolve in acid. The formation and properties of the polymer are described in more detail in Section 7.9.1.d.

(*vi*) *Miscellaneous precipitations*

Other precipitation methods have been tested for plutonium processing operations, but have not been deployed or as widely used as those reviewed above. These include $CaPuF_6$ and Cs_2PuCl_6 from acid solutions for metal production operations (Christensen *et al.*, 1988; Muscatello and Killion, 1990) and $(NH_4)_4PuO_2(CO_3)_3$ or mixed $(NH_4)_4(Pu, U)O_2(CO_3)_3$ from alkaline solution for the preparation of MOX fuels (Roepenack *et al.*, 1984).

7.5.4 Solvent extraction separation processes

Liquid–liquid (or solvent) extraction partitions solutes between two immiscible liquid phases. The two phases are generally intimately mixed to improve the rate of transfer of solutes between them. The use of a laboratory separatory funnel by a synthetic chemist illustrates the operation of a single stage of liquid–liquid extraction. The two immiscible phases, commonly an organic and an aqueous phase, are shaken vigorously for some time to approach the equilibrium distribution of solutes between the phases and then the phases are allowed to coalesce and reform layers that can be separated. On an industrial scale, the labor-intensive separatory funnel is replaced by a wide variety of equipment that pumps, mixes and separates the phases in a continuous operation so that multiple stages of extraction and back-extraction can be accomplished in an efficient manner. Solvent extraction is a very versatile and useful industrial separation method and has proven to be very important for the recovery and purification of plutonium and other actinides. In fact, as discussed in Chapter 24 of these volumes, the industrial practice of solvent extraction advanced considerably because of the new development work needed to solve the separation challenges of processing neutron-irradiated fuels and targets for military and industrial applications.

In the case of plutonium and other actinide metal ions, the two immiscible phases used in solvent extraction processes are usually an aqueous acid solution and an organic solvent containing components that stabilize certain metal ion complexes in the organic phase. Nitric acid is the most common acidic solution used; hydrochloric acid has seen more limited application. Acids with more strongly complexing anions such as sulfuric, phosphoric, or hydrofluoric acids can have problems with limited solubilities of actinide ions (see Table 7.5) and also some fission product metal ions and are used less commonly. In some cases, these acids with more strongly complexing anions are used in controlled amounts in the acidic aqueous phase as ‘masking agents’ to hold certain metal ions in the aqueous phase and to improve the selectivity of the extraction into the organic phase. They can also be deployed in an aqueous phase to ‘strip’ or back-extract metal ions from an organic phase that has been ‘loaded’ with metal ions in a previous step of the process.

The organic phases used for actinide extractions comprise a wide range of solvents (or diluents) and organic-soluble compounds (extractants) that stabilize metal complexes in an organic phase. Aliphatic and aromatic hydrocarbons, chlorinated hydrocarbons, ethers, and ketones represent some of the major solvent groups. In some cases the solvent and the extractant are the same. For example, chemists used diethyl ether to extract uranyl nitrate from aqueous solutions long before the nuclear age dawned. The influence of the solvent on the extraction system is manifested in various ways such as the solubility of the extractant and metal ion species, the overall thermodynamic activity of the extractant, and the concentration of water in the organic phase (Cox and Flett, 1983).

Metal ions can be stabilized in the organic phase in a variety of structures. While uncharged individual metal ion complexes are solvated in the organic phase in many cases, ion-pairs, reverse micelles, and other aggregated structures are observed, especially as higher concentrations of metal ions are loaded into the organic phase (Borkowski *et al.*, 2003; Chiarizia *et al.*, 2003). For many extraction systems, a third phase can form if the metal ion concentration becomes too high in the organic phase (Rao and Kolarik, 1996). This is a situation to be avoided because the extraction equipment is designed to separate two liquid phases, not three, and any solid phase is particularly troublesome. Phase-modifying reagents are sometimes added to the organic solvent to inhibit third-phase formation and to allow higher levels of metal loading.

When two or more extractant compounds are combined in a single solvent they may act independently or the extraction equilibrium for a metal ion can be enhanced over what each extractant would give independently. This effect is referred to as synergism. It is most typically observed when an acidic extractant is combined with a neutral donor extractant and the major extractant complex contains both extractants bound to the metal ion (Cox and Flett, 1983).

The range and combinations of compounds that have been used in organic solvents to extract plutonium is very extensive and cannot be reviewed here. The extractant compounds can be generally divided into two large groups: compounds with donor atoms that form organic-soluble complexes with the metal ion, and ion-pair reagents that stabilize a charged metal ion complex in the organic phase. Given the hard Lewis acid character of the actinide metal ions, it is not surprising that most of the ligand-type extractants have one or more oxygen donor atom sites that coordinate to the metal ion in the organic phase. The major actinide extractant classes are alkyl and aryl phosphates, $(RO)_3P{=}O$, phosphonates, $(RO)_2RP{=}O$, phosphinates, $(RO)R_2P{=}O$, and phosphine oxides, $R_3P{=}O$; alkyl and aryl phosphoric, $(RO)_2PO_2H$, phosphonic, $(RO)RPO_2H$, and phosphinic acids, R_2PO_2H; ethers, R_2O; ketones, $R_2C{=}O$; 1,3-diketones, $RC(O)CH_2C(O)R$; amides, $RC(O)NR_2$, malonamides, $R_2NC(O)CHRC(O)NR_2$, and carbamoylmethylphosphine oxides, $(RO)_2P(O)CH_2C(O)NR_2$ (the R groups in the formulas can all have different or identical alkyl or aryl functionality). The major ion-pair extractant classes for actinides are tetraalkylammonium salts, $R_4N^+X^-$, and protonated tertiary amines, $R_3NH^+X^-$. More detail on the classes of solvent extraction systems and their use for actinide separations is found in Chapter 24. Tri(*n*-butyl) phosphate (TBP), $(n\text{-BuO})_3P{=}O$, is of particular importance for plutonium separations as the key component of the PUREX process and will be discussed below.

(a) The PUREX process

As mentioned previously, nearly all of the roughly 500 metric tons of plutonium that has been separated to date has been recovered using the PUREX solvent extraction process. The use of TBP to extract nitrate complexes of uranium and other actinides was examined as early as 1944 during the Manhattan Project (Orlemann, 1944; Spedding *et al.*, 1945; Warf, 1945) and a patent application for a solvent extraction process for plutonium based on TBP and other trialkylphosphates was submitted in 1947 – the patent was not issued until 1960 because of security concerns (Anderson and Asprey, 1960). The development work leading to deployment of the process started in the late 1940s principally at Oak Ridge National Laboratory (Coleman and Leuze, 1978). The PUREX process was first used in 1954 at the Savannah River site of the U.S. Atomic Energy Commission and then in 1956 at the Hanford site (Swanson, 1990). With many variations in operational details, the process has since been used around the world as the principal method to separate plutonium and uranium from used reactor fuel and neutron-irradiated actinide materials (McKay *et al.*, 1990). The key to this process is the selective extraction of U(VI) and Pu(IV) from a nitric acid solution of dissolved irradiated fuel into an aliphatic hydrocarbon solvent containing TBP while leaving most of the fission products in the acid solution. The plutonium and then the uranium can be back-extracted separately from the loaded organic solvent into an aqueous strip phase. Additional solvent extraction stages with TBP can be used to further purify the uranium and plutonium or another method such as ion exchange can be used. Most PUREX operations target very pure uranium and plutonium products with high decontamination factors from the fission products of about 10^8 and high recovery (typically about 99.9%).

The following equilibrium equations represent the major separation steps of the PUREX process:

$$\mathrm{Pu}^{4+}_{(\mathrm{aq})} + 4\mathrm{NO}^-_{3\,(\mathrm{aq})} + 2\mathrm{TBP}_{(\mathrm{org})} \rightleftharpoons \mathrm{Pu(NO_3)_4(TBP)}_{2\,(\mathrm{org})} \tag{7.8}$$

$$\mathrm{UO}^{2+}_{2\,(\mathrm{aq})} + 2\mathrm{NO}^-_{3\,(\mathrm{aq})} + 2\mathrm{TBP}_{(\mathrm{org})} \rightleftharpoons \mathrm{UO_2(NO_3)_2(TBP)}_{2\,(\mathrm{org})} \tag{7.9}$$

$$\mathrm{HNO}_{3\,(\mathrm{aq})} + \mathrm{TBP}_{(\mathrm{org})} \rightleftharpoons \mathrm{TBP}\cdot\mathrm{HNO}_{3\,(\mathrm{org})} \tag{7.10}$$

The subscripts (aq) and (org) refer to species present in the aqueous and organic phases, respectively. The distribution coefficient (D) in liquid–liquid extraction is defined as the ratio of the concentration of the solute in the organic phase to that in aqueous phase under a particular set of conditions, e.g. volume ratio of the aqueous to organic phase, temperature, extractant concentration, pH, metal ion concentration. Tetravalent and hexavalent actinide ions are selectively extracted under the PUREX conditions (typically 1–3 M nitric acid and 20–30 vol % TBP in an aliphatic hydrocarbon diluent) but the trivalent and pentavalent oxidation states of the actinides and most of the fission products are poorly extracted. This is illustrated by the data in Table 7.7 that lists the single-stage distribution coefficients for U(VI), Pu(VI), Pu(IV), Pu(III), and a group of fission products for TBP and two other compounds, hexone [$CH_3C(O)CH_2CH(CH_3)_2$] and dibutylcarbitol [$CH_3(CH_2)_3O(CH_2)_2O(CH_2)_2O(CH_2)_3CH_3$] that were the basis for two other competing solvent extraction processes, REDOX and BUTEX (Peterson and Wymer, 1963). The REDOX and BUTEX processes were used for a time at Hanford and in the United Kingdom, respectively, but eventually were replaced by the PUREX process. The data in Table 7.7 illustrate that the modest *D* values like those for uranium of 1.5–8.1 can be exploited for high recovery by using multiple stages of extraction. The data in the table also show that the bulk of the fission product have very low *D* values, but there are exceptions (Zr, Ru, and Tc). These fission product contaminants can be removed in various ways during the additional uranium and plutonium purification operations.

The equations shown above for Pu(IV) and U(VI) extraction indicate that higher nitrate concentrations in the aqueous phase and higher TBP concentrations in the organic phase should increase the *D* values for these metal ions. This is indeed observed as long as the activities of the various species are taken into account and metal ion concentrations are low. However, the extraction of nitric acid by TBP indicated in (7.10) competes with metal ion extraction for the TBP and limits the increase in the *D* value with increasing nitric acid concentration. The *D* values will continue to increase at a low fixed nitric acid concentration if nitrate salts are added to the aqueous phase rather than nitric acid. Pure TBP is

Table 7.7 *Distribution coefficients of uranium, plutonium, and some fission products using TBP, hexone, and Butex extractants.*

Solvent	*U(VI)*	*Pu(VI)*	*Pu(IV)*	*Pu(III)*	*Fission products*[a]
hexone[b]	1.6	2.9	0.84	4.5×10^{-4}	0.03
TBP[c]	8.1	0.62	1.55	0.008	0.001
Butex[d]	1.5	1.8	7	<0.01	~0.02

[a] Combined β emitters (without Zr, Ru, Ca).

[b] From 0.3 M HNO_3/1.0 M $Al(NO_3)_3$/(U,Pu) into hexone at 25°C, or from 0.25 M HNO_3/1.5 M $Al(NO_3)_3/\Sigma FP$ into hexone at 25°C.

[c] From 3.0 M HNO_3 into 30 vol.% TBP in kerosene at 25°C.

[d] From 4 M HNO_3 into dibutylcarbitol (Butex).

a liquid and can be used as the organic phase in an extraction, but it is quite viscous. PUREX plants typically operate with 20–30 vol % TBP in an aliphatic hydrocarbon diluent (Swanson, 1990).

Adjusting the oxidation state of plutonium from Pu(iv) to Pu(iii) is the most commonly used way of selectively stripping plutonium from the loaded organic phase. As shown in Table 7.7, the *D* value of Pu(iii) is quite low and it will preferentially distribute to the aqueous nitric acid phase. Reducing agents that have been used to strip plutonium from the TBP phase are Fe(ii), hydroxylamine, and U(iv). The addition of ferrous sulfamate in the aqueous acid solution used to strip the plutonium has given some of the best results as indicated by the purity of the uranium and plutonium products that result (Miles *et al.*, 1990). The overall equation for the Fe(ii) reduction and stripping reaction is:

$$\mathrm{Pu(NO_3)_4(TBP)_2}_{\,(\mathrm{org})} + \mathrm{Fe}^{2+}_{(\mathrm{aq})} \rightarrow \mathrm{Pu}^{3+}_{(\mathrm{aq})} + 4\mathrm{NO}^{-}_{3\,(\mathrm{aq})} + \mathrm{Fe}^{3+}_{(\mathrm{aq})} + 2\mathrm{TBP}_{(\mathrm{org})} \qquad (7.11)$$

After the removal of plutonium, the uranium can be stripped from the TBP phase with a dilute acid solution. The TBP solution can then be reused to extract more uranium and plutonium. A generalized PUREX flow sheet is shown in Fig. 7.5.

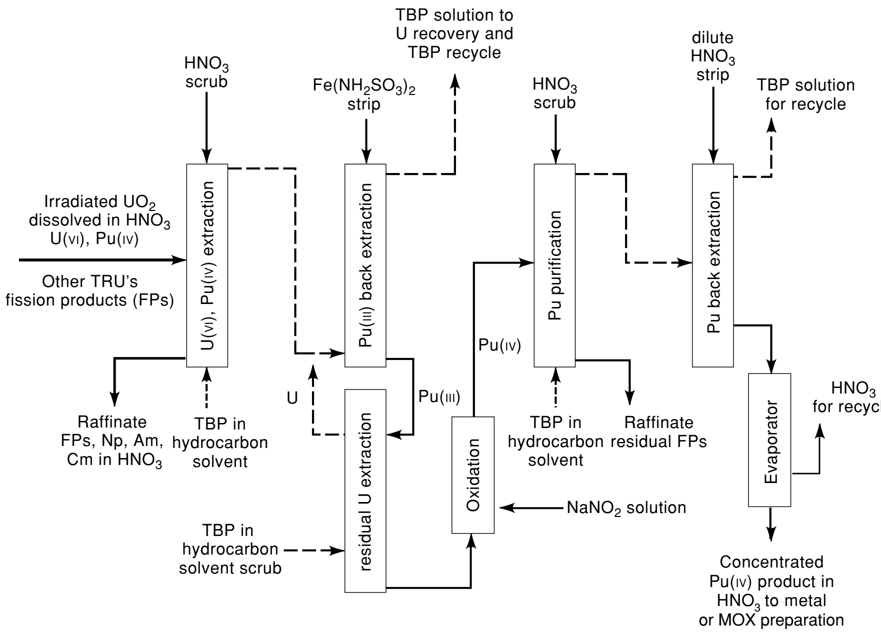

Fig. 7.5 *A generalized PUREX flow sheet where the dashed line indicates the organic stream.*

Of course, there are many other operations needed for running an actual PUREX plant that are not indicated by the simple extraction equations above. A few will be mentioned here and the references can be consulted for more detail. The decladding and dissolution of the fuel in nitric acid in a highly shielded facility are major operations that prepare the feed for the PUREX process. During the extraction process, the organic solvent and TBP undergo degradation reactions because of reactive species produced by the high level of ionizing radiation, particularly in the first extraction cycle where all the fission products are present. Some of the degradation products of TBP, dibutylphosphoric and monobutylphosphoric acids can cause problems by forming solids and modifying the *D* values for certain metal ions. This is dealt with by adding a washing operation to keep the concentration of these compounds below certain levels. The slight solubility of TBP and any entrainment of organic phase droplets in the aqueous phase also cause losses that must be replaced. Maintaining the oxidation states of various actinide and fission product metal ions in the intense radiation field requires careful adjustments at various points in the process. To improve process efficiency and to minimize wastes, evaporators are used to recover nitric acid and concentrate solutions at various points in the process. Finally, the products and wastes from all the operations must be handled properly and transported to their next destination.

During more than 50 years of use around the world, the PUREX process has undergone many improvements. Enhancements continue to be made at operating plants and new plants that will begin operations in the future. As options are considered for advanced nuclear fuel cycles, additional separations operations are under development for potential deployment in PUREX-type plants (see Chapter 24, section 4). Among these operations are solvent extraction processes for recovery of neptunium, americium, and curium to allow their transmutation in advanced reactor systems and for technetium, cesium, and strontium to allow these fission products to be disposed of more efficiently. Solvent extraction systems are certainly the most developed separation processes to accomplish these goals in the near future. The use of other separation approaches to augment or replace solvent extraction in advanced nuclear fuel cycles will require large technology development efforts.

(b) Extraction chromatography and supported liquid membranes

Liquid–liquid extraction can be deployed in forms other than the typical methods of mixing and separating the immiscible liquid phases. In extraction chromatography, the extractant and solvent (in some cases) are prepared in a thin layer on a solid support that usually consists of small spherical particles of a polymer or inorganic material. Inorganic materials such as silica require a surface treatment to generate a relatively hydrophobic surface that will be compatible with the organic extraction components. Aqueous solutions are contacted with the solid and metal ions are extracted into the thin surface layer much as occurs in a liquid–liquid extraction system. However, the composition of the surface layer can be quite different from that of the liquid–liquid system and this must be taken into account when predicting extraction behavior. Extraction chromatography materials are used most commonly for analytical separations of plutonium and other actinides and have been deployed for a limited number of gloved box scale process operations. These materials generally do not have the radiation stability or capacity for use in large-scale processing of irradiated fuels. However, such an approach has been proposed and tested at a small scale with a spent fuel solution using some silica-based extraction materials by Wei and coworkers (Wei *et al.*, 2002).

Supported liquid membranes consist of a liquid phase that separates two fluid phases: two gases, two liquids, or a gas and a liquid. Components in the fluid phases can be separated by differential transport through the liquid membrane phase driven by the chemical potential gradients. For metal ion separations, the fluid phases on each side of the membrane are usually aqueous solutions and the membrane consists of a porous solid support with an organic extractant solution filling the pores. Supported liquid membranes have been demonstrated on the laboratory scale to be an efficient separation method for metal ions, but have seen relatively few industrial applications because of long-term stability problems. With time, the components of the liquid membrane are lost to the aqueous phases and the membrane fails. Many approaches have been considered to overcome this problem, but none have yet seen widespread industrial use (Sastre *et al.*, 1998).

In the extraction chromatography and supported liquid membrane systems the active extractant is not chemically bound to the support. Solids that do contain such chemically bound groups that can selectively bind plutonium and other actinides will be discussed under ion-exchange processes (see Section 7.5.5).

7.5.5 Ion-exchange processes

Ion-exchange materials are insoluble solid materials with groups of one charge fixed in a three-dimensional solid matrix and mobile or exchangeable ions of the opposite charge associated with these fixed sites that balance the charge in the solid. In contact with a liquid phase that contains dissolved ions, the mobile ions will be exchanged for ions of like charge in the solution if the overall free energy of the system is lowered after the exchange. The relative affinity of the ion-exchange material for various cations or anions can be used to separate particular ions from solution. By using a regeneration solution under different conditions, it is usually possible to recover the adsorbed ions from the ion-exchange material (often in more concentrated and pure form) and prepare the ion-exchanger for additional cycles of exchange and regeneration. Both inorganic solids and organic polymers, including natural materials such as clays and zeolites, can function as ion exchangers. Ion exchange has long been an important process for water treatment. One of the first industrial applications of ion exchange described in 1905 was the use of synthetic sodium aluminosilicates (zeolites) to exchange Ca^{2+} from hard water with Na^+ (Simon, 1991).

Ion exchangers are commonly deployed in industrial processes as a packed bed of small particles to obtain a high surface area and accessible exchange sites with minimal diffusion path lengths to the sites. In the loading phase, liquid feed solution is passed through the bed until the mobile ions in the solution have been exchanged for mobile ions in the solid to the extent that the target ion or ions are no longer being removed from solution to the required level. If the ions loaded on the exchanger are to be recovered as a product (e.g. plutonium), one or more wash solutions may be passed through the bed to improve the final purity by removing residual feed solution and exchanging more weakly held ions. In the elution phase a different solution is passed through the column to recover the product ions. The conditions during the elution phase are changed (pH, ion concentration or type, temperature, etc.) so that the target ions bound during the loading phase are exchanged back into the solution. After elution the ion exchanger may be ready for reuse directly or may require an additional regeneration step. Most ion-exchange processes are operated in such a batch mode with separate loading and elution or regeneration steps. Continuous ion-exchange processes have also been developed, but are not as widely used as batch operations (Simon, 1991).

Ion-exchange processes for metal ion separation most commonly use an organic polymer solid phase (often referred to as an ion-exchange 'resin') containing charged functional groups fixed to the polymer structure to selectively bind metal ions or complexes of metal ions with a net opposite charge from an aqueous solution. The organic polymer is usually prepared in the form of small spherical particles or beads with a large internal porosity. The structure of the polymer greatly affects the final ion-exchange properties and the synthetic conditions are adjusted to control properties such as the degree of crosslinking, the number of ion-exchange sites, the size distribution of the pores, and the bead size. The polymer structure in most commercial ion-exchange materials is formed from styrene (vinyl benzene)–divinylbenzene copolymers with the fixed charged groups attached to the phenyl rings. The most common functional groups are sulfonic acid and carboxylic acid groups with protons that exchange for cations (cation exchangers) and alkylamine, alkanolamine, and tetraalkylammonium groups that act as anion exchangers. Other polymer structures have been used to make ion exchangers including polyacrylates and polyvinylpyridines (Simon, 1991; Harland, 1994).

(a) Plutonium ion-exchange separations

Both cation- and anion-exchange processes have been used for concentrating and purifying plutonium from aqueous solutions that result from processing operations ranging from solvent extraction (e.g. PUREX) to recovery of plutonium leached from scrap or debris material. Ion exchange is generally not used as the primary step to separate plutonium and other actinides from fission products in nuclear fuel or neutron-irradiated targets because the intense radiation field degrades the polymer matrix too rapidly. However, organic ion exchangers are very useful for separations in acidic solutions where the radiation dose comes mostly from plutonium and other actinides. Inorganic ion exchangers are generally more radiation-resistant than organic exchangers, but have other problems for large-scale processing such as limited stability over wide pH ranges, difficulty in obtaining reproducible behavior from batch to batch, and the greater difficulty of preparing particles of suitable size and shape for processing (Pekarek and Marhol, 1991).

Plutonium in any of its oxidation states can be taken up onto cation exchangers from dilute acid solutions with weakly binding anions such as nitric, hydrochloric, or perchloric acids. The strength of the binding of the oxidation state decreases in the order $Pu^{4+} > Pu^{3+} > PuO_2^{2+} > PuO_2^+$ as expected with the decreasing net charge on the cation. The ion-exchange process on a strong acid cation exchanger can be represented by the reaction:

$$Pu^{n+}_{(aq)} + nRH_{(org)} \rightarrow Pu(R)_{n\,(org)} + nH^+_{(aq)} \tag{7.12}$$

where RH represents a proton exchange site on the organic resin (usually a sulfonic acid site) and $n+$ is the net charge on the plutonium species. Separations can be made based on the ionic charge alone, but the greater utility of ion exchange results from using the exchange material in combination with complexants in the aqueous solution that bind the various oxidation states of plutonium and other metal ions differently. For example, in dilute hydrofluoric acid, Pu(III) will bind to a cation-exchange resin more strongly than Np(IV), in apparent disagreement with the expected order based on oxidation state alone. This is because Np(IV) forms complexes with fluoride to a greater extent than Pu(III) thereby reducing its overall net charge, e.g. NpF_3^+ and NpF_2^{2+} (Zagrai and Sel'chenkov, 1962). Measuring the change in the ion-exchange equilibrium as a function of metal ion binding in the aqueous phase is one method for determining stability constants and can be particularly useful for radioactive metal ions like plutonium that can be analyzed at low concentrations.

The formation of anionic complexes of plutonium, especially by Pu(IV) and Pu(VI), is the basis for separations using anion-exchange resins. For example, in moderate concentrations of hydrochloric acid (~6 M) both Pu(IV) and Pu(VI) absorb strongly on a Dowex 1 resin (quaternary ammonium exchange sites), but Pu(III) shows no significant uptake even in concentrated HCl. Spectroscopic and ion-exchange capacity data indicate that the anionic species bound in the resin are $PuCl_6^{2-}$ and $PuO_2Cl_4^{2-}$ (Ryan, 1975). If high concentrations of chloride salts (e.g. 10 M LiCl) are used with a relatively low acid concentration, Pu(III) can also be taken up on Dowex 1 as an anionic complex. The absorbed plutonium species can be eluted from the resin by using low concentrations of HCl.

Anion exchange of Pu(iv) from moderate concentrations of nitric acid or nitrate salts is a particularly useful separation method for plutonium and has been applied from the process scale to the analytical scale. Applications range from concentrating and purifying the plutonium product stream from PUREX plants, to recovering and purifying plutonium dissolved from a wide range of scrap, residue, and debris materials, to preparation of analytical samples. The basis for the separation is the strong adsorption of Pu(iv) onto the anion-exchange resin from moderate concentrations of nitric acid or nitrate salts. Few other elements are significantly retained under these conditions by an anion exchanger and large separation factors can be obtained (Faris and Buchanan, 1964). The iii, v, and vi oxidation states of plutonium and other actinides are also not bound strongly. Fig. 7.6 shows the Pu(iv) distribution coefficients (K_d) onto Dowex 1×4 resin plotted as a function of nitrate concentration for HNO_3 and $Ca(NO_3)_2$ solutions at 25 and 60°C (Ryan, 1959). The high distribution coefficients for Pu(iv) near 7 M nitric acid when combined with

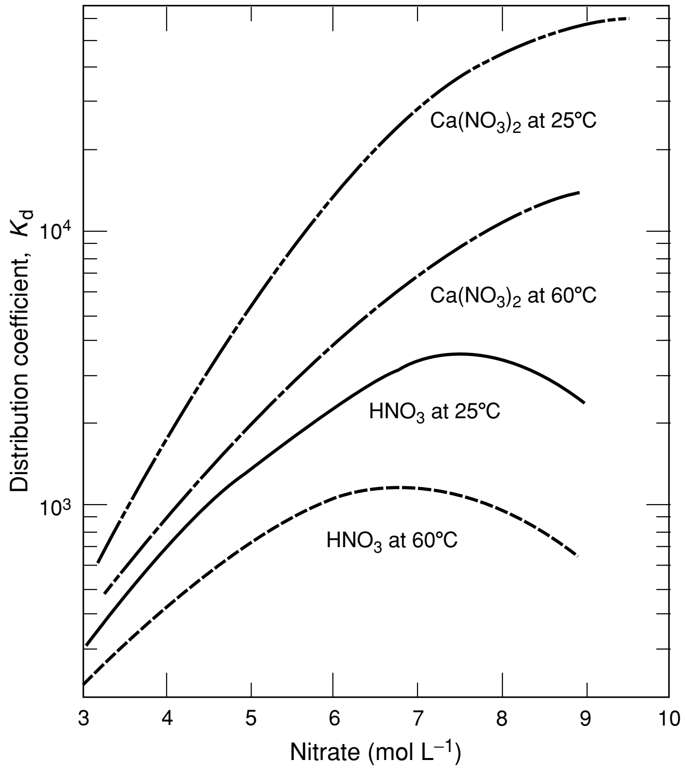

Fig. 7.6 *Plutonium(iv) distribution coefficients from nitric acid and calcium nitrate onto Dowex* 1 × 4 *anion-exchange resin (Ryan,* 1959*).*

an efficient elution method make large concentration factors possible. Elution of the plutonium is usually accomplished using a low nitric acid concentration alone or a low concentration of nitric acid and a reducing agent that generates Pu(III). The data in Fig. 7.6 show that the K_d values are lower at higher temperature, however, the kinetics of loading and elution are faster at higher temperature and this factor can be used as an advantage in process design (Ryan, 1975).

Visible absorption spectroscopy and resin capacity data show that Pu(IV) is absorbed on anion exchangers from nitric acid or nitrate salt solutions as the hexanitrato complex, $Pu(NO_3)_6^{2-}$ (Ryan, 1960, 1975). This has been confirmed by recent extended X-ray absorption fine structure (EXAFS) studies of anion exchange resins loaded with plutonium (Marsh *et al.*, 2000). Visible absorption, nuclear magnetic resonance (NMR), and EXAFS spectra of Pu(IV) and Th(IV) in nitric acid have also refined the information on the complexes formed in nitric acid solution (Veirs *et al.*, 1994; Allen *et al.*, 1996b; Berg *et al.*, 1998, 2000). At low nitric acid concentrations (~0.1 to 3 M) Pu^{4+}, $Pu(NO_3)^{3+}$, and $Pu(NO_3)_2^{2+}$ are the major species present (water molecules fill the rest of the plutonium coordination sphere in these complexes). At high nitric acid concentrations (>10 M), $Pu(NO_3)_6^{2-}$ is the dominant complex. At intermediate nitric acid concentration, in addition to $Pu(NO_3)_2^{2+}$ and $Pu(NO_3)_6^{2-}$, one major additional species is present that has been assigned as $Pu(NO_3)_4$. The trinitrato and pentanitrato complexes do not appear to be present at levels that can be easily observed (See Section 7.9.1.e). The concentration profile of the putative $Pu(NO_3)_4$ complex peaks at about 7 M nitric acid and correlates well with the distribution coefficient profile for Pu(IV) on anion-exchange resins from nitric acid (Marsh *et al.*, 1991). This observation suggests that the uncharged $Pu(NO_3)_4$ species might be important to the mechanism of uptake for Pu(IV) on an anion exchanger, but further work will be needed to verify this.

A general flow sheet for the operation of an anion-exchange process for plutonium recovery is illustrated in Fig. 7.7 (Christensen *et al.*, 1988). The oxidation state of plutonium dissolved in the nitric acid feed solution is carefully adjusted to maximize the amount of Pu(IV) because plutonium in other oxidation states is not retained on the exchanger. A variety of methods can be used for the oxidation state adjustment based on the composition of the feed. If fluoride is present in the feed solution, aluminum may be added to preferentially complex the fluoride and improve plutonium recovery. The nitric acid concentration is adjusted to 7 M and the solution is pumped through the packed bed of anion exchange beads so that $Pu(NO_3)_6^{2-}$ binds to the exchanger. The loaded resin is washed with 7 M nitric acid to remove impurities. Nitric acid at low concentration (0.35–0.6 M) is then pumped through the bed to elute the Pu(IV), or a solution of hydroxylammonium nitrate (or another suitable reducing agent) in dilute nitric acid is used to elute Pu(III). The plutonium in the eluate is commonly precipitated as an oxalate complex of either Pu(III) or Pu(IV) and the washed and dried oxalate solid is calcined to give a PuO_2 product.

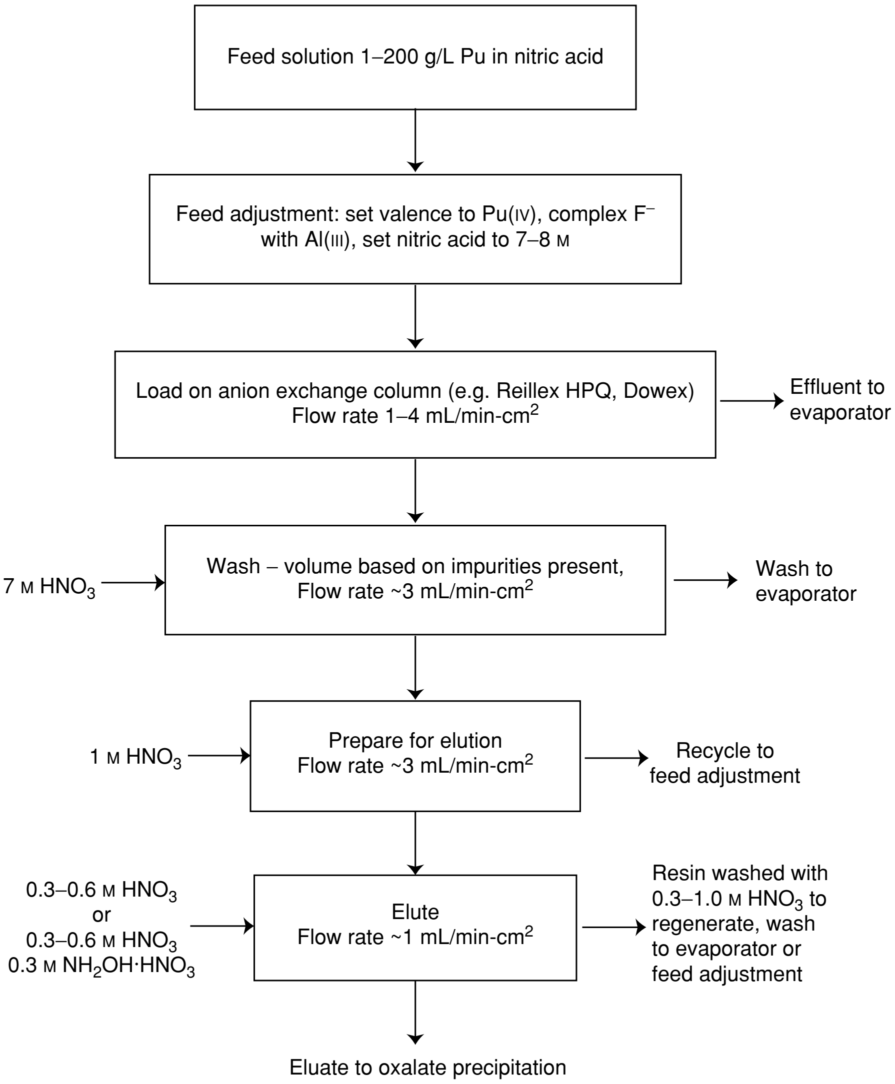

Fig. 7.7 *General flow sheet for operation of Pu*(IV) *anion-exchange purification process in nitric acid.*

There are a number of important features that must be controlled to safely and efficiently operate such an anion-exchange process for plutonium purification. Some of these features will be mentioned here. More detail can be found in the references (Cleveland, 1980; Christensen *et al.*, 1988). The batch size and the geometry of the packed bed are set up so that criticality cannot occur during normal operation. During elution of plutonium from the column, the nitric acid concentration should not drop so low as to allow the formation of the Pu(IV) polymer (see Section 7.9.1.d) as this material can clog the column and can be difficult to redissolve. The nitric acid–organic resin system can undergo a runaway oxidation reaction if temperatures are allowed to reach an initiation point around 160–180°C. A variety of safety devices and operating procedures are used to avoid this situation. For example, in using anion exchange to purify plutonium with a high percentage of the ^{238}Pu isotope for radioisotope heat sources, smaller batch sizes and columns are used to allow removal of the additional heat generated by decay of ^{238}Pu in comparison to 'regular' plutonium with a high ^{239}Pu content (Pansoy-Hjelvik *et al.*, 2001).

Ion exchange has been employed for separating plutonium and studying its chemistry since its discovery of more than 60 years ago. Considerable advances have been made in the processes used to manufacture ion-exchange materials during this time, partly driven by the need to separate plutonium and other actinides more efficiently. Highly uniform ion-exchange beads with reproducible behavior are now standard. The development of methods to synthesize macroporous polymer structures in the beads has reduced swelling and shrinkage of the bed as a function of changing solution conditions while retaining good kinetics of absorption (Simon, 1991). The organic ion-exchange polymers are degraded by radiation-induced reactions as noted above, including the alpha-induced radiolysis reactions of plutonium solutions in nitric acid. Anion exchange polymers made from 4-vinylpyridine crosslinked with divinylbenzene (e.g. Reillex HPQ) were demonstrated to be substantially more resistant to radiation-induced degradation than related polystyrene-based anion exchangers while maintaining excellent properties for plutonium processing (Marsh *et al.*, 1991; Buscher *et al.*, 1999). Reillex HPQ has thus replaced the polystyrene-based materials for plutonium recovery operations at some facilities.

Of course, improvements in ion-exchange technology will continue. Exchange columns that consist of a microporous polymer monolith with uniform flow paths and relatively short diffusion pathways compared to packed beds of beads have been developed. These materials could greatly improve future ion-exchange processes (Buchmeiser, 2001; Viklund *et al.*, 2001). Inorganic ion exchangers are continuing to become more versatile and should see wider applications. Membrane-based ion-exchange processes are also seeing wider application and offer potentially very efficient separation operations, but generally will require membrane materials with better long-term stability, including radiation stability, to replace the more common column method.

(b) Liquid ion exchangers and chelating ion exchangers

The solvent extraction processes discussed in Section 7.5.4 that use organic-soluble tetraalkylammonium salts or trialkylamines to extract anionic metal ion complexes as ion pairs are ion-exchange processes as well. These extractants are sometimes referred to as 'liquid anion exchangers.' Liquid cation exchangers are also used, for example, aliphatic and aromatic sulfonic acid compounds. Also, many types of functional groups have been placed on polystyrene and other polymer supports that can bind directly to the inner coordination sphere of a metal ion and help to stabilize a complex of the metal ion on the solid phases. This includes essentially all of the oxygen donor functionalities that were discussed in Section 7.5.4 (e.g. phosphates, phosphonates, phosphinates, and phosphine oxides). These polymers containing fixed ligand sites resemble solid versions of solvent extraction systems. However, fixing of the ligand to the polymer structure can considerably alter the metal ion-binding properties relative to an analogous ligand in solution. These kinds of materials are often referred to as 'chelating ion-exchange polymers' or resins, but it must be recognized that more than exchange of ion pairs is occurring in such materials and the thermodynamics of complex formation must be included in determining the selectivity and strength of the metal ion binding in these polymers. The use of chelating ion-exchange materials for separations of actinides is reviewed in Chapter 24 and a more general review for metal ion separations was published by Beauvais and Alexandratos (1998).

7.5.6 Separations in aqueous alkaline solutions

As noted in the brief discussion of aqueous actinide chemistry above, alkaline solutions are generally not used for actinide processing because the hydroxide complexes are quite insoluble. Large amounts of high-level caustic waste containing small amounts of actinides have been generated at Hanford and Savannah River as a result of neutralizing nitric acid solutions from PUREX recovery operations. A large body of work has been performed to better define the speciation of the actinides and to examine some potential processes for removing actinides from highly caustic tank wastes, including plutonium removal with various precipitants and absorbents. An overview of this work with references to the extensive literature has been published (Clark and Delegard, 2002).

Alkaline solutions containing strong ligands that can compete with hydroxide such as carbonate, fluoride, and peroxide can give high solubility to actinides in some oxidation states and even stabilize unusual oxidation states such as Pu(vii). The relatively small amount of work that has been done on extraction of actinides from alkaline solutions is reviewed in Chapter 24 (Section 3.7). One method to produce MOX fuels uses crystallization of Pu(vi) and U(vi) from ammonium carbonate solutions as $(NH_4)_4PuO_2(CO_3)_3$ or $(NH_4)_4UO_2(CO_3)_3$, respectively. The ammonium plutonyl and uranyl carbonates can be crystallized separately and blended or coprecipitated as the mixed carbonate (Roepenack *et al.*, 1984). An alkaline processing scheme for separation of the components of spent fuel in sodium carbonate/bicarbonate has been proposed and tested at a small scale on uranium and nonradioactive fission product elements (Asanuma *et al.*, 2001).

7.5.7 Nonaqueous separation processes

As noted above, the recovery of plutonium from irradiated uranium fuels has been dominated by the PUREX process, which requires dissolution of the fuel matrix in nitric acid. Alternative fluid media have been used or are under study to dissolve the uranium matrix and allow separation of the fission products from uranium, plutonium, and the other actinides, but none of these methods have been deployed on a large scale. The types of fluid media used include molten salts, molten metals, volatile halide compounds, ionic liquids, and supercritical fluids. The potential advantages for separation processes using these types of media compared to aqueous-based separations include: (1) greater resistance to radiation damage relative to water and organic solvents, (2) fewer and sometimes less complex steps to obtain products, (3) smaller highly shielded processing area, (4) smaller waste volumes that may also allow ready preparation for disposal, (5) simpler criticality control with reduced amounts of neutron moderating and reflecting materials, and (6) new separation selectivity. The separation selectivity for some of the nonaqueous processes are lower on a per stage basis relative to some of the aqueous technology, but that is not always a disadvantage when considering that more impurities may be acceptable in future reactor fuels and that safeguards benefits may result from keeping some components of the original mixture together. The advantages listed above do not apply to every process, but serve to give an indication of why there is continuing interest around the world in nonaqueous processing for advanced nuclear power systems.

The nonaqueous separation methods have disadvantages as well. The major disadvantage has already been mentioned, in that these processes have not been developed as extensively as the aqueous methods and thus have less well-defined costs, safety envelopes, and operational experience. The chemistry of these nonaqueous separation methods is presented in more detail in Chapter 24, especially as they apply to advanced methods for partitioning of spent nuclear fuel. In this chapter, we will briefly review the nonaqueous separation methods most relevant to plutonium processing.

(a) Pyrochemical separation and conversion processes

After plutonium has been separated from the fission products, pyrometallurgical operations have been used since the days of the Manhattan Project to prepare and purify metallic plutonium from various compounds (Hammel, 1998). Plutonium is a very electropositive and reactive metal, and preparation and purification methods based on molten salts and molten metals under inert atmospheres were adapted from industrial practice with adjustments required for actinide-specific factors such as radioactivity and criticality. The major pyrochemical processes used to prepare and purify plutonium metal (bomb reduction of PuF_4, direct oxide reduction (DOR) of PuO_2, molten salt extraction (MSE) of americium, electrorefining (ER), and pyroredox) are discussed in Sections 7.7.1 and 7.7.2. The pyrochemical operations occur in mixtures of molten Group 1 or 2 chloride or fluoride salts at temperatures of 700–900°C, although temperature spikes near 2000°C may occur during the bomb reduction of PuF_4 with calcium metal. Preparing the feed materials for these pyrochemical operations using aqueous processing operations is reviewed in Section 7.5.3(b).

A wide variety of pyrochemical processes have been considered to separate the components of spent nuclear fuels in advanced nuclear fuel cycles. The processes range from early work on use of molten metals such as silver, cadmium, zinc, and magnesium that are immiscible with molten uranium as extractants for plutonium (Dwyer *et al.*, 1959; Wiswall *et al.*, 1959) to recent work on the pyroelectrochemical deposition of PuO_2 and UO_2 from molten chloride salts for direct fabrication by vibropacking into fast reactor fuel elements (Grachev *et al.*, 2004). An entire reactor system, the Molten Salt Reactor Experiment, based on a molten BeF_2 and ^7LiF core containing fissile UF_4 and fertile ThF_4 was studied at Oak Ridge National Laboratory in the 1960s. Reviews of these processes, both historical and those under development, have been published (Long, 1978; Bychkov and Skiba, 1999).

(b) Room temperature ionic liquids

Room temperature ionic liquids (RTILs) are salts that are liquid at or near room temperature. The RTILs currently under study consist of an organic cation (e.g. quaternary ammonium, $R_1R_2R_3R_4N^+$, or alkylpyridinium) paired with a wide variety of inorganic and organic anions (e.g. $AlCl_4^-$, PF_6^-, $CF_3CO_2^-$). The RTILs are under study for a wide array of applications, such as organic synthesis, battery electrolytes, catalyst systems, and metal ion separations (Rogers and Seddon, 2002). It should be noted that the RTILs and the inorganic molten salts discussed above under pyrochemistry are part of the larger class of ionic liquids. The inorganic salts generally have much higher melting points, but that situation may change to some extent as new classes of ionic liquids are investigated. For example, the sodium/potassium nitrate eutectic has a melting point near 170°C.

Potential applications of RTILs to plutonium and actinide separations are under development in two main areas: use as low temperature ionic liquid solvents for electrochemical deposition of metal or oxide and as liquid–liquid extractants for actinide metal ions from aqueous solutions. A research team led by the Queen's University of Belfast and British Nuclear Fuels, Ltd. has also proposed using RTILs to process spent nuclear fuel (Baston *et al.*, 2002; Pitner *et al.*, 2003). It is not yet known if the present generation of organic-containing RTILS is sufficiently radiation resistant for the processing of spent fuel.

(c) Halide volatility processes

The isotopic separation of volatile UF_6 using processes such as gaseous diffusion or gas centrifugation has been practiced at a large scale since the 1940s. In 1949, Sheft, Andrews, and Katz proposed a separation process for irradiated nuclear fuel based on fluorination using liquid interhalogen compounds. This was the beginning of an extensive research and development program into what is commonly called the fluoride volatility process (Sheft *et al.*, 1949). In this type of process, the irradiated fuel (uranium oxide, uranium alloys, even fuel assemblies with cladding intact) is dissolved in a liquid fluorinating solution, a molten salt sparged with fluorine, or fluorinated directly in a fluidized bed. The volatile UF_6 (along with NpF_6 and PuF_6 depending on the process details) and fission product fluorides such as TcO_3F, RuF_6, NbF_6, and MoF_6 are collected and separated using volatility differences and differences in reactivity of the fluorides with beds of solid reagents. In some proposed fluoride volatility processes, neptunium and plutonium are left with the nonvolatile fission product fluorides and separated by another method such as solvent extraction (Amano *et al.*, 2004).

The major advantages of the fluoride volatility process are relatively simple chemistry, radiation resistance of the reagents, high decontamination factors, and separation of uranium in a form suitable for re-enrichment. The disadvantages are the use of extremely corrosive reagents and the attendant corrosion of materials of construction, the criticality concerns associated with the high reactivity of hexafluorides, especially PuF_6, and controlling their deposition in the process equipment. Investigations of variants of fluoride volatility continue today, but these processes have not yet been deployed on a large scale. A fluoride volatility process for recovery of plutonium from certain scrap materials was demonstrated at the Rocky Flats Plant on a pilot scale, but was never deployed as a regular plant operation (Standifer, 1968).

Chloride volatility processes for separating the components of spent fuels have also been investigated (Bohe *et al.*, 1997). In general, this appears to be a less selective process because of the greater number of volatile fission product chlorides that could accompany the volatile actinide species, but the separation of the various volatile chloride species has not received as much effort as the fluoride system. The removal of zirconium alloy cladding materials by chlorination with HCl or Cl_2 and collection of the volatile $ZrCl_4$ has also been examined (Gens, 1961). This process could potentially provide an attractive alternative to mechanical decladding methods and could allow recycling of the slightly radioactive zirconium.

(d) Supercritical fluid extraction processes

Supercritical fluids, principally carbon dioxide, have been investigated to extract actinides from waste materials, for separating actinides and fission products from spent nuclear fuels, and as an alternative to conventional liquid–liquid extraction. Reagents required for forming metal ion complexes (which include complexing agents, acids, and/or redox reagents) such as 1,3-diketones or $TBP \cdot HNO_3$ are dissolved in supercritical carbon dioxide and this fluid phase is contacted with a solid material (e.g. uranium oxides or a waste solid) or an aqueous phase. The extracted metal ions can be recovered by a number of methods: changing the pressure to modify solubility and filtering a solid product, removing the carbon dioxide as a gas to leave a solid or liquid product, or back-extracting the metal ions into an aqueous phase. The bulk of the studies in this area with actinides have used uranium and thorium, but some work with plutonium and other transuranic elements has appeared. Extraction of U(VI) and Pu(IV) from aqueous nitric acid solutions into supercritical CO_2 solutions of TBP has been studied as a function of temperature and pressure (Iso *et al.*, 2000). Some data on the dissolution of oxides with $TBP \cdot HNO_3$ dissolved in supercritical CO_2 have been reported for PuO_2 and solid solutions of $(Pu,U)O_2$ and $(Pu,Am,U)O_2/Eu_2O_3$ (Trofimov *et al.*, 2004). The use of chelating agents dissolved in supercritical CO_2 or liquid CO_2 with modifiers such as pyridine or water for decontamination of various solid materials including stainless steel, rubber, cotton, plastic, and soil from plutonium and other radionuclides has been studied (Murzin *et al.*, 2002b). The solubility of some 1,3-diketone complexes of U(VI), Np(IV), Pu(IV), and Am(III) in supercritical CO_2 has been measured (Murzin *et al.*, 2002a,b). Removal of plutonium and americium from soil using TBP and thenoyltrifluoroacetone (TTA) or hexafluoroacetone in supercritical CO_2 has been investigated (Mincher *et al.*, 2001; Fox and Mincher, 2002). The studies of supercritical fluid extraction for actinides are reviewed extensively in Chapter 24 (section 3.10).

(e) Combination processes

A great variety of aqueous, nonaqueous, and combined aqueous and nonaqueous processes have been proposed for partitioning of spent fuel. As described above, to prepare and purify plutonium metal, a combination of aqueous (PUREX and precipitation-crystallization methods) and nonaqueous (pyrochemical) processes has been used. A few recent examples proposed in the literature will be briefly described to indicate that combination processes are being considered in future separation facilities for processing used nuclear fuels. Amano and coworkers proposed the use of fluoride volatility on irradiated fuel to separate uranium for re-enrichment. Some volatile fission product fluorides such as technetium would also be collected separate from the uranium. The residual solid would then be dissolved in nitric acid for PUREX-type solvent extraction to separate plutonium and other transuranic actinides from the fission products to recycle the actinides to a fast reactor system, the so-called FLUOREX process (Amano *et al.*, 2004). Another group in Japan has proposed separating uranium, neptunium, and plutonium from spent fuel dissolved in nitric acid by oxidizing the neptunium and plutonium to the hexavalent state and then cooling the nitric acid solution to crystallize out the mixed nitrate complex $(\mathrm{U, Np, Pu})\mathrm{O_2(NO_3)_2} \cdot x\mathrm{H_2O}$ (Kikuchi *et al.*, 2003). A variety of other combined aqueous/nonaqueous processes that have been proposed for processing irradiated fuels are reviewed in Chapter 24.

7.6 ATOMIC PROPERTIES

Plutonium, like all of the heaviest elements, has a very complex electronic structure. The free atom and free ion spectra of plutonium are among the richest and most thoroughly studied of any chemical element. The complexity of the electronic structure is apparent in the spectral properties, such as X-ray absorption and emission spectra, and arc, spark, and discharge emission spectra. Early measurements were made with electrodeless discharge lamps and large grating spectrographs such as the 9.15 m Paschen–Runge spectrograph at Argonne National Laboratory (ANL). Very high-resolution grating spectrographs have been replaced by Fourier transform (FT) spectrometers such as those at the Laboratoire Aimé Cotton (LAC) (built in 1970) and at the Kitt Peak National Solar Observatory. The plutonium free atom, Pu^0, designated Pu I, has 94 electrons of which 86 electrons are in filled shells as found in the radon atom. It is customary in discussing the actinide series to only list the electrons in shells outside the radon core. The outermost electrons of the free actinide atoms and ions outside the radon core are found in the 7s, 7p, 6d, and 5f shells. For example, the ground state (lowest energy) configuration for Pu I is $5f^67s^2$. Identified excited configurations of Pu I within the first 3 eV ($\sim$24,000 cm^{-1}) of the ground state include $5f^56d7s^2$, $5f^66d7s$, $5f^56d^27s$, $5f^67s7p$, $5f^57s^27p$, and $5f^56d7s7p$. In the free atoms and ions, many low-lying configurations interact strongly with each other, giving rise to a large number of electronic states, and tens of thousands of spectral lines. A detailed discussion and review of the spectra of actinide free atoms and ions can be found in Chapter 16, and in reviews by Blaise *et al.* (1983a, 1986), Reader and Corliss (1980), and Blaise and Wyart (1992).

7.6.1 Optical emission spectra of Pu I and Pu II

The emission spectrum of neutral (Pu I) and singly ionized (Pu II) plutonium, which can be excited by arc, spark, hollow cathode, or inductively coupled plasmas, has been extensively studied. The first measurements of plutonium were conducted in 1943 by Rollefson and coworkers (Rollefson and Dodgen, 1943; Dodgen *et al.*, 1944, 1949) who measured the wavelengths and intensities of about 125 spectral lines. In the initial publications of plutonium spectra, only the wavelengths and intensities of unidentified transitions were reported. In 1959, McNally and Griffin reported the first energy level analysis for Pu II, where seven levels of the lowest terms of the $5f^67s$ (^8F and ^6F) electronic configuration were determined (McNally and Griffin, 1959). In 1961, Bovey and Gerstenkorn determined the five lowest levels of $5f^67s^2$ (^7F) for Pu I (Bovey and Gerstenkorn, 1961). In 1961, a collaboration was formed between scientists at ANL, LAC, and Lawrence Livermore National Laboratory (LLNL) to continue studies of the term analyses of Pu I and Pu II spectra. In 1970, the FT spectrometry at LAC was used to record the spectra of ^{240}Pu and of a mixture of ^{240}Pu, ^{242}Pu, and ^{244}Pu isotopes up to 3.59 μm. A portion of one of these spectra is shown in Fig. 7.8. The high resolution and extension into the infrared spectral region greatly enhanced the spectral analysis and allowed the connection between the lowest odd and even levels (Blaise *et al.*, 1983a).

The first comprehensive description of Pu I and Pu II spectra became available in 1983, when Blaise, Fred, and Gutmacher collected wavelengths, wavenumbers, intensities, classifications, and isotope shift data in a 612 page ANL report (Blaise, 1983b). In 1992, Blaise and Wyart published all known energy levels of the actinide elements that had been analyzed up to that time and listed ionization stage, energies, intensities, *J*-values, and level assignments of selected lines (Blaise and Wyart, 1992). The contents of that compilation are available on an updated database at LACs website (www.lac.u-psud.fr).

At the time of this writing (2005), 9500 isotope shifts have been measured, and half of them are in the IR region. More than 31,000 lines of the Pu I and Pu II spectra have been observed, of which 52% have been classified as transitions between pairs of levels (Blaise *et al.*, 1983a, 1986; Blaise and Wyart, 1992). With the aid of Zeeman and isotope-shift data, a total of 606 even and 589 odd levels for Pu I, and 252 even and 746 odd levels for Pu II, have been identified. For all

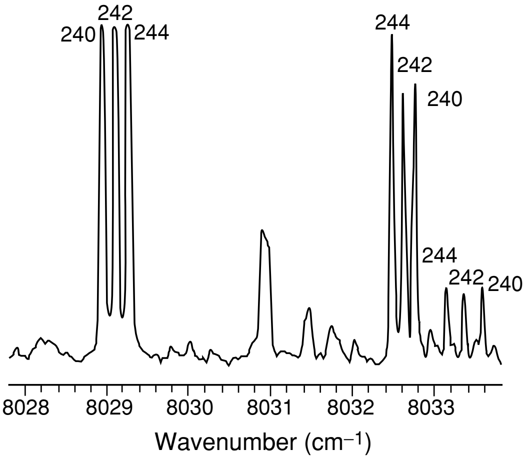

Fig. 7.8 *Fourier transform spectrum of a mixture of ^{240}Pu, ^{242}Pu, and ^{244}Pu isotopes (Blaise* et al., 1983a).

these levels the quantum number J has been assigned, and for many levels Landé g-factors are given. To date, levels belonging to 14 different electronic configurations in Pu I, and 9 electronic configurations in Pu II have been identified. The lowest levels of these configurations are given in Table 7.8 along with the Landé g-factors and experimental isotope shifts (Blaise *et al.*, 1983a; Blaise and Wyart, 1992).

The full-term analysis of plutonium spectra is still not yet complete because, even in 2005, a detailed quantum-mechanical treatment is hindered by the extreme complexity of the spectra. Even though the emission spectra of plutonium are still not completely assigned, they are among the best-understood spectra of the heavy elements.

7.6.2 Ionization potentials

The first ionization potential (IP) is a fundamental physical and chemical property of an element, and it is directly connected to the atomic spectra. Its accurate determination is important for identifying systematic trends within the actinide series of elements. In 1973 and 1974, Sugar derived values for the ionization energies of neutral plutonium and other actinides by using interpolated spectral properties of the atoms (Sugar, 1973, 1974). For neutral plutonium, the first IP was calculated to be 6.06(2) eV or 48,890(200) cm^{-1}. Worden *et al.* (1993) measured the first IP of ^{239}Pu by laser resonance techniques requiring as much as 2 g of ^{239}Pu. The photoionization threshold value for the ^{239}Pu I IP was determined to be 48,582(30) cm^{-1}, and the more accurate value from the Rydberg series measurements was 48,604(1) cm^{-1} or 6.0262(1) eV. In 1998, Erdmann and coworkers reported the first IP of ^{239}Pu using resonance ionization mass spectrometry (RIMS), a technique that requires only a few hundred picograms of material. In this approach, one- or two-step resonant laser excitation in a well-defined electric field promotes the atoms to a highly excited state, and ionization is obtained by scanning the wavelength of an additional tunable laser across the threshold, and extrapolation to zero field strength. From RIMS data, the first IP was found to be 48,601(2) cm^{-1} or 6.0258(2) eV (Erdmann *et al.*, 1998; Waldek *et al.*, 2001).

7.6.3 X-ray spectra

Plutonium X-ray spectra have been studied in detail by several authors (Cauchois *et al.*, 1954; Cauchois and Manescu, 1956; Shacklett and DuMond, 1957; Merrill and DuMond, 1958, 1961; Nelson *et al.*, 1969, 1970), and detailed wavelength and energy tables have been published by Bearden (Bearden, 1967; Bearden and Burr, 1967). The reader is also referred to the *Gmelin Handbook* (Koch, 1973c). The K and L series of the Pu X-ray spectra are known, and a few lines of the M and N series have been measured (Cauchois *et al.*, 1963a,b; Bonnelle, 1976). The L edges of the X-ray absorption spectra have been used

Table 7.8 *The lowest energy level of each electronic configuration of neutral Pu I and monovalent Pu II with their corresponding term symbol, energy, Landé g-values, and isotope shifts* (*Blaise and Wyart*, 1992).

for plutonium oxidation state determination through the X-ray absorption near edge structure (XANES) in a variety of matrices (Conradson *et al.*, 1998, 2004a; Duff *et al.*, 1999; Richmann *et al.*, 1999; Fortner *et al.*, 2002; Antonio *et al.*, 2004; Lechelle *et al.*, 2004).

7.6.4 Core-level spectra

A few core-level spectra on plutonium compounds have been measured and comprehensively reviewed by Teterin and Teterin (2004). Core-level spectra that probe plutonium 4d, 4p, 4f, 5d, 5p, 6s, and 6p levels have been applied to determination of oxidation states and local environment, the magnetic properties of compounds, the nature of the chemical bonding, and secondary electronic processes that accompany photoemission. The use of fine structure spectral parameters, together with the electron binding energies and line intensities, significantly extends the scope of application of the X-ray photoelectron spectroscopy (XPS) method in structural studies. We mention only a few recent applications of core-level spectra.

Kotani and coworkers examined 4f core XPS of PuO_2 and other actinide dioxides and employed the Anderson impurity model to show that PuO_2 is a strongly mixed-valent compound and that a crossover between Mott–Hubbard and charge-transfer insulators occurs near NpO_2 (Kotani and Ogasawara, 1993; Kotani *et al.*, 1993). Allen and coworkers examined Pu 4f XPS of the α, β, γ, and δ phases of plutonium metal. They found that the 4f core-level spectra display features that vary systematically for the α, β, γ, and δ phases. For all phases they observed a sharp feature at binding energy 422 eV and a much broader shoulder that is approximately 2.5 eV higher. Application of an Anderson impurity model indicates that these features represent well-screened ($5f^6$) and poorly screened ($5f^5$) final states, respectively (Allen *et al.*, 1996a; Cox *et al.*, 1999). More recently, Gouder *et al.* (2002) employed 4f core-level spectroscopy to demonstrate dramatic changes in the electronic structure of ultrathin layers of α-Pu, and suggest that the surface of α-Pu should have δ-Pu character.

7.6.5 Mössbauer spectra

It is possible to obtain Mössbauer spectra on plutonium using excited states of ^{238}Pu, ^{239}Pu, and ^{240}Pu. In the case of ^{238}Pu, the β decay of ^{238}Np yields the 44 keV excited state of ^{238}Pu, which decays to the ground state with $T_{1/2} = 183$ ps and E2 dipole radiation. The 44 keV γ-ray may be used in resonance absorption measurements. A disadvantage is the short half-life of the 44 keV level (170 ps), which causes line broadening, and the relatively short half-life (2.1 days) of the source nuclide ^{238}Np, which makes it difficult to prepare sufficient amounts of the latter for a Mössbauer spectroscopy source.

For ^{239}Pu, the β decay of ^{239}Np produces a 57.3 keV state of ^{239}Pu, which decays through E2 γ radiation, which may be used in resonance fluorescence spectroscopy. Gal *et al.* (1972) studied the resonance fluorescence of the 57.3 keV γ ray using a $^{239}NpO_2$–ThO_2 source and ^{239}Pu as the absorber. At 4.2 K, a resonance with a half-width of (5.13 ± 0.10) cm s^{-1} was observed. Assuming a Debye temperature of (250 ± 50) K for PuO_2, they calculated a natural linewidth of (473 ± 0.25) cm s^{-1}. This corresponds to a half-life of (101 ± 5) ps, in agreement with the lifetime of rotational levels, which decay by E2 transitions.

For ^{240}Pu, the α decay of ^{244}Cm yields a 42.9 keV state in ^{240}Pu in 23.3% of all occurring α decays. This state decays to the ground state with $T_{1/2} = 164$ ps. The 42.9 keV transition has an internal conversion coefficient of $\alpha_T = 920$. The use of this transition for Mössbauer spectroscopy was first demonstrated by Kalvius *et al.* (1978), who studied tetravalent $^{240}PuO_2$ and hexavalent $^{240}PuO_2C_2O_4$. In the tetravalent system, at 4.2 and 77 K, a single resonance line was found with a width of about 20% larger than the natural width of about 40 mm s^{-1}. In the hexavalent plutonyl oxalate, $PuO_2C_2O_4$, at 4.2 K a quadrupole interaction $|e^2qQ| = 95$ mm s^{-1} was found, but no isomer shifts were detected.

7.7 PLUTONIUM METAL AND INTERMETALLIC COMPOUNDS

Plutonium metal, alloys, and intermetallic compounds have important technological applications principally because of the nuclear properties of isotope 239. Plutonium metals and alloys are the materials of choice for the nuclear explosive in nuclear weapons and for fuel elements for some advanced reactor designs. The metallic properties of plutonium are important not only for nuclear weapons design, but also for the safe storage and disposition of excess weapons-grade plutonium. Plutonium alloys were used in some early reactor concepts (Anderson *et al.*, 1960; Kiehn, 1961; Burwell *et al.*, 1962) and are under development for advanced designs such as the Integral Fast Reactor (Keiser *et al.*, 2003). Much of the early work on plutonium metal and alloys was done in secrecy in the declared nuclear weapons states (mostly in the United States, Soviet Union, U.K., and France). President Eisenhower's Atoms for Peace initiative, which was launched with his December 8, 1953 speech to the United Nations brought most of the scientific work and many of the engineering properties into the open through a series of international conferences, starting with the first Atoms for Peace Conference in Geneva in 1955. Today, the threats of proliferation and terrorism cause concern about the amount of practical information regarding the construction of nuclear devices available in the open literature. Over the years, the U.S. government has taken the position that the fundamental scientific and engineering properties of plutonium be treated as open information. However, practical manufacturing methods, including those specific to weapons manufacture and the performance of nuclear weapons, remain classified. These guidelines are followed in this chapter.

In addition to its technological importance, plutonium in condensed matter also proves to be fascinating scientifically. The unusual nature of plutonium in the solid state is the result of its peculiar electronic structure. It lies near the middle of the actinide series – precisely at a transition point between the 5f electrons participating in bonding or being localized and chemically inert. Exploring the properties of plutonium and its compounds is an area of great interest in condensed matter physics. From a metallurgical perspective, the peculiarities associated with plutonium's electronic structure cause plutonium to defy most conventional metallurgical wisdom. These peculiarities, along with much of the interesting chemistry of plutonium, have been the subject of several recent reviews (Guerin, 1996; Cooper and Schecker, 2000; Terminello *et al.*, 2001; Hanrahan *et al.*, 2003; Jarvinen, 2003). In this section, we focus on the basic properties of plutonium, but we also explore properties of the neighboring actinides to better understand plutonium within the context of the entire actinide series.

Although our focus is on properties, we state at the outset that to delineate plutonium's metallic behavior it is imperative to understand what is called in the materials science community the processing–structure–properties relationship. Metallurgical practitioners routinely adjust properties by tailoring structure through careful control of chemistry and processing of metals and alloys. By structure we mean crystal structure, grain structure, and defect structure on the nano- and microscale. Plutonium is notoriously unstable with respect to temperature, pressure, and chemical additions, and its surface is reactive, especially in the presence of hydrogen or water. The synthesis and processing of plutonium are quite complex. There is considerable concern over lot-to-lot variations in processing and structure because criticality considerations limit the production of plutonium metal and alloys to small lots (at most on the order of kilograms). Also, microcracks, surface reactions, inclusions from impurities, and retained second phases can affect sample properties. In addition, the self-irradiation of plutonium (especially the prevalent isotopes ^{239}Pu and ^{238}Pu) causes microstructural changes that may affect its properties as it ages. Hence, the age of plutonium samples, or the time elapsed since the material was last molten or heat treated, can affect the properties. Unfortunately, most publications on plutonium properties provide little structural information, and detailed descriptions of processing conditions or sample age are typically limited.

We will draw attention to those cases for which the properties are especially sensitive to structure, processing, and age. The reader is also advised to examine reported density data and X-ray crystal structure information as both provide a good indication of what phases were present in the samples studied.

7.7.1 Preparation of plutonium metal

Plutonium metal may be obtained by a number of reduction reactions of plutonium compounds. Summaries of the various reactions have been given by Harmon *et al.* (1961), Leary and Mullins (1966), McCreary (1955), Christensen and coworkers (Christensen and Mullins, 1983; Christensen *et al.*, 1988), Coops *et al.* (1983), and Baldwin and Navratil (1983). Not all of the reactions that produce plutonium metal are ideally suited for metal preparation in production work. For production processes, the chemical reactions must (a) produce a dense, coherent mass of pure plutonium in high yield; (b) generate sufficient heat to melt both the metal and the resulting slag; (c) result in a slag that stays molten and nonviscous long enough to allow the plutonium to coalesce; and (d) work on the scale desired (a reaction suitable for microgram-scale reductions might be less useful for gram- or multigram-scale reductions and vice versa). In reactions where one of the conditions (a–d) is not initially fulfilled, modified process conditions may still make the technique usable. For example, if the heat of reaction for a Ca reduction is insufficient (condition b), then addition of an iodine booster or use of a laser can provide sufficient heat to make the overall process usable. The resulting CaI_2 in turn helps to improve condition (c).

The pyrochemical preparation of plutonium metal is best carried out by reduction of PuF_4, PuF_3, $PuCl_3$, PuO_2, or a PuO_2–PuF_4 mixture with calcium metal in a high-temperature molten salt. Quite often a booster (such as iodine) initiates the reaction and provides sufficient energy to ensure the complete reaction:

$$PuF_4 + 2Ca^0 \rightarrow Pu^0 + 2CaF_2 \tag{7.13}$$

$$2PuCl_3 + 3Ca^0 \rightarrow 2Pu^0 + 3CaCl_2 \tag{7.14}$$

$$PuO_2 + 2Ca^0 \rightarrow Pu^0 + 2CaO \tag{7.15}$$

These methods of preparation do not produce any purification (Leary and Mullins, 1966); they simply produce metallic plutonium. Of these approaches, the reduction of PuO_2 has become the preferred route for preparation of plutonium metal. $PuCl_3$ is extremely hygroscopic, which poses handling difficulties, particularly for large quantities of material. The plutonium fluorides (PuF_4, PuF_3) are neutron emitters (due to α-n reactions), and working with plutonium fluorides requires considerable protective shielding. A related lithium reduction of PuO_2 has been developed as a pyrochemical process for the recycle of oxide fuels (Usami *et al.*, 2002).

Hydriding and dehydriding or hydriding followed by oxidation can recover plutonium metal scraps adhering to other metal surfaces (Haschke, 1991; Flamm *et al.*, 1998). Even at room temperature, plutonium metal reacts reversibly with hydrogen to form a metallic PuH_x powder (see Section 7.8.1).

$$2Pu^0 + xH_2 \rightleftharpoons 2PuH_x \tag{7.16}$$

The hydride spalls off the inert substrate and subsequent heating of the hydride product in a vacuum recovers the plutonium metal.

7.7.2 Modern pyrochemical preparation and refining

Over time, the general process for obtaining, preparing, and refining plutonium has evolved based on the kinds of feed materials available. Historically, plutonium was first produced in production reactors; extracted, concentrated, and converted to either an oxide or fluoride; and then reduced to metal. The resulting metal was used for fabrication of various parts and components. The fabrication process itself generates major quantities of waste and scrap plutonium that must then be recovered and recycled. In modern times, the feed material for preparation and refining of metallic plutonium has evolved to recovery and recycle of residues and scrap material. This in turn drives the current technology selection for metal preparation and refining. In addition, the technology selection must take nuclear material safeguards, accountability, criticality safety, and radiation exposure into consideration. The major pyrochemical processes that are currently employed in large facilities are bomb reduction of PuF_4, DOR, MSE, anode casting, ER, and pyroredox, and these techniques are integrated into a general processing flow diagram, such as the Los Alamos approach indicated in Fig. 7.9. As the figure shows, each operation produces residues that are treated either by pyrochemical or aqueous means to recover plutonium. We will discuss these pyrochemical processes in some detail.

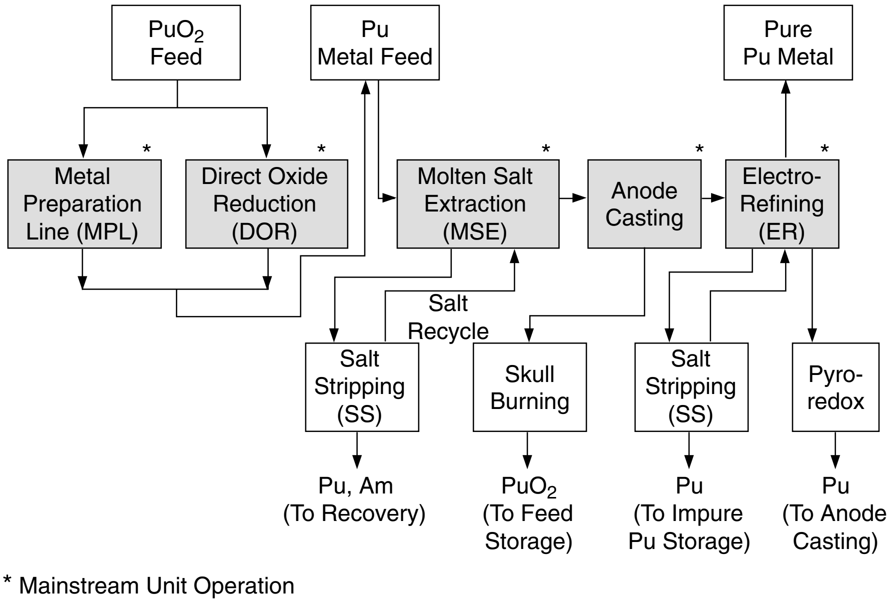

Fig. 7.9 *A general integrated pyrochemical processing system for plutonium metal preparation* (*Christensen* et al., 1988).

(a) Fluorination and reduction

The fluorination and reduction process produces plutonium metal from PuF_4 by the high-pressure reaction between the fluoride and calcium metal (Baker, 1946). Plutonium dioxide is converted to PuF_4 with HF in a hydrofluorination reaction, or by direct fluorination with F_2 (see Section 7.8.6.a). After fluorination of oxide, a chemical booster, such as iodine, initiates the reduction reaction:

$$PuO_2 + 4HF \rightarrow PuF_4 + 2H_2O \tag{7.17}$$

$$PuO_2 + 2F_2 \rightarrow PuF_4 + O_2 \tag{7.18}$$

$$PuF_4 + 3Ca^0 + I_2 \rightarrow Pu^0 + 2CaF_2 + CaI_2 \tag{7.19}$$

An illustration of a typical bomb reduction furnace is shown in Fig. 7.10. The PuF_4, calcium metal, and MgO (magnesia) slag are thoroughly mixed in a molded, open-porosity magnesia crucible. Iodine, added before the equipment is assembled and heated, acts as an initiator and reaction booster. At approximately 325°C, calcium and iodine react exothermically to rapidly raise the temperature. At 600°C, the PuF_4 reduction reaction begins and the system temperature rises rapidly to nearly 2000°C. The slag remains molten while the liquid plutonium sinks to the bottom of the crucible and solidifies. After the equipment has cooled, the crucible is broken to recover the metal button, which is mechanically separated from the slag (Christensen *et al.*, 1988). Little or no purification occurs during the process, and the metal purity is similar to that of the feed material. If the reagents are of high purity, and sufficiently pure plutonium feed is used, then the resulting metal is satisfactory for high-purity applications. Yields usually range from 97 to 99% (Baker and Maraman, 1960). This reaction can be carried out on a relatively large scale, and up to 6 kg batches of plutonium metal are not uncommon.

(b) Direct oxide reduction (DOR)

In the DOR process, plutonium dioxide is reduced with calcium metal to produce plutonium metal and calcium oxide (Mullins *et al.*, 1982; Mullins and Foxx, 1982; Christensen and Mullins, 1983). The reaction takes place in a molten $CaCl_2$ or $CaCl_2$–CaF_2 solvent, which dissolves the resulting CaO and allows the plutonium metal to coalesce in the bottom of the crucible to form a metal button. The PuO_2, calcium metal, and fused $CaCl_2$ are loaded into a vitrified magnesia crucible. The $CaCl_2$ is cast before use and contains no detectable water. The generic DOR apparatus is shown in Fig. 7.11 (Christensen and Mullins, 1983). The crucible is heated in a resistance furnace to 800°C. Once the $CaCl_2$ is molten, a Ta stirrer and a Ta–Ni thermocouple sheath are lowered in the melt. The reaction typically begins at about 820°C with a temperature

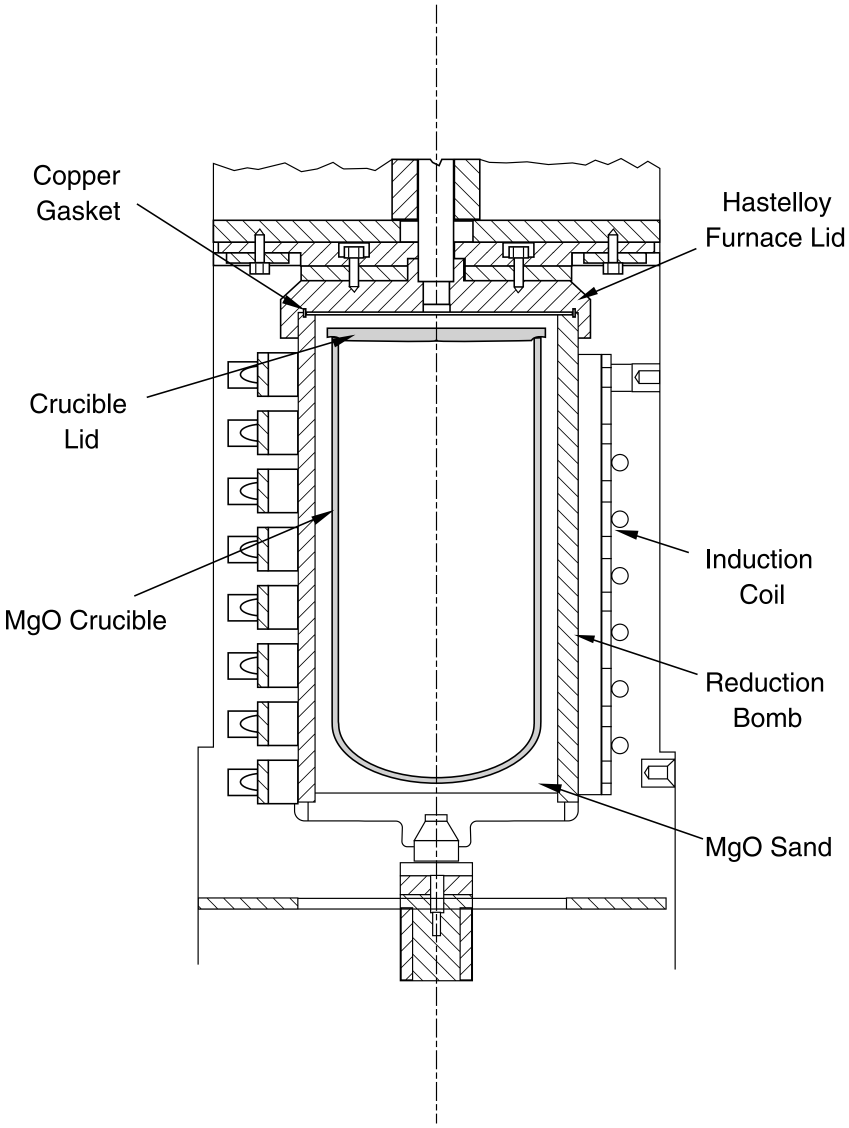

Fig. 7.10 *A furnace assembly for plutonium metal production by reduction of* PuF_4 (*Christensen* et al., 1988).

spike to 875°C. The reaction is complete within 15 min. The reaction proceeds to completion when excess calcium is present, sufficient $CaCl_2$ is available to dissolve the CaO that is produced, and rapid stirring is applied. While stirring, the reaction is monitored with a thermocouple. After completion of the

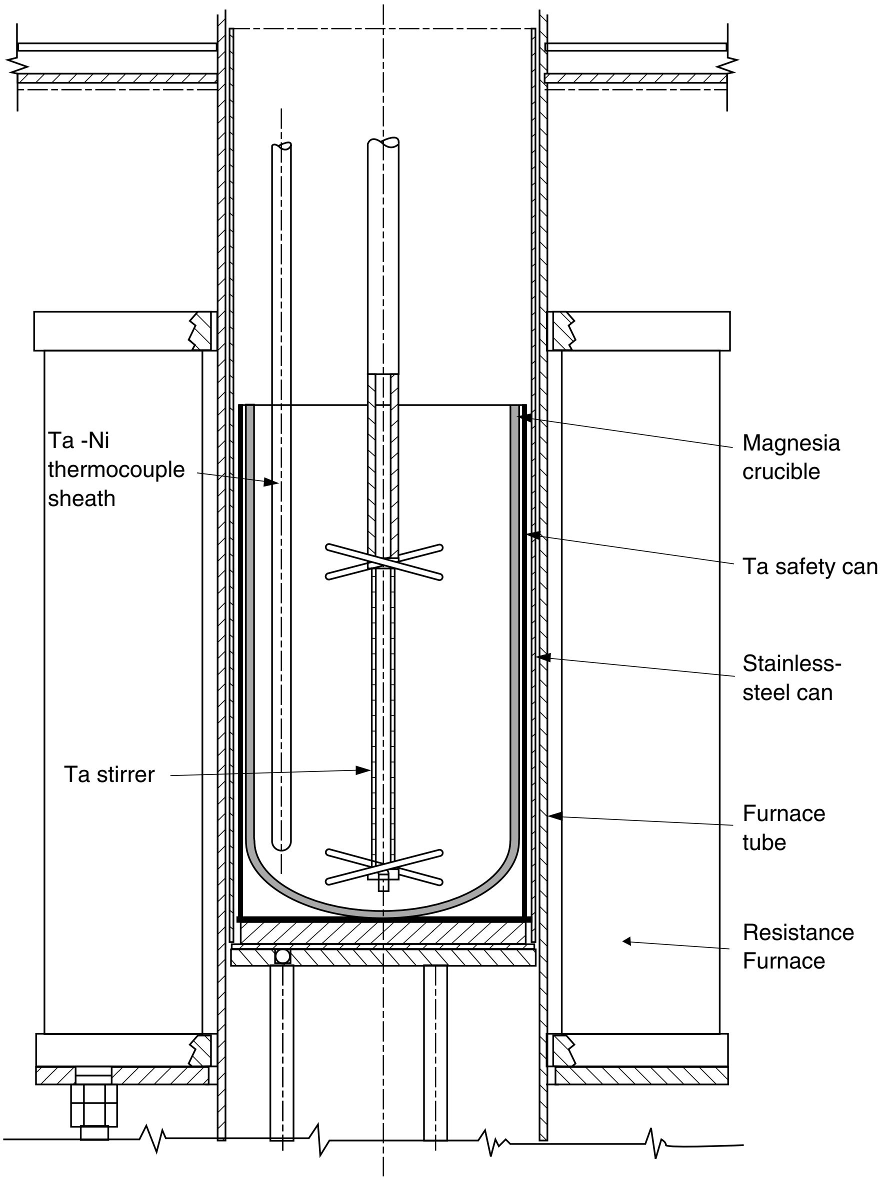

Fig. 7.11 *A general furnace assembly for direct oxide reduction* (*DOR*), *molten salt extraction of americium* (*MSE*) *and pyroredox operations* (*Christensen* et al., 1988).

reaction, the thermocouple well and stirrer are retracted, and the melt is allowed to settle and cool. Almost all the plutonium forms a metal button at the bottom of the crucible, and a typical DOR reaction product is shown in Fig. 7.12. The salt immediately above the button contains a layer of metal shot, and the bulk of

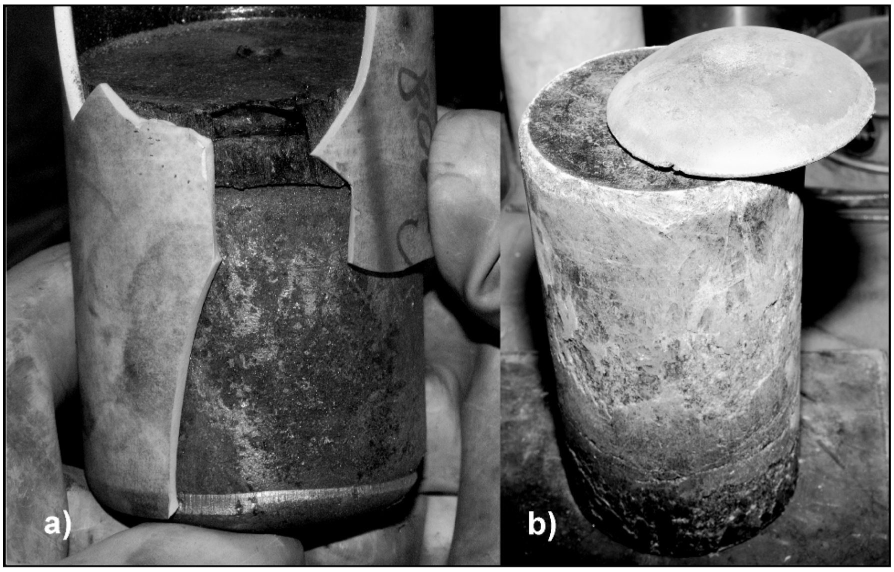

Fig. 7.12 (*a*) *A photograph of a DOR breakout showing the MgO crucible, residues, and metal product at the bottom.* (*b*) *The DOR metal button* (*top*) *and residues* (*photographs courtesy of Los Alamos National Laboratory*).

the salt solidifies above the metal. The plutonium button is mechanically separated, and the shot is recovered by reheating the shot-rich (usually with calcium present) material above the melting point to consolidate the metal. Product yields are greater than 95% (Mullins *et al.*, 1982).

(c) Molten salt extraction (MSE)

The plutonium metal produced in PuF_4 and PuO_2 reduction is impure and needs to be refined. The MSE process is specifically designed to reduce the americium content of plutonium metal (^{241}Am spontaneously grows into plutonium as a result of ^{241}Pu β-decay), but it also separates the more reactive elements, such as rare-earths, alkali-metals, and alkaline-earth metals (Knighton and Steunenberg, 1965; Knighton *et al.*, 1976; Coops *et al.*, 1983). The general principle of MSE is to oxidize the americium to Am(III) to extract it into the salt phase, leaving plutonium in the metallic phase. The extraction procedure is identical to the DOR process and uses essentially the same apparatus shown in Fig. 7.11, with the exception that a reusable tantalum vessel replaces the magnesia crucible, an oxidant is added, and the stirring time is typically 30 min instead of only a few minutes. To run the reaction, workers place impure plutonium metal in contact with a ternary salt, consisting of

$MgCl_2$ as the oxidizing agent in a NaCl/KCl eutectic. The major reactions are (Mullins *et al.*, 1968; Leary and Mullins, 1974):

$$2Am^0 + 3MgCl_2 \rightarrow 2AmCl_3 + 3Mg^0 \tag{7.20}$$

$$2Pu^0 + 3MgCl_2 \rightarrow 2PuCl_3 + 3Mg^0 \tag{7.21}$$

$$Am^0 + PuCl_3 \rightarrow AmCl_3 + Pu^0 \tag{7.22}$$

A typical batch size is 4.5 kg with a 12-h temperature cycle to 750°C. (The actual reaction time is only 30 min.) After the equipment has cooled to room temperature, the fused salt containing the americium and other impurities is separated from the plutonium metal button and crucible. Usually, each feed button goes through two batch extractions. In a typical 4.5-kg run containing 3000 ppm americium, 90% of the americium is oxidized at the expense of ca. 100 g plutonium. A typical product weighs 4.4 kg and contains 98% of the feed plutonium (Christensen and Mullins, 1983; Christensen *et al.*, 1988).

(d) Vacuum melting and casting

After the americium is extracted from the impure metal, the plutonium metal must be cast into a cylindrical geometry that is compatible with the ER cell (Anderson and Maraman, 1962). The ER operation is typically carried out with 6 kg of plutonium, in which case the high-density α phase must be avoided due to nuclear criticality concerns. This requires alloying with sufficient gallium to bring the density from >19 to <16.5 g cm^{-3}. Casting is accomplished by mixing about 6 kg of impure metal with an appropriate amount of gallium in a tantalum pour crucible as shown in Fig. 7.13 (Christensen *et al.*, 1988). The metal and gallium mix upon melting and are bottom-poured from the tantalum crucible into a graphite mold. A casting residue, or "skull", always forms and contains light element impurities, oxide films (thorium, americium, alkali metals, alkaline-earth, and rare-earth metals) or other high melting contaminants. A typical ingot is shown in Fig. 7.14 with yields generally averaging more than 90%.

(e) Electrorefining (ER)

In the ER process, liquid plutonium oxidizes from the anode ingot into a molten-salt electrolyte (Mullins *et al.*, 1960, 1963a,b, 1982; Mullins and Leary, 1965; Mullins and Morgan, 1981). The resulting Pu(III) ion is transported through the salt to the cathode, where it is reduced back to metal. The process is carried out at 740°C in a molten salt consisting of an equimolar mixture of NaCl/KCl containing a small amount of $MgCl_2$ as an oxidizing agent. The $MgCl_2$ reacts with the impure plutonium metal to charge the electrolyte with Pu(III) before a current is passed and ensures the initial reduction of plutonium at the cathode.

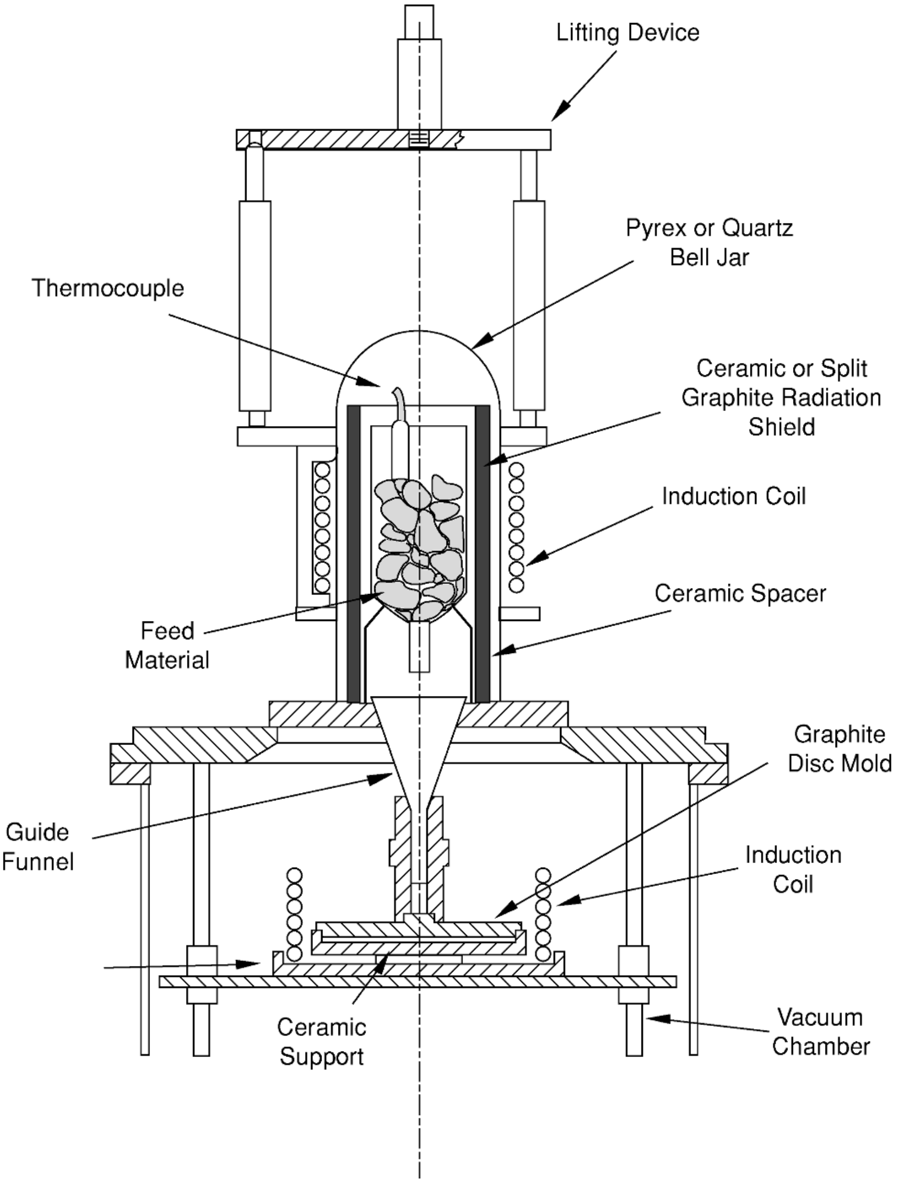

Fig. 7.13 *A general furnace assembly for vacuum casting of plutonium metal* (*Christensen* et al., 1988).

The process is performed in a double-cupped, vitrified magnesia crucible as shown in Fig. 7.15 (Mullins and Morgan, 1981). The inner cup contains the impure metal ingot that serves as the anode material. The electrolyte salt casting is placed on top of the ingot. The crucible is placed inside a tantalum safety can

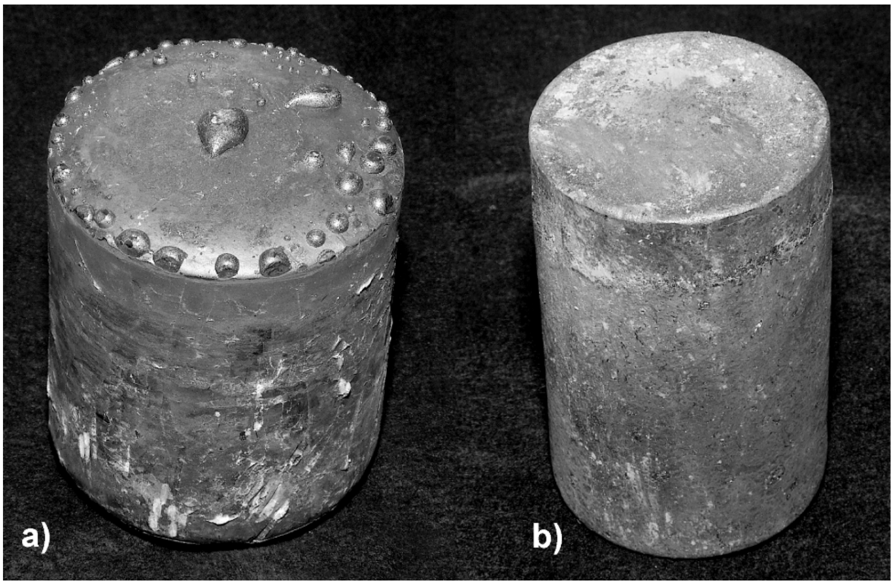

Fig. 7.14 *Photographs of plutonium ingots from vacuum casting.* (*a*) *Metal feed for electrorefining, and* (*b*) *for double electrorefining* (*photographs courtesy of Los Alamos National Laboratory*).

and placed inside the furnace. The assembly is heated using a resistance furnace (the entire assembly is shown in Fig. 7.16). A tantalum or vitrified magnesia stirrer stirs both the impure metal and the molten salt electrolyte. A tungsten rod is suspended in the impure metal pool to serve as the anode rod, and electrically insulated from the salt by a magnesia sleeve. A cylindrically shaped sheet of tungsten is suspended in the annular space between the two cups and serves as the cathode. Stirring and passing a dc current between the anode and cathode accomplish the process. Plutonium oxidizes at the anode and reduces back to metal at the cathode. The liquid metal drips off the cathode and into the annular space. After cooling to room temperature, the cell is broken apart and the plutonium recovered as an annular metal casting, or 'ER ring,' as shown in Fig. 7.17. The product yield from a Pu-1 wt % Ga alloy is greater than 80%. Approximately 10% of the residual plutonium remains in the anode as a very impure anode heel. The rest of the plutonium remains in the salt either as uncoalesced metal shot or as Pu(III), both of which can be recovered and recycled.

(f) Pyroredox or anode recovery

The pyroredox process recovers the plutonium from impure scrap materials and has found application in recovering plutonium from the spent anode heels from

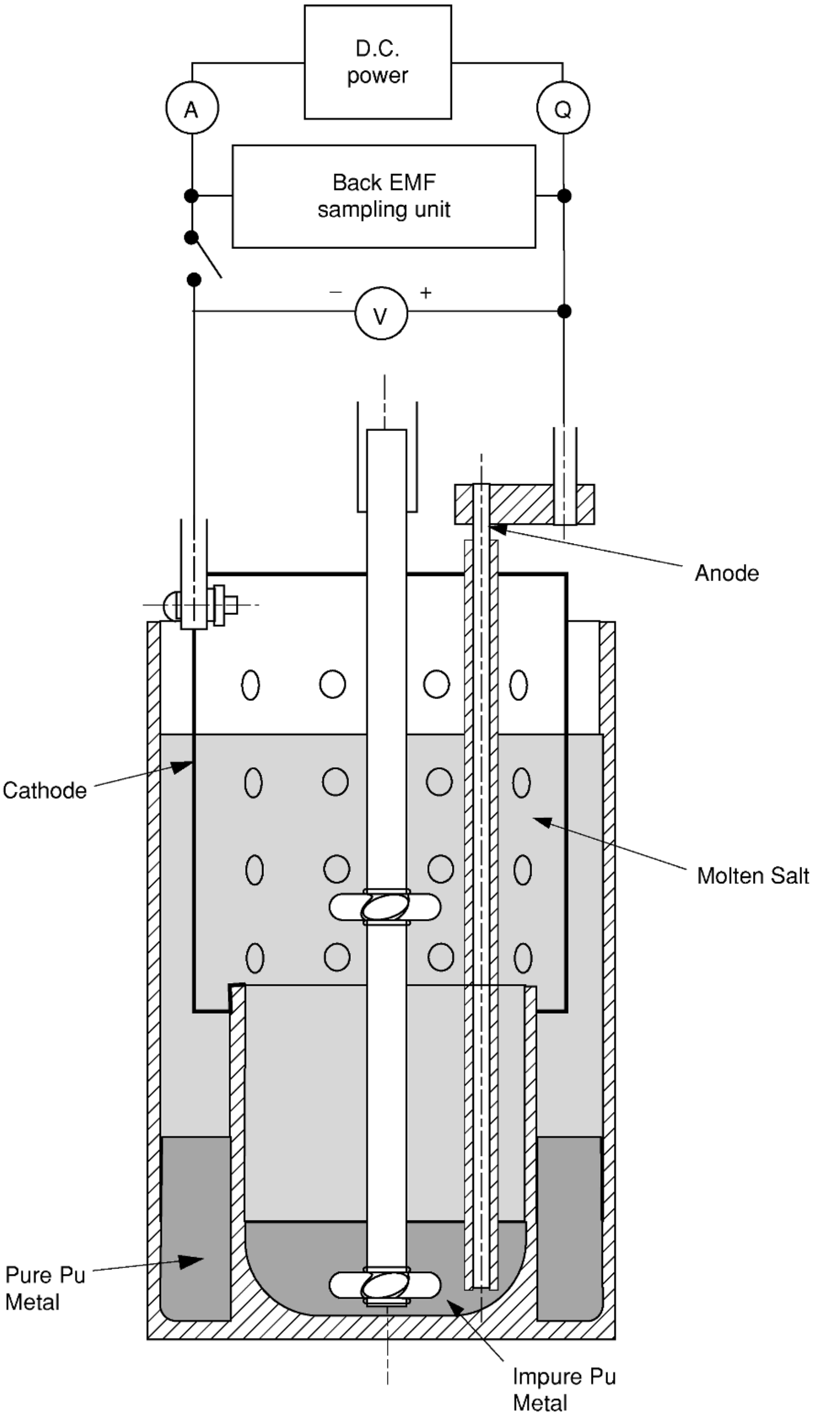

Fig. 7.15 *A general schematic of an electrorefining* (*ER*) *cell showing major features* (*Christensen* et al., 1988).

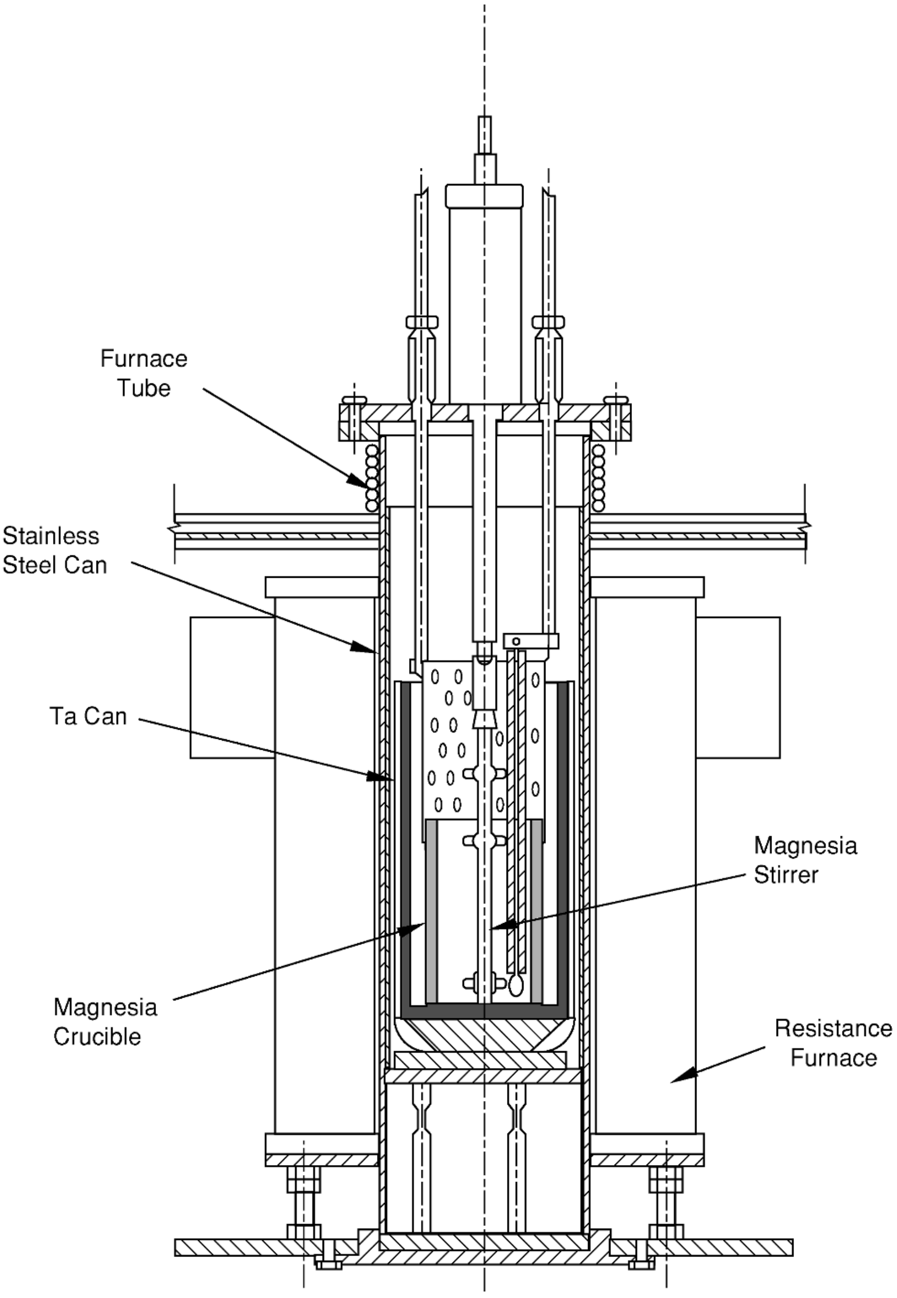

Fig. 7.16 *A general schematic of an electrorefining* (*ER*) *furnace apparatus showing major features* (*Christensen* et al., 1988).

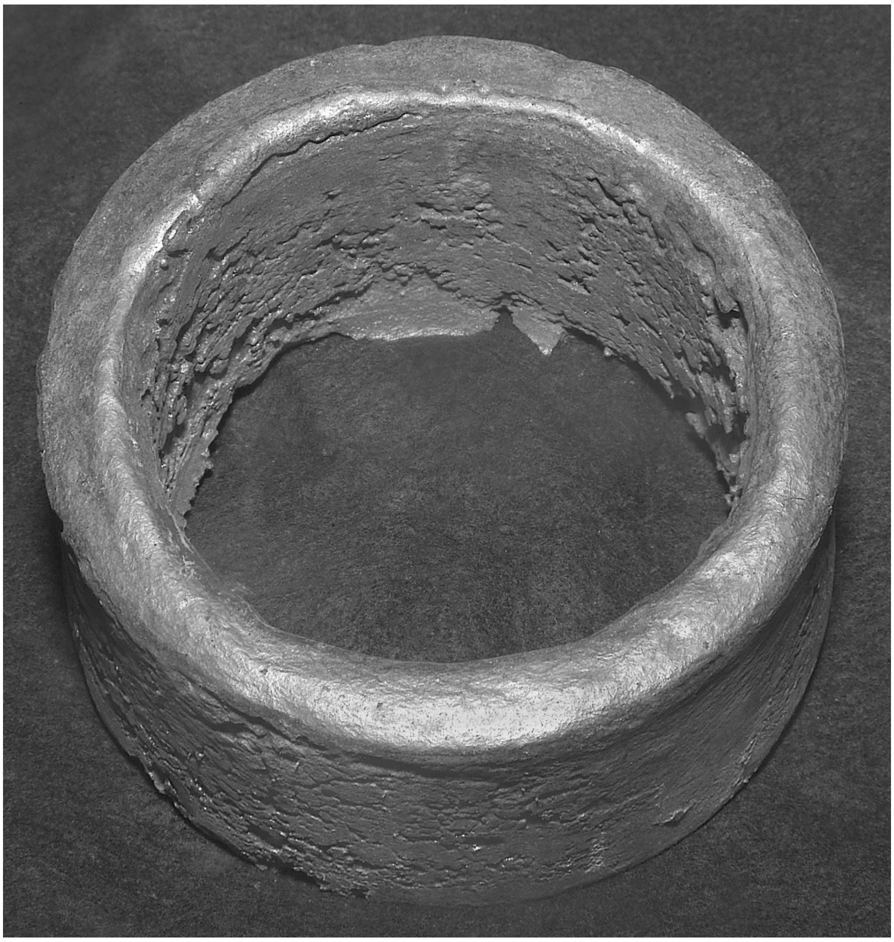

Fig. 7.17 *Photograph of a plutonium product ring from electrorefining* (*ER*) (*photograph courtesy of Los Alamos National Laboratory*).

the ER process (Baldwin and Navratil, 1983; Coops *et al.*, 1983; McNeese *et al.*, 1986; Christensen *et al.*, 1988). The process equipment is identical to that used in DOR (Fig. 7.11). In the pyroredox process, workers initially polish the spent anode with calcium to ensure that all the plutonium is present as metal. The metal is then oxidized to Pu(III) with $ZnCl_2$ dissolved in KCl at 750°C with stirring. After an hour, the mixture is heated to 850°C to promote phase separation. In addition to plutonium, all other elements more active than zinc are oxidized into the salt phase. This process forms a zinc button that may be mechanically separated from the salt and discarded. For the reduction step, the salt containing $PuCl_3$ is crushed and mixed with a $Ca/CaCl_2$ mixture, pressed into an ingot, and placed back into a magnesia crucible and inserted into the furnace assembly. The vessel is heated to 850°C with stirring, and then allowed to cool after removing the stirrer. The chemical reactions are:

$$2Pu^0 + 3ZnCl_2 \rightarrow 2PuCl_3 + 3Zn^0 \qquad (7.23)$$

$$2PuCl_3 + 3Ca^0 \rightarrow 2Pu^0 + 3CaCl_2 \qquad (7.24)$$

The reaction product is a salt phase above a two-phase metal button. The salt phase is mechanically separated and discarded. The bottom, denser metal phase is composed of plutonium and small quantities of calcium and zinc. The upper phase is typically 50% plutonium with the remainder being primarily zinc. Several buttons are allowed to coalesce at 850°C for 6 h to separate the ingots into a plutonium-rich lower phase suitable for ER and a less-pure upper phase that is recycled back to the oxidation step.

(g) Zone-refining of small research samples

Plutonium metal that has been doubly electrorefined is considered of high purity for most applications but still contains small amounts of Fe, U, Mg, Ca, Ni, Al, K, Si, O, C, and H. For small-scale research applications, it can be further purified via levitation zone-refining using a floating molten zone to minimize introduction of impurities from crucible materials. Tate and Anderson (1960) originally observed the phenomenon when they reported that zone melting promoted a reduction of impurity elements within a plutonium rod. Spriet (1965) conducted a more detailed investigation to include quantification of rates and impurity analyses. In more recent work, levitation zone-refining in concert with levitation distillation at reduced pressure has proven to be quite successful at producing ultrahigh purity specimens (Blau, 1998; Lashley *et al.*, 1999). Levitation zone-refining targets metals and metalloids while levitation vacuum-distillation targets daughter products and gases. In the levitation apparatus, radio frequency (rf) power-induced electric current flows into a crucible while the crucible acts as a transformer, inducing a current in the opposite direction to the current in the crucible. Magnetic fields in the crucible and the plutonium are opposed, causing repulsion and levitation of the plutonium a small distance from the crucible walls. Magnetic levitation of plutonium metal rods between 700 and 1000°C enables purification while eliminating plutonium-crucible interactions and minimizing the contact with other elements. The magnetic levitation is the fundamental operating basis for both the zone-refining apparatus and the distillation apparatus.

The zone-refining process involves casting a rod of unalloyed plutonium and then serially passing a molten zone through the rod in one direction at a slow rate. Impurities travel in the same or opposite direction to the direction of motion of the zone, depending on whether it lowers or raises the melting point of the plutonium. Consequently, impurities are swept and become concentrated in the ends of the rod, thereby leaving the remainder purified. The degree of separation approaches an infinitesimal limit as the number of passes increases. Recent work has shown that ten passes through a molten zone can result in the reduction of impurities in double-electrorefined and vacuum-cast unalloyed plutonium from 727 to 184 ppm through levitation zone-refining (Blau, 1998; Lashley *et al.*, 1999).

Since americium exhibits a high vapor pressure relative to plutonium it is possible to remove ^{241}Am daughters from plutonium samples via vaccum distillation. The ^{241}Am is separated when plutonium metal is heated to the liquid state under reduced pressure (10^{-7} Torr). The molten plutonium is levitated while ^{241}Am is distilled off and condensed onto a cold finger. The plutonium is cooled and solidifies. Recent results from levitation distillation show that the concentration of ^{241}Am was reduced from 1100 to 500 ppm (Lashley *et al.*, 1999). These general principles have been combined into a floating zone refining followed by an *in situ* distillation, alloying, and casting technique for high-purity research samples of δ-Pu. In the procedure, a mixture of α-Pu is first levitation zone-refined. The α-Pu and gallium are then added to a levitation crucible. The mixture is heated to the melt while suspended in a magnetic levitation field. As the gallium mixes with the plutonium in the melt, it will stabilize the δ phase upon solidification. While in the melt, ^{241}Am is distilled from the plutonium and collected on a water-cooled condenser. Next, the furnace power is reduced, and plutonium is cast directly from the electromagnetic field into a ceramic mold. The apparatus is illustrated in Fig. 7.18.

7.7.3 Phase stability – allotropes, crystal structures, and transformations

It is important to understand the different allotropic phases of plutonium and the limits of stability with temperature, pressure, chemical additions, and time. We describe the stability of unalloyed plutonium along with the characteristics of its phases as a function of temperature and pressure in this section. We deal with the effects of chemical additions and time subsequently.

C. S. Smith and his Manhattan Project team of metallurgists and chemists were the first to come to grips with the unstable nature of this enigmatic element (Hammel, 1998). During their initial work in 1944, they routinely found the densities of their freshly prepared plutonium samples to vary by more than a factor of two. They quickly determined that unalloyed plutonium has at least five allotropes (a sixth was eventually found) over a very narrow temperature range and that it exhibits large volume changes at the various phase transitions during cooling from the melt, making it difficult to cast. Smith soon found that most of the transformations and the large volume changes could be avoided by alloying pure plutonium with a few atomic percent aluminum or gallium. Such alloying additions retained the high-temperature face-centered cubic (fcc) δ-phase, which is less dense, weak, and ductile, in contrast to the typical room temperature α-phase, which is very dense, strong, and brittle. The profound influence of chemical additions to plutonium on phase stability and the

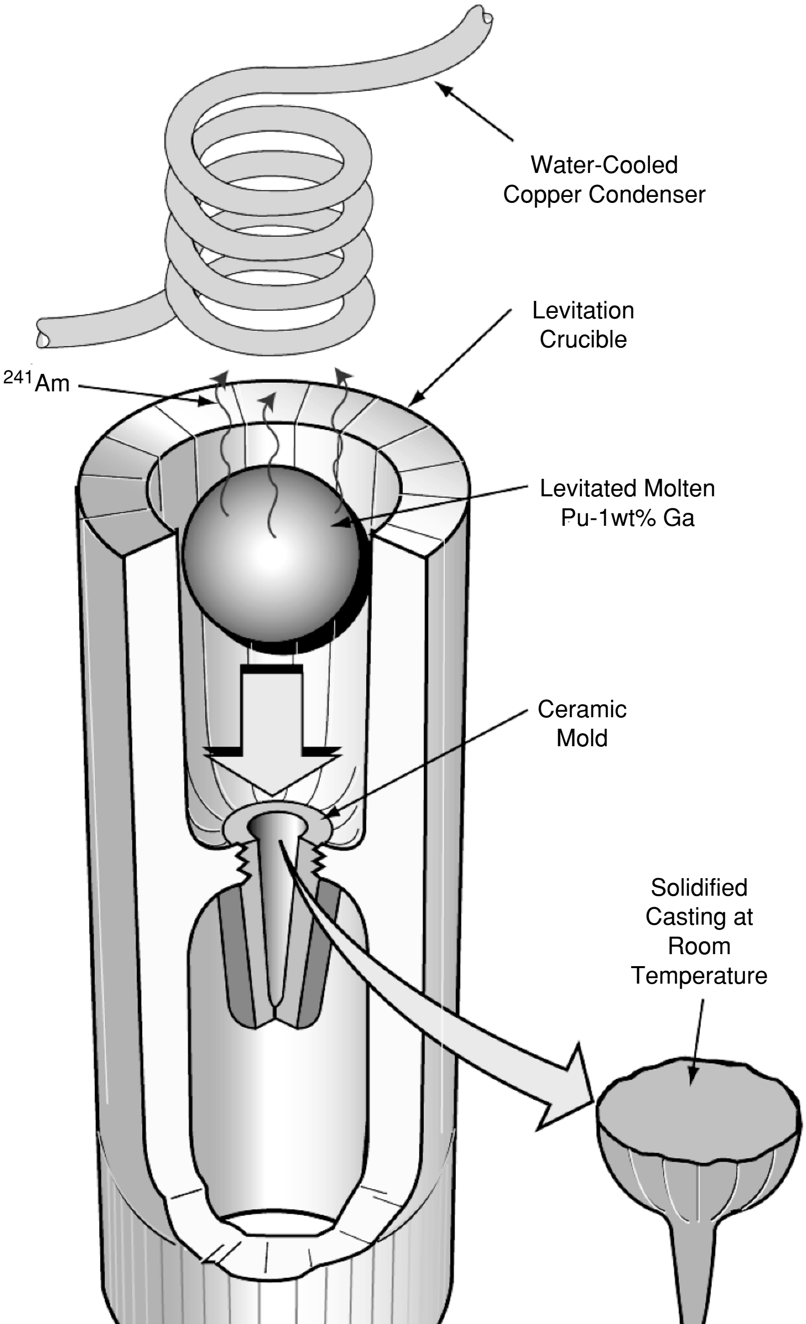

Fig. 7.18 In situ *americium distillation, alloying, and chill casting apparatus* (*Lashley* et al., 1999).

dramatic differences in properties exhibited by the different plutonium allotropes must be kept firmly in mind when considering plutonium and its properties. Moreover, phase transformations between the different allotropes are difficult to avoid during sample preparation, especially if samples are heated, cooled, worked, ground, or polished.

Zachariasen (1944) was the first to suggest that the large density and property variations in the early separated plutonium samples were due to crystallographic modifications of plutonium. Five solid allotropes designated by the Greek symbols α, β, γ, δ, and ϵ were identified during the early studies. A sixth, designated by the symbol δ', was discovered in 1954 by Cramer (Cramer *et al.*, 1961) in high-purity plutonium. An idealized thermal expansion curve is shown for pure plutonium in Fig. 7.19 (Miner and Schonfeld, 1980), along with the crystal structures and densities of the solid phases and the liquid phase. The stability ranges and crystal structure data for the individual allotropes are shown in Table 7.9. The transformation temperatures of the α, β, and γ phases are only approximate because the transformations are kinetically sluggish. The limits represent the approximate transformation temperatures as obtained by dilatometry and thermal analysis at slow heating or cooling rates of 1 to 1.5°C min^{-1}. The actual heating and cooling curves show significant hysteresis.

The data shown in Fig. 7.19 and Table 7.9 demonstrate the idiosyncratic behavior of plutonium. The six solid allotropes at ambient pressure (a seventh was found under pressure by Morgan (1970)) are the most of any element in the periodic table. Plutonium has an unusually low melting point of 640°C, and it contracts upon melting. The maximum density difference between the phases is a very large 20%. Moreover, the classical close-packed fcc phase is the least dense (less dense than the liquid). The two low-temperature phases are low-symmetry monoclinic structures, atypical of metals. The thermal expansion coefficients of these phases are very large and positive, whereas that of the fcc phase is negative.

The low-density, high-temperature phases of plutonium are easily transformed to the higher density phases under hydrostatic pressure as shown in Fig. 7.20 (Liptai and Friddle, 1967). Morgan (1970) clearly demonstrated the existence of a seventh phase at high pressure, designated ζ phase, as shown in Fig. 7.21. Its structure has yet to be determined. Elliott (1980) pointed out the similarity of the new ζ phase to the η phase in the Pu–U and Pu–Np systems. As shown in Fig. 7.20, at 3.0 GPa the ζ phase and all other high-volume phases collapse to the two low-temperature α and β allotropes.

The low-symmetry monoclinic ground-state α phase of plutonium results from the peculiar nature of the 5f electron bonding in plutonium as discussed below. Zachariasen and Ellinger (1957, 1963a) and Zachariasen (1961a) demonstrated that the α phase is a simple monoclinic crystal structure ($P2_1/m$) with 16 atoms per unit cell and eight unique atom positions. All 16 atoms lie in the reflection planes with coordinates $\pm(x,\frac{1}{4},z)$. Several views of the crystal structure of α plutonium are shown in Fig. 7.22. The 16 structural parameter values

	Pu Crystal structure	Density (g cm^{-3})
α	Simple monoclinic	19.86

γ	Face-centered orthorhombic	17.14
δ	Face-centered cubic	15.92
δ'	Body-centered tetragonal	16.00
ε	Body-centered cubic	16.51
L	Liquid	16.65

Fig. 7.19 *Thermal expansion of unalloyed plutonium. This idealized curve was generated by Schonfeld and Tate* (1996) *based on the best available expansion data. Of particular relevance is the correction to the α-Pu thermal expansion, as detailed in Fig.* 7.44.

are listed in Table 7.10 along with the bond lengths. The monoclinic structure of α plutonium is a slight distortion from a hexagonal lattice. This similarity was used by Crocker (1971) in modeling the crystallographic relationships of phase transformations involving the α phase. In addition, the bonding characteristics of the eight atom positions are markedly different. Position 1 has the greatest number of short bonds, whereas position 8 has the fewest short bonds (as shown in Table 7.11). All positions have the same point symmetry. The bonding characteristics are important in determining how the α phase accommodates

[a] Although space group I2/*m* is not one of the 'standard' space groups tabulated in the International Union of Crystallography, *International Tables for X-ray Crystallography*, vol. 1, Kynoch Press, Birmingham, its notation is retained to obtain a β angle of approximately 90° (data from Miner and Schonfeld, 1980).

[b] Data from Lemire *et al.* (2001). The reader is cautioned that the transformation temperatures vary between sources, and are sensitive to heating and cooling rates and metal purity.

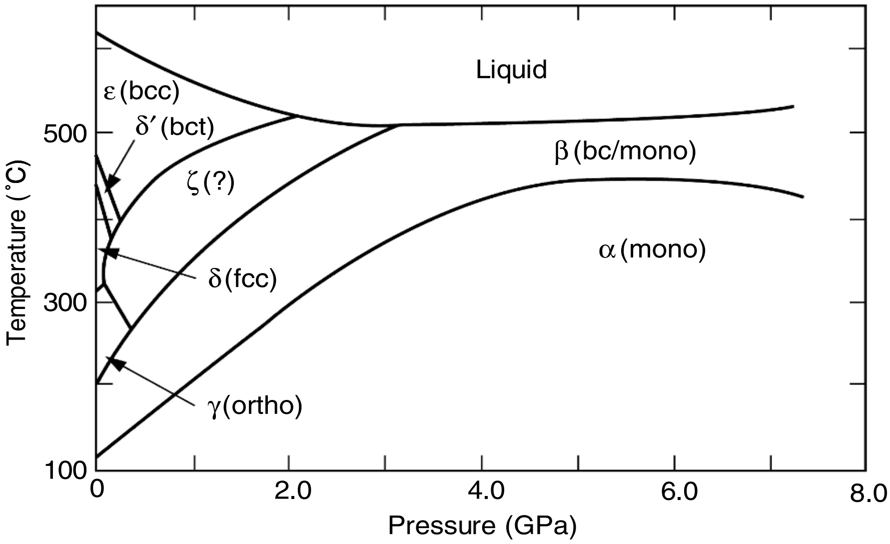

Fig. 7.20 *Pressure–temperature phase diagram of unalloyed plutonium from Liptai and Friddle* (1967).

impurity atoms. Lawson *et al.* (1996) pointed out that with eight unique atom positions, α plutonium looks like a self-intermetallic, much like α manganese. The low-symmetry monoclinic structure of the α phase has a profound influence on its properties; it has no macroscopic ductility, and most properties are highly directional.

The β phase is a body-centered monoclinic (*I2/m*) and equally complex. The atomic coordinates, the structural parameters, and the bond lengths are shown in Table 7.12 (Zachariasen and Ellinger, 1963b). It is considerably less dense than the α phase (17.7 g cm^{-3} compared to 19.85 g cm^{-3}), and it has 34 atoms per unit cell with seven unique atom positions. Properties are also quite anisotropic. The crystal structure of the β phase is compared to the other five allotropes in Fig. 7.23.

The γ phase is a face-centered orthorhombic (*Fddd*) with eight equivalent atoms per unit cell and a density of 17.14 g cm^{-3} (Zachariasen and Ellinger, 1955, 1959; Crocker, 1971). Each atom has four neighbors at 3.026 Å, two at 3.159 Å, and four at 3.228 Å. Roof (cited by Miner and Schonfeld, 1980) pointed out that placing the origin at the center of symmetry places the positions of the eight atoms of the unit cell at ± (1/8,1/8,1/8) + (0,0,0; 0,½, ½; ½,0, ½; ½,½,0). The crystal structure of the γ phase is shown along with the other allotropes in Fig. 7.23.

The δ phase is fcc (*Fm3m*) with four equivalent atoms per unit cell as shown in Fig. 7.23. It is the least dense of the plutonium allotropes at 15.92 g cm^{-3}. Each

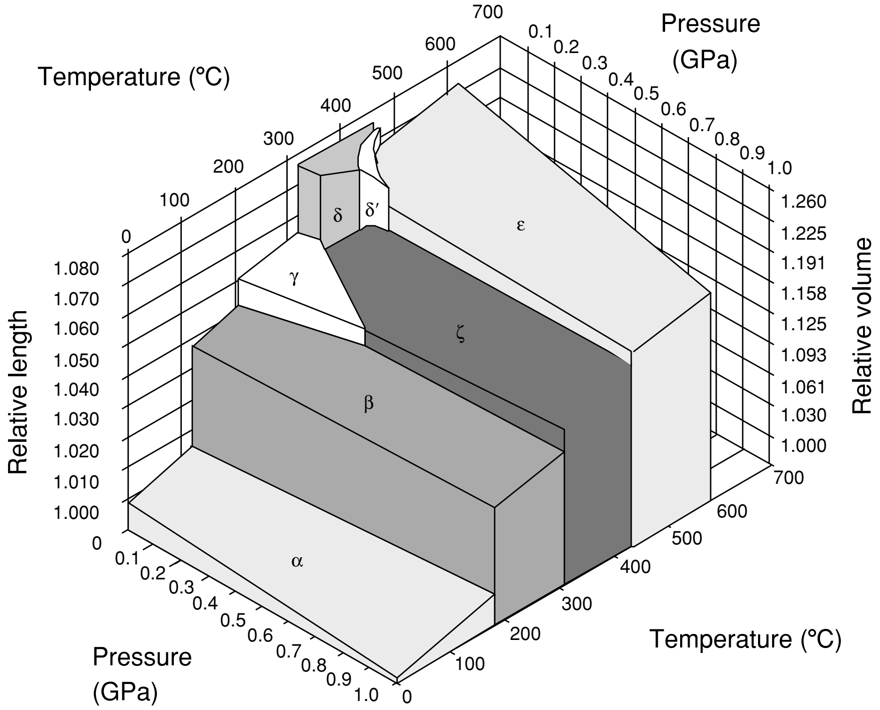

Fig. 7.21 *Pressure–temperature phase diagram from Morgan* (1970) *showing the existence of a seventh phase, ζ.*

atom has 12 neighbors at 3.279 Å in the standard fcc arrangement (0,0,0; 0,½,½; ½,0,½; ½,½,0). The δ′ phase is described by Ellinger (1956) as body-centered tetragonal (*I4/mmm*) with two atoms per unit cell at (0,0,0) and (½,½,½), with a density of 16.00 g cm^{-3}. He pointed out that the structure can be alternatively described as a face-centered tetragonal cell containing four atoms per unit cell, derived from the close-packed arrangement by a slight compression along the [001] direction. The ϵ phase is body-centered cubic (bcc) (*Im3m*) with two equivalent atoms per unit cell at (0,0,0) and (½,½,½). Each atom has eight neighbors at 3.149 Å.

As shown in Figs. 7.20 and 7.21, a seventh solid allotrope, the ζ phase, appears with the application of hydrostatic pressure at elevated temperatures. Very little is known about the precise crystal structure of this phase. However, Elliott (1980) suggested a similarity of this structure with the η phase of the PuU and PuNp systems.

The local coordination and interatomic distances for the four higher-temperature allotropes are shown in Table 7.13. Based on the crystal structure

information presented above, Zachariasen (1961b, 1973) derived metallic radii by normalizing the radii to coordination number 12 and extrapolating the high-temperature data to room temperature. His results are shown in Table 7.14. Zachariasen and others also calculated the valences for the plutonium allotropes. We do not present these here because we do not consider these estimates to be useful in considering the complexity of the f-electron bonding. We also list Dormeval's (2001) compilation of atomic volumes for the various allotropes in Table 7.14.

The liquid phase of plutonium is denser than the three highest-temperature solid phases. Density as a function of temperature is listed in Table 7.15, based on the work of Herrick *et al.* (1959) and Serpan and Wittenberg (1961). Extrapolation of the data in Table 7.15 yields a density of 16.65 g cm^{-3} at the melting point of 640°C. Hence, plutonium contracts approximately 2.5% upon melting. Plutonium liquid has a high surface tension and high viscosity.

The transitions (or, in metallurgical terms, phase transformations) between the various allotropes are important. Most studies of such transformations in unalloyed plutonium were conducted before 1970. A typical thermal expansion curve from Goldberg and Massalski (1970) for high-purity, electrorefined plutonium heated and cooled at 4.5°C min^{-1} is shown in Fig. 7.24. The sluggish nature of the transformation among the lower temperature phases results in

significant hysteresis, compared with the idealized curve shown in Fig. 7.19, and makes it difficult to conclusively determine the transformation temperatures. These temperatures depend on metal purity, microstructural variables (such as grain size and dislocation density), heating or cooling rates, applied stress,

sample size and shapes (resulting in stress effects), and prior transformation history.

Lemire *et al.* (2001) compared various phase transformation studies and compiled the best estimates of transformation temperatures and stability ranges for the various allotropes listed in Table 7.9. Precise transformation temperatures are difficult to measure not only because they depend on the variables mentioned above, but also because all transformations exhibit significant time dependence. The isothermal (as opposed to athermal, where no thermal activation is needed) nature of the α→β and β→α transformations is best illustrated by the so-called time–temperature–transformation (TTT) diagram shown in Fig. 7.25 (after Nelson (1980)). The 'C-curve' shape of the transformation demonstrates how the temperature for the onset of transformation depends on the cooling rate. By determining the curves for both transformations, Nelson was able to establish the equilibrium transformation temperature as 112°C (compared with the average transformation temperature of 122°C during heating at relatively slow rates reported in Table 7.9).

Significant uncertainty still exists about the nature of the transformation mechanisms among the allotropes of plutonium (Hecker, 2000). The transformations among the high-temperature allotropes (δ, δ′, and ϵ) are generally considered to be of a diffusion-controlled (diffusive) nature. However,

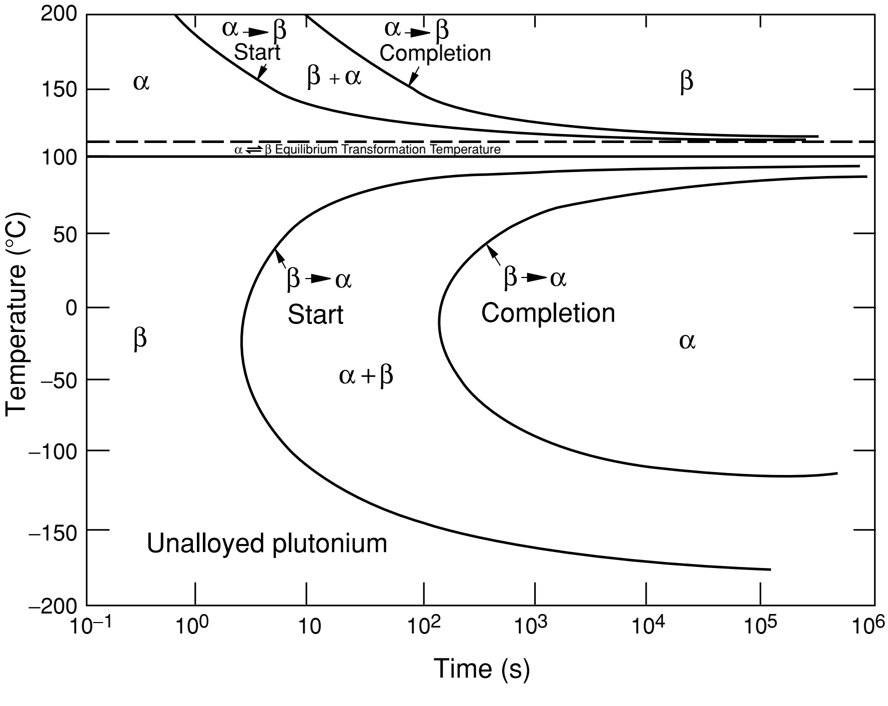

Fig. 7.25 *Representative time–temperature-transformation (TTT) curves of the β→α and α→β transformations in high-purity, electrorefined plutonium. The sample was taken to the β phase for* 45 min *at* 170°C (*from Nelson*, 1980).

transformations at lower temperatures among the δ, γ, β, and α phases show signs of diffusive and diffusionless, shear-type transformations. Shear transformations (of a martensitic nature) involve cooperative shear motion of the atoms and typically result in specific crystallographic relationships between the parent and the transformed phases. The evidence for such relationships was reviewed by Nelson (1980) and by Goldberg and Massalski (1970), who described the highly textured α-phase transformation product that can be formed when the β→α transformation is induced by cooling under applied stress.

Microcracking is difficult to avoid in most unalloyed plutonium as it cools from the melt or from annealing at elevated temperatures. The volume fraction of microcracks can range from 0.1 to 3%. High purity, large sample size, and slow cooling rates result in more extensive microcracking. Thermal cycling between the α and β allotropes greatly exacerbates the microcracking problem and results in sample distortion and surface rumpling (Hecker, 2000). On the other hand, quenching samples from the β phase to –80°C minimizes microcracking. Nelson pointed out that α-phase densities greater than 19.65 g cm^{-3} are generally considered to be good-quality plutonium. Densities around 19.8 g cm^{-3} have been achieved by cooling through the β→α transformation under pressure or by hydrostatic extrusion and concurrent recrystallization (Merz, 1970).

Another important consideration in sample preparation and subsequent property determination is the amount of retained high-temperature phases at ambient temperature. As noted in Figs. 7.24 and 7.25, the transformation from β→α is time-dependent and, hence, not necessarily complete at room temperature, resulting in retained β phase (or sometimes retained γ or δ phases). Impurities generally shift the onset of transformation (the 'C-curve' in Fig. 7.25) to the right. Spriet (1967) demonstrated that the onset of transformation was retarded by a factor of ten as the purity level changed from 200 to 400–1000 ppm. The impurities Ti, Hf, Zr, and U retard the β→α transformation and lead to greater β-phase retention at ambient temperature (Oetting *et al.*, 1976; Hecker, 2000). The impurities Ga, Al, and Si favor retention of the δ phase (Hecker, 2000). The most convenient method to determine the presence of retained high-temperature phases in α plutonium is to measure the density. The best way to identify the retained phases is by XRD; however, by using XRD it is difficult to identify retained phases at the level of less than a few volume percent.

Thermodynamic properties related to phase transformations can be measured directly by calorimetry or estimated from phase diagrams. Such properties are summarized in Table 7.16 along with the best estimates of the equilibrium transformation temperatures and volume changes. The scatter is quite large for reasons mentioned above. Nevertheless, these values are important to help guide the theory and modeling activities. Transformation enthalpies for the pressure-induced ζ phase are shown in Fig. 7.26, as derived from the data of Morgan (1970).

Table 7.16 *Entropies and enthalpies of transformations of the plutonium allotropes.*

Phase transformation	ΔS^a ($J\ K^{-1}\ mol^{-1}$)	ΔS^b ($J\ K^{-1}\ mol^{-1}$)	ΔH^c ($J\ mol^{-1}$)	ΔH^d ($J\ mol^{-1}$)	ΔH^e ($J\ mol^{-1}$)

7.7.4 Alloys and phase transformations

Equilibrium phase diagrams provide a map of phase stability as a function of chemical concentration and temperature (most of the work of this nature has been done at ambient pressure and for binary alloy systems). All of the early work on phase diagrams of plutonium done during and after the Manhattan Project was classified. It was not until President Eisenhower launched the

'Atoms for Peace' initiative that much of that work was declassified and published. The Russian research group associated with A. A. Bochvar (Konobeevsky, 1955) published the first series of plutonium phase diagrams (with elements Be, Pb, V, Mn, Fe, Ni, and Os, as well as the ternary Pu–U–Fe) at a Moscow conference during the summer of 1955 in the preface to the first Conference on Peaceful Uses of Atomic Energy held in Geneva that fall. The U.S., U.K., and France rapidly followed suit. The Russian group added the Pu–Cu, Pu–Al, Pu–Bi, Pu–Zr, Pu–Mo, Pu–Th, and Pu–U systems at the second Geneva conference held in 1958 (Bochvar *et al.*, 1958). Coffinberry *et al.* (1958), and Schonfeld *et al.* (1959) published plutonium phase diagrams based on their work at Los Alamos Scientific Laboratory. Waldron *et al.* (1958) and Cope *et al.* (1960) published the U.K. results and Hocheid *et al.* (1967) the French results.

By 1968, most of the binary phase diagrams of plutonium were determined and published in the classic report of Ellinger *et al.* (1968b). Additional compilations were published in the *Plutonium Handbook*, edited by Wick (1980) and in the *Plutonium Metallurgy Handbook* (Hasbrouk and Burns, 1965). The most recent compilation is presented by Peterson and Kassner (1988). We review the salient features of binary plutonium phase diagrams below. The reader is referred to the reviews mentioned above for a discussion of available ternary plutonium diagrams. We also note that Blank provides a comprehensive compilation of phase diagram data in Table 2/1 of the *Gmelin Handbook of Inorganic Chemistry* (Blank, 1976). In addition, Blank (1976, 1977) provides a comprehensive treatment of the properties of plutonium alloys.

(a) Elements that expand the δ-phase field

Chemical additions (or alloying) significantly affect plutonium phase stability with temperature and pressure. The dramatic effects of the addition of a few atomic percent gallium to plutonium on its thermal behavior are demonstrated in Fig. 7.27. The addition of gallium retains the attractive feature of expansion during solidification while avoiding all of the large volume perturbations during cooling because the addition of gallium retains the fcc δ phase to room temperature. The thermal expansion is essentially zero, or 'Invar-like,' (Hecker, 2004) making Pu–Ga alloys much easier to cast. Moreover, the soft and ductile nature of the fcc δ phase makes these alloys much easier to shape than unalloyed plutonium. Consequently, most of the detailed work on properties of plutonium alloys has focused on systems that retain the δ phase. However, interest in metallic reactor fuels (Keiser *et al.*, 2003) has also resulted in work on β-phase retainers and on lean plutonium alloys involving uranium.

The complexity of chemical alloying is demonstrated in Fig. 7.28 for the Pu–Ga system. In addition to the six allotropes of plutonium, several new binary phases and 11 intermetallic compounds are formed. The fcc δ phase is retained to room temperature over a substantial range of gallium concentrations.

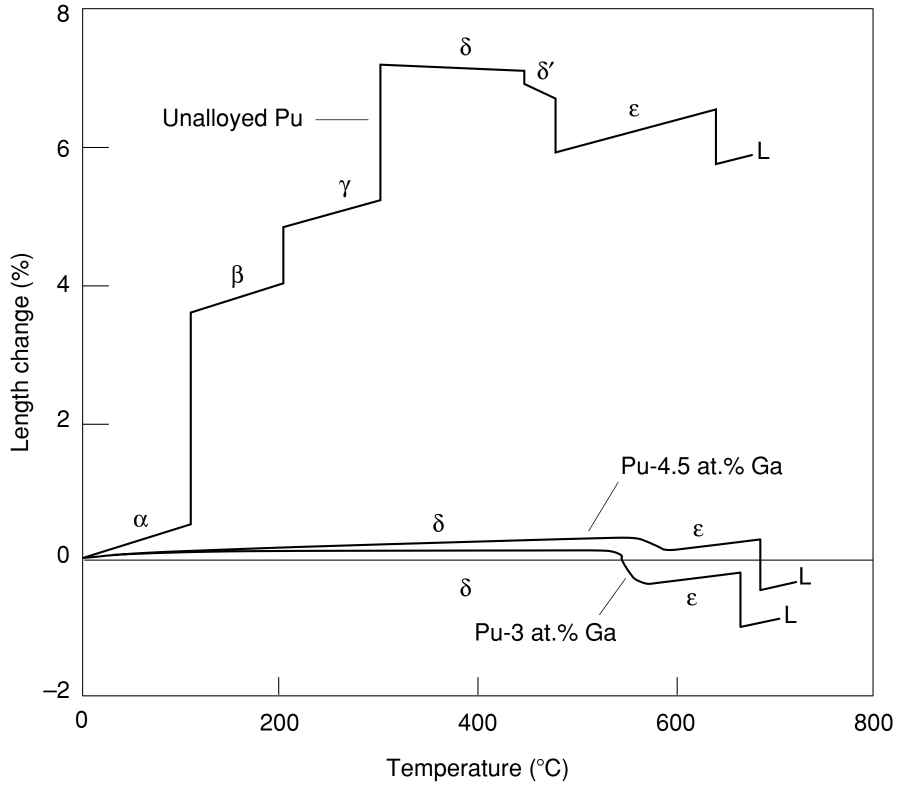

Fig. 7.27 *Length changes for unalloyed plutonium compared to Pu-*3.0 at.% *Ga and Pu-*4.5 at.% *Ga alloys.*

The question of whether the retained δ phase is stable or metastable was resolved only recently when Hecker and Timofeeva (2000) reconciled the U.S. (as well as the U.K. and French) and Russian versions of the Pu–Ga phase diagram. A comparison of the two versions of this fundamental phase diagram is shown in Fig. 7.29. They now believe that the Russian diagram (Fig. 7.29b), which shows an eutectoid point at 97°C and 7.9 at.% Ga, is the true equilibrium phase diagram (or as close a representation as possible, recognizing that radioactive decay in plutonium precludes true equilibrium). This diagram indicates that the δ phase should decompose below 97°C into α-Pu + Pu_3Ga. Such decomposition has never been observed because the kinetics are too slow. Timofeeva (2001) built her case on a clever set of experiments that demonstrated conclusively that the phase boundaries just above the eutectoid temperature clearly point to a decomposition (Hecker and Timofeeva, 2000). In fact, Timofeeva (2001) estimated that such decomposition requires more than 10,000 years at room temperature because the kinetics of the decomposition are exceedingly slow.

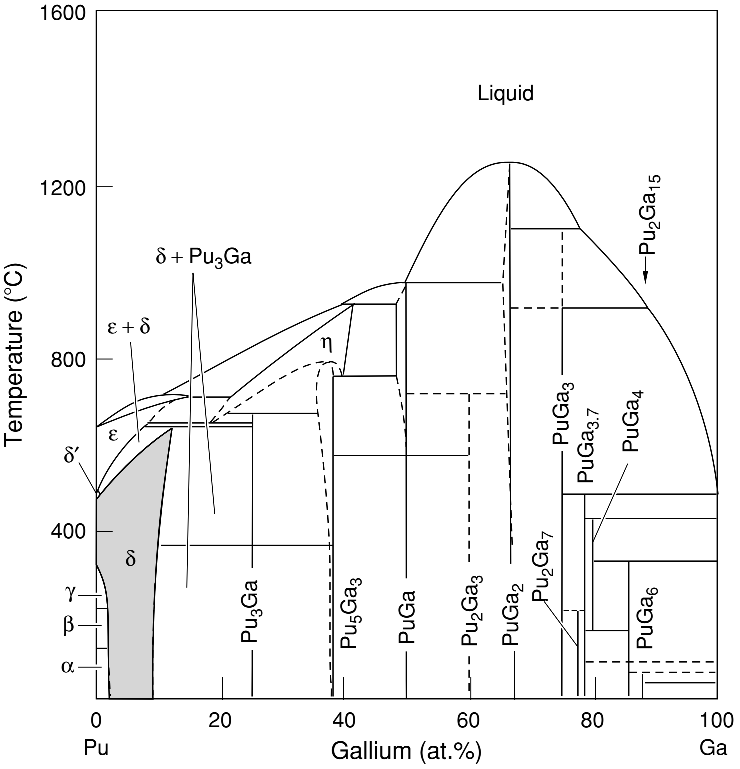

Fig. 7.28 *The Pu–Ga phase diagram at ambient pressure (from Peterson and Kassner*, 1988).

Therefore, the U.S. version (Fig. 7.29a), in which the δ phase is retained at least down to room temperature, represents an adequate 'working' diagram. Blank (1977), in his Table 2/105, presented the most complete table of crystal structures, atom positions, and atomic distances.

Timofeeva (2001) also demonstrated that the Pu–Al system undergoes a similar eutectoid decomposition near 100°C. The plutonium-rich end of the U.S. and Russian diagrams are shown in Fig. 7.30. In addition to the difference in findings related to the stability of the δ phase, Timofeeva also concluded that the intermetallic compound Pu_3Al does not extend to room temperature at thermodynamic equilibrium but rather only to 380°C. The eutectoid decomposition below 93°C is to α-Pu + PuAl (Timofeeva, 2001, 2003a). This finding differs from the conclusions of both the prior U.S. work reported by Ellinger *et al.* (1968b) and the prior Russian work reported by Bochvar *et al.* (1958). Timofeeva (2001) pointed out that the differences result because of slow kinetics. Her experiments allowed for sufficient time to demonstrate that PuAl is the intermetallic compound stable at room temperature.

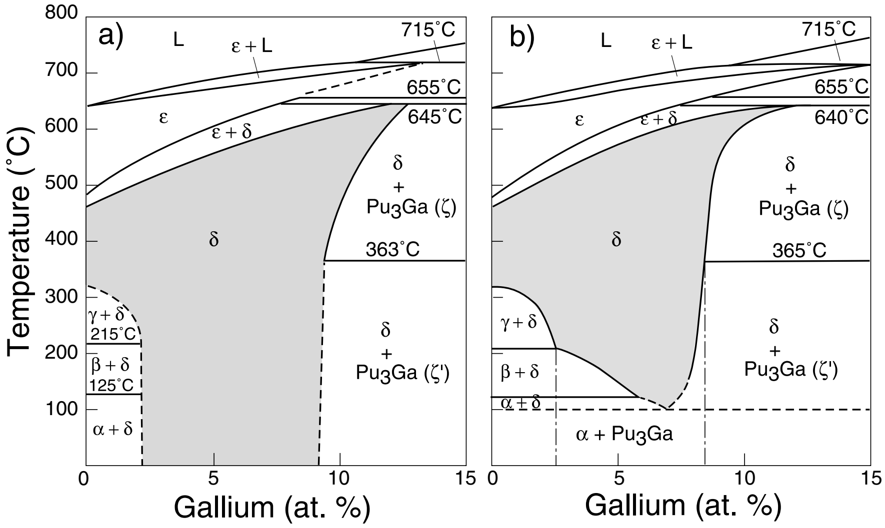

Fig. 7.29 *Comparison of* (*a*) *US and* (*b*) *Russian Pu–Ga phase diagrams from Hecker and Timofeeva* (2000).

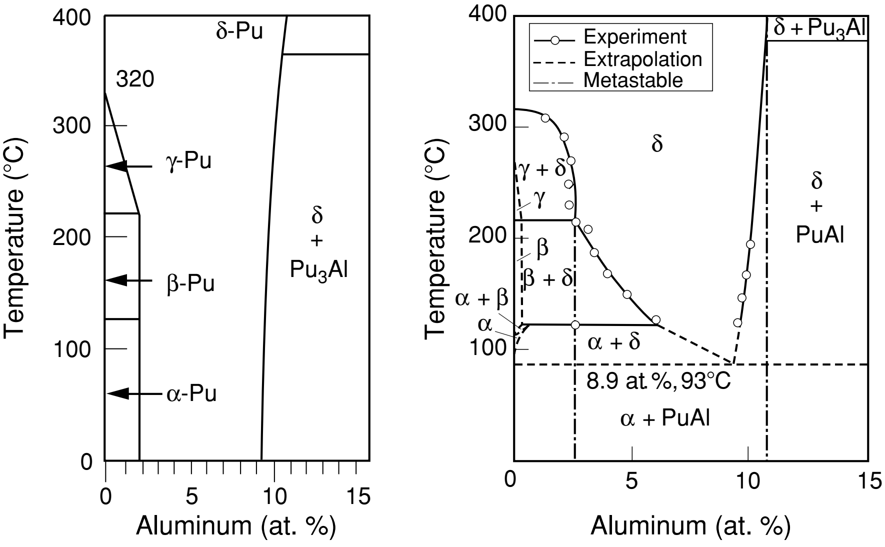

(a)

(b)

Fig. 7.30 *US* (*a*) *and Russian* (*b*) *versions of the Pu-rich side of the Pu–Al phase diagram. The US version is from Ellinger* et al. (1962*b*), *and the Russian version is from Hecker and Timofeeva* (2000).

Timofeeva (2003a) recently published data on 53 eutectoid transformations found in 30 binary plutonium phase diagrams. Eutectoid transformations are observed in binary systems of plutonium with transition metal elements (12), lanthanides (7), actinides, and elements of group IIIB (4 each). Only one eutectoid transformation exists with the elements of groups II, IV, and V. An interesting set of results is shown in Fig. 7.31 for four elements that expand the δ-phase field, Al, Ga, In, and Tl. Timofeeva demonstrated that the compositional range of the δ-phase field decreases and the eutectoid temperature increases monotonically with increasing atomic number of the alloying element. Additions of most trivalent elements expand the δ-phase field (Hecker, 2000), and in addition to Al, Ga, In, and Tl listed above, Ellinger *et al.* (1968b) showed that Sc, Ce, and Am also retain the δ phase. However, as discussed above, the retention appears to be metastable for most of these elements. It is likely that only Am results in a thermodynamically stable δ phase at room temperature. Timofeeva (2003a) reports a eutectoid transformation in Pu–Ce, and Pu–Sc systems that appears not to have received the same scrutiny as the other elements, so its status remains inconclusive.

In addition to the elements that readily retain the δ phase to room temperature (Al, Ga, Ce, Am, Sc, In, and Tl), there is a second class of elements (Si, Zn, Zr, and Hf) that retain the δ phase in a metastable state under conditions of rapid cooling. There are also some indications that the δ phase in Pu–Th alloys can be retained by rapid quenching (Gschneidner *et al.*, 1960).

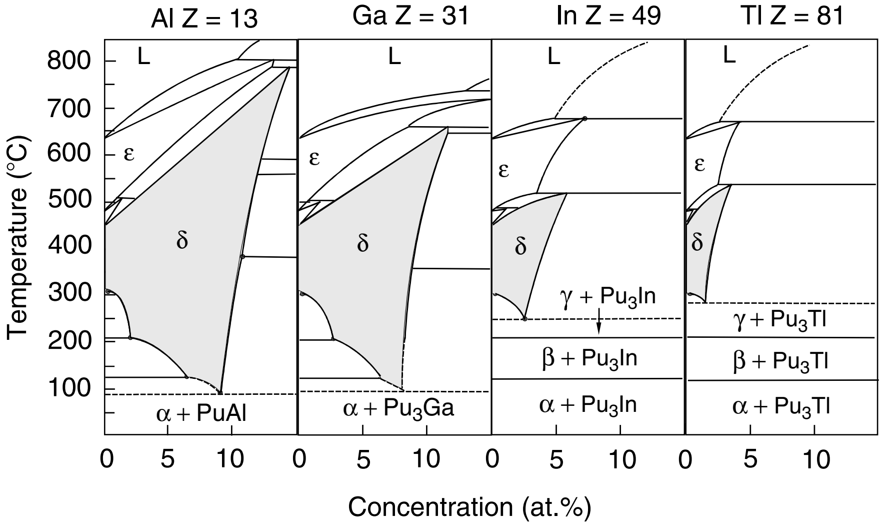

Fig. 7.31 *Phase diagrams of plutonium with several group* III*B elements show the eutectoid parameters and δ-phase region dependence (from Timofeeva,* 2003b).

Gschneidner *et al.* (1960) also found a number of the trivalent lanthanides (Dy, Er, Tm, Lu, and possibly Tb) to favor δ-phase retention, but their phase diagrams exhibit no δ-phase stability. Elliott and coworkers (Elliott and Giessen, 1975; Giessen *et al.*, 1975) demonstrated that retention of the δ phase and the bcc ε-phase can be extended in a metastable manner by splat cooling (rates from 10^6 to 10^8 s^{-1}). For example, both of these phases can be retained in splat-cooled Pu–Ti alloys. In Pu–Ga alloys, the maximum solubility of gallium in plutonium at room temperature is extended from 12.5 to 20 at.%. In Pu–Ce alloys, fcc δ phases can be retained across the entire range of cerium additions by splat cooling.

(b) α-Phase and β-phase stabilizers

Only neptunium has been found to expand the α-phase field. No other element is known to have any equilibrium solubility in the monoclinic α phase. Neptunium is also the only element that significantly expands the β-phase region. However, limited solubility of U, Hf, and Zr has been found in the β phase. Also, additions of Ti, Hf, and Zr will retain the β phase to room temperature and below by rapid quenching. Neptunium and uranium lower the melting point of plutonium slightly. The elements Hf, Zr, and Ti raise it significantly, even with small additions.

(c) Eutectic-forming elements

Additions of Mn, Fe, Co, or Ni lower the melting point of plutonium substantially. These elements form a low-melting eutectic much as does lead alloyed with tin to make solder. For example, the Pu–Fe phase diagram, shown in Fig. 7.32, exhibits the eutectic decomposition at 410°C and close to 10 at.% Fe from the liquid to δ-Pu + Pu_6Fe. This eutectic alloy was used in the first metallic plutonium fuel elements in the Los Alamos Molten Plutonium Reactor (LAMPRE) in the late 1940s (Kiehn, 1961; Burwell *et al.*, 1962). The elements Mn, Co, and Ni exhibit eutectic temperatures at approximately, 525°C, 405°C, and 465°C, respectively. These elements decompose to the intermetallic compounds $PuMn_2$, Pu_6Co, and PuNi, respectively. Other elements form eutectics but at somewhat higher temperatures. These include Si, Mn, Os, Ru, Rh, and Th. Eutectic-forming elements such as Mn, Fe, Ni, or Co are of special significance because they limit the useful temperature range of plutonium and its alloys. For example, plutonium metal heated above 410°C contained in steel will melt through the steel by forming the eutectic. Even when present in small amounts in plutonium, the alloying elements can segregate to grain boundaries, enriching the local alloying concentration and causing local melting or embrittlement at temperatures close to the eutectic temperature. Blank (1977) presented a thorough review of the properties of plutonium alloys and intermetallics with the eutectic-forming elements.

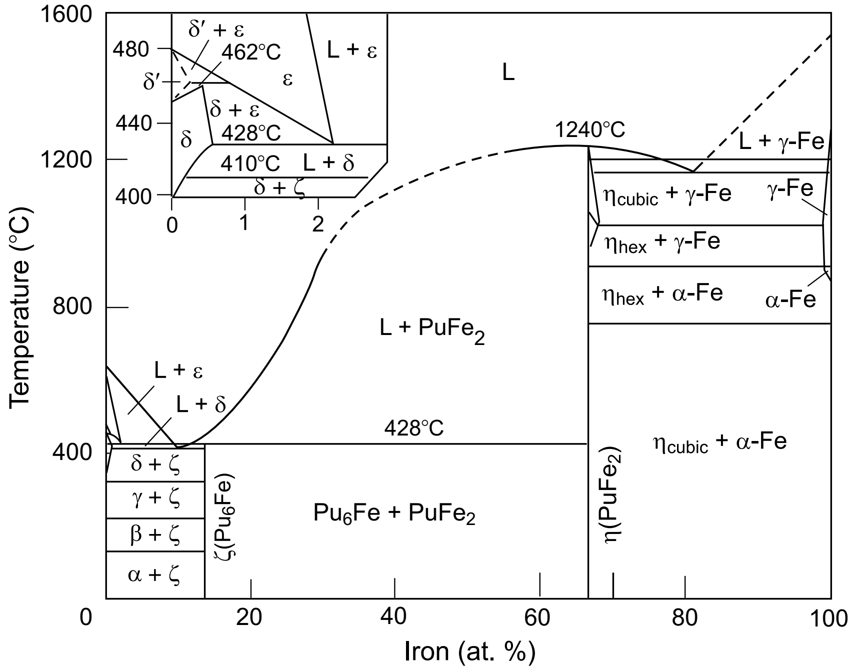

Fig. 7.32 *The Pu–Fe phase diagram at ambient pressure from Ellinger* et al. (1968*b*) *and first reported by Schonfeld* (1961).

(d) Interstitial compounds

When nonmetallic elements with very small radii are alloyed with metals, they tend to form interstitial solid solutions. A general rule of thumb is that if the radius of the nonmetallic element is <0.59 that of the metallic element, then an intermetallic compound with a simple structure (often fcc or hcp) forms. If the ratio is greater, then compounds with complex structures form. The most important nonmetallic elements for plutonium in the solid state are O, C, N, and H. None of these elements shows any solubility in the equilibrium phase diagrams. The Pu–O phase diagram is shown in Fig. 7.90. The elements O, C, and N all form several high-melting, refractory ceramic compounds. The structure and properties of these ceramic compounds will be discussed in greater detail in Section 7.8. Hydrogen also has a tendency to form compounds, but these readily decompose, rather than being refractory.

(e) The rest of the elements

Most other elements show only limited solubility in the δ phase, while some elements such as Ba, Sr, and Ca are immiscible. Most elements increase the melting point. Some have shallow eutectics before the melting point increases. More than half of the elements, namely Th, Np, U, Ti, Ru, Rh, Pt, Os, and most lanthanides, show solubility in the ϵ phase.

Detailed X-ray crystal structure data are presented for many intermetallic compounds of plutonium in Table 7.17.

(f) Microsegregation in δ-phase alloys

Since alloys in which the fcc δ phase is retained to room temperature are of particular interest, we discuss the problem of microsegregation, which can dramatically influence the properties of δ-phase alloys. We use the Pu–Ga system shown in Fig. 7.33 for the purpose of illustration. During solidification and cooling, alloys within the range of gallium content to 13 at.% must cool through the liquid + ϵ and $\epsilon + \delta$ two-phase regions. In a two-phase region, assuming gallium diffusivity is infinite in both phases, the composition of each phase is given by the phase boundaries at that temperature (the lever rule), giving rise to possible microsegregation. We track the gallium content through the $\epsilon + \delta$ two-phase field in Fig. 7.33a. As the temperature reaches point A, the first δ phase to form has the gallium concentration shown at point B. As the temperature is lowered, the gallium concentration in the δ phase moves along the line BD, whereas the gallium concentration in ϵ moves along the line AC – if diffusion is sufficiently rapid to allow migration of gallium consistent with the imposed cooling rate. (Of course, the average gallium concentration in the alloy must be the initial concentration.) The diffusion rate of gallium is approximately 10^4 faster in the ϵ phase (because of its open bcc structure) than the δ phase, thereby not allowing equilibration in the δ phase for typical cooling rates. As a consequence, the gallium concentration of the remaining ϵ phase is pushed to lower values as cooling proceeds, resulting in increased segregation over that expected from equilibrium conditions.

As a result, the microstructure of a typical as-cast δ-phase alloy exhibits a range of gallium concentrations between points B and C. The interior of the δ-phase grains reflects the gallium concentration at point B and the grain boundaries may have very little gallium because they are the last ϵ-phase areas to transform with gallium at or below point C. The resulting microstructure appears heavily 'cored' or segregated as shown in Fig. 7.33b. It consists of gallium-rich δ phase in the center, a gallium-lean δ-phase shell (dark areas) at the core boundaries, and a gallium-lean intercore region that transformed to the α phase during cooling because of insufficient gallium. This type of microsegregation typically occurs during cooling through liquid + solid two-phase regions because diffusion in the liquid is so much faster than in the solid. However, the anomalously high diffusion rate in ϵ-plutonium avoids the problem in the liquid + ϵ region, only to have it reappear in the $\epsilon + \delta$ two-phase region. Equilibrating the gallium concentration requires a sustained return to temperatures high in the δ-phase region, typically hundreds of hours, to achieve

a uniform gallium concentration. The progression of gallium 'homogenization' and consequent change in microstructure are also shown for a homogenization temperature of 460°C in Fig. 7.33(b).

Such microsegregation can occur with any of the alloying elements that retain the δ phase to room temperature. The extent of microsegregation depends on the cooling rate and on the shape of the two-phase field. A typical gallium

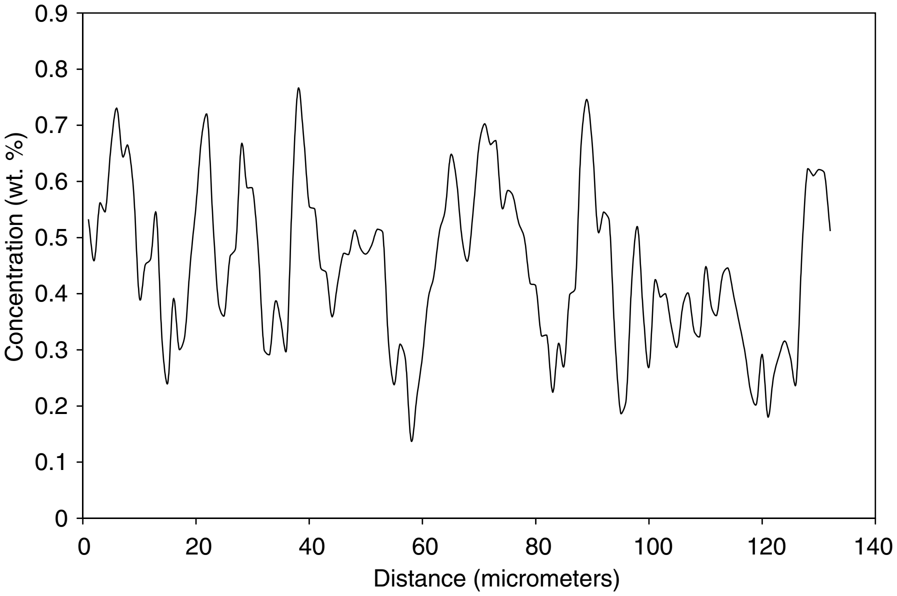

Fig. 7.34 *A typical gallium concentration profile for a nominal Pu-*1.7 at. *% Ga* (0.5 wt. *% Ga*) *alloy by electron microprobe. The grain size was roughly* 30 μm (*from unpublished work of one of the authors, S. S. Hecker*).

profile taken with an electron microprobe is shown in Fig. 7.34 for Pu–1.8 at.% Ga cooled at a rate of ~5°C min^{-1}. At such rates, all areas with <1.4 at.% Ga transform to the α phase upon cooling to room temperature. If initial cooling rates are rapid, and homogenization times of hundreds of hours at 460°C are employed, then the δ phase can be retained to room temperature with as little as 1 at.% Ga. However, the retained δ phase is metastable and will transform at low temperatures and/or hydrostatic compression. Hence, proper homogenization treatments for δ-phase alloys are important in studying plutonium alloys. If not properly homogenized, such alloys exhibit continuously varying gallium gradients (on the scale of the grain size as shown in Fig. 7.34), or they may consist of two-phase mixtures. Either one of these conditions can significantly affect the properties of the alloy.

(g) Phase transformations in δ-phase alloys

Hecker *et al.* (2004) and Deloffre (1997) presented comprehensive overviews of phase transformations in δ-phase plutonium alloys. During cooling the retained fcc δ phase transforms to the monoclinic α phase (sometimes through an intermediate phase such as the β phase or γ phase). The transformation behavior as monitored in a dilatometer is shown for a constant cooling rate for several

Pu–Ga alloys (Hecker *et al.*, 2004) in Fig. 7.35. The transformation is martensitic, that is, diffusionless and displacive (shear). The transformation start temperature depends strongly on the gallium concentration (all three alloys shown were thoroughly homogenized before cooling) as shown in Fig. 7.35. The transformation behavior depends on cooling rate and is, therefore, characterized as an isothermal martensitic transformation. Orme *et al.* (1976) determined the TTT kinetics for Pu–Ga alloys as illustrated by the double C-curves shown in Fig. 7.36. Thermal activation appears to be necessary to nucleate the transformation before the martensite transformation product grows by a shear mechanism at sonic velocities. The C-curve kinetics result from insufficient

driving force at the higher temperatures and insufficient thermal activation at the lower temperatures. The overall kinetics is shown to be dependent on gallium concentration.

Similar transformation behavior is observed for δ-phase Pu–Al alloys as demonstrated by Hecker *et al.* (2004) and shown in Fig. 7.37. The well-homogenized Pu–2 at.% Al alloys begin to transform at approximately −130°C during cooling. After cooling to liquid nitrogen temperature and heating back to room temperature, metallographic and X-ray examination showed that the resulting microstructure (shown in Fig. 7.37) consisted of 25% α′ phase (in the form of martensite platelets) and 75% residual δ phase. The α′-phase designation is used here to indicate that the aluminum or gallium atoms, which have no equilibrium solubility in the α phase, are trapped by the martensitic transformation and expand the lattice of the α phase (Hecker *et al.*, 2004). During hydrostatic compression at room temperature, the δ phase collapses just below 0.4 GPa (as shown in Fig. 7.37), transforming martensitically first to the β′ followed by the α′ phase. The microstructure is more complex as shown in Fig. 7.37. If such

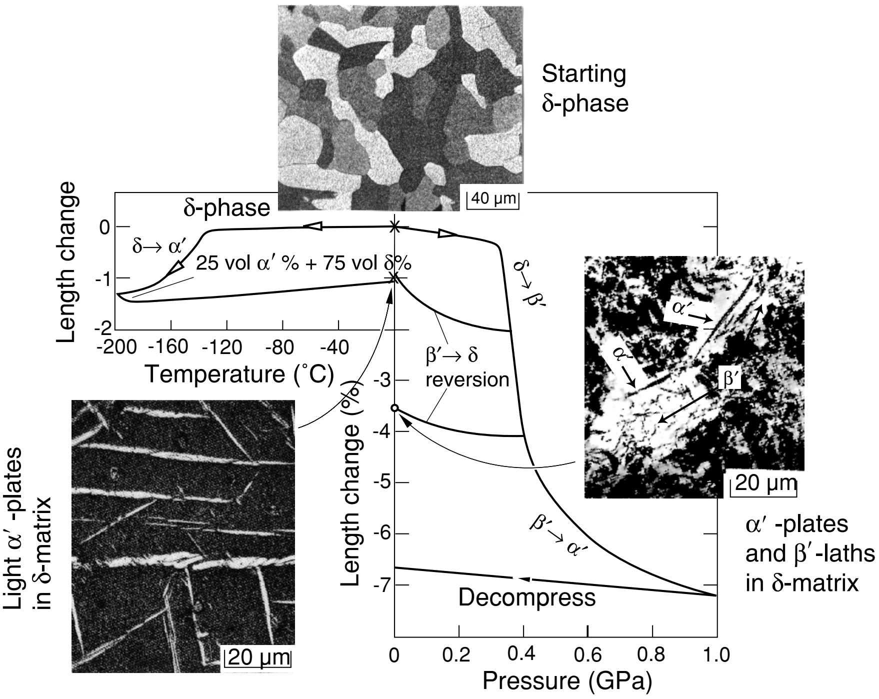

Fig. 7.37 *Temperature and pressure-induced transformations in Pu-*2.0 at. *% Al alloys* (*Zukas* et al., 1981*; Hecker* et al., 1982). *The starting δ-phase microstructure is shown on top and the transformed microstructures on the left and right for temperature and pressure-induced transformations, respectively.*

samples are compressed only partially, then both product phases appear in the residual δ-phase matrix.

Adler and coworkers (Olson and Adler, 1984; Adler *et al.*, 1986) modeled the crystallography of the δ→α′ transformation during cooling. Zocco *et al.* (1990) subsequently confirmed their predictions by transmission electron microscopy (TEM) and determined the lattice correspondence between the parent and product phases and the α′-phase habit plane. The details of the experimental and theoretical results are reviewed by Hecker *et al.* (2004). Heating the transformed α′ phase above room temperature for Pu–Ga alloys results in the transformation behavior shown in Fig. 7.35. The low-gallium alloys transform from α′→β→γ, whereas the higher-gallium alloys transform directly from α′→δ at temperatures significantly lower than the α→β transformation temperature.

Complex stress states such as those found during cold rolling, machining, or mechanical polishing all trigger the δ→α′ transformation. Machining most likely produces a complex mixture of α′ and α-phases (that is, expanded and unexpanded) because of the heat generated. Mechanical polishing is especially effective in promoting the γ'-phase as an intermediary phase (Zukas *et al.*, 1983). These authors also observed that samples that had previously undergone a $\delta\rightarrow\alpha$ transformation were susceptible to the reverse $\alpha'\rightarrow\delta$ transformation at the crack tip of tensile specimens. Hydrostatic tension favors the larger volume δ phase. Hecker and Stevens (2000) reported this behavior for both transformed samples and for unalloyed α plutonium. The reversion results reinforce the importance of the sign and magnitude of the hydrostatic stress component in triggering martensitic transformations in plutonium.

The complex nature of the transformation behavior for plutonium and its alloys must be taken into account during sample synthesis and preparation. In plutonium alloys, the slightest mechanical polishing or machining procedures can leave a layer of transformation product that may influence the properties to be measured. Such transformation products can be avoided or removed, but only if sufficient care is taken. For example, electropolishing is quite effective to remove surface products. Heating is also effective but must be done with care so as to not introduce new artifacts or changes in structure (this is especially true for aged samples in which helium has been generated by self-irradiation damage).

7.7.5 Electronic structure, theory, and modeling

The complex electronic structure of plutonium has been a subject of intense study for theorists and modelers for more than 50 years. Arko *et al.* (2006) present the most recent review of electronic structure in the actinides, including plutonium, in Chapter 21 of this work. As mentioned above, the actinides mark the filling of the 5f atomic subshell much like the rare earths mark the filling of the 4f subshell. Yet, the 5f electrons of the light actinides behave more like the 5d electrons of the transition metals than the 4f electrons of the rare earths. The peculiar properties described in Section 7.7.3, and shown in Fig. 7.19, are telltale signs of novel interactions and correlations among electrons, which result in behavior that cannot be explained by the one-electron band theory of metals. Boring and Smith (2000) point out that such novel interactions typically result from a competition between itinerancy (bonding electrons that form bands in metals) and localization (electrons with local moments that magnetically order at low temperature). In these elements, we find that such novel interactions occur in the d- and f-electron metals near iron, at cerium, and near plutonium. Based on these considerations, Smith and Kmetko (1983) rearranged the periodic table for the transition metals, the rare earths, and the actinides as shown in Fig. 7.38. This representation shows that most transition metals, lanthanides, and actinides have predictable ground states and become either superconducting or magnetic as the temperature is lowered. The elements along the diagonal have two or more partially filled bands that are close in energy. One of the bands is typically relatively narrow with a high density of states (DOS) at the Fermi

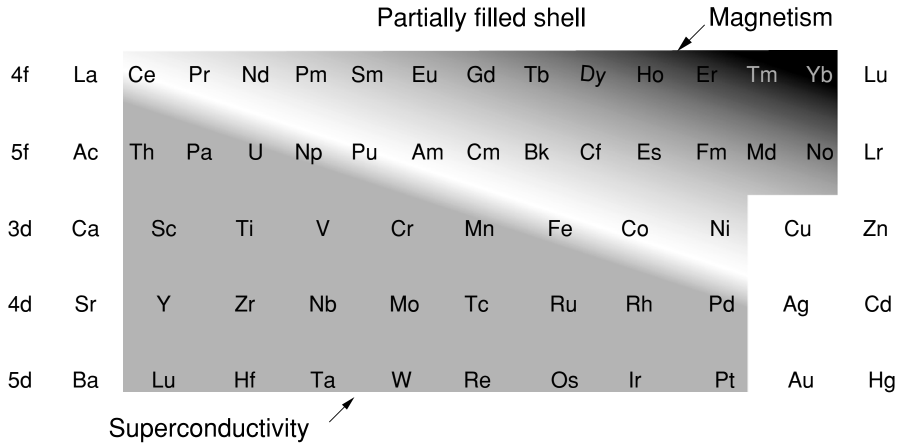

Fig. 7.38 *Smith and Kmetko* (1983) *rearranged periodic table that highlights the transition in electronic behavior from localized electrons* (*resulting in magnetism*) *to itinerant electrons* (*resulting in superconductivity*).

energy (the f-bands are 2 to 4 eV wide and the d-bands span 5 to 10 eV). Narrow bands tend to mix or hybridize with other bands close in energy. The electrons in these narrow bands can be strongly correlated, but still bonding. They spend much more of their time close to their atomic cores than do the 'free' (valence) s-electrons. The electrons in the narrow bands are highly sensitive to small perturbations, which enhances polymorphism and causes instability in the solid state. Smith and Boring point out that in addition to exhibiting multiple crystal structures, the elements along the diagonal also exhibit strong catalytic activity, have a great affinity for hydrogen, and spark easily when struck. Moreover, the behavior of the elements can easily be moved across the diagonal by changes in temperature, pressure, or by alloying.

The electronic configuration of isolated plutonium atoms is $7s^2 5f^6$ (see Section 7.6). In the metallic state the electronic configuration is $7s^2 6d^1 5f^5$. The atomic volumes in the solid state change abruptly across the actinide series at plutonium, as shown in Fig. 7.39. This change indicates a major electronic transition between the light and the heavy actinides. In the light actinides up to plutonium, each additional 5f electron (like each d-electron in the transition metals) goes into the conduction band, where it increases the chemical bonding forces, pulling the atoms closer together and resulting in a decrease in atomic volume. Beginning at americium, the 5f electrons behave like the 4f electrons of the rare earths, localizing at each lattice site and becoming chemically inert. With no 5f contribution to bonding, the atomic volume suddenly increases at americium, and contracts only slightly with increasing atomic number because the 5f electrons remain localized in the remainder of the series. As shown in

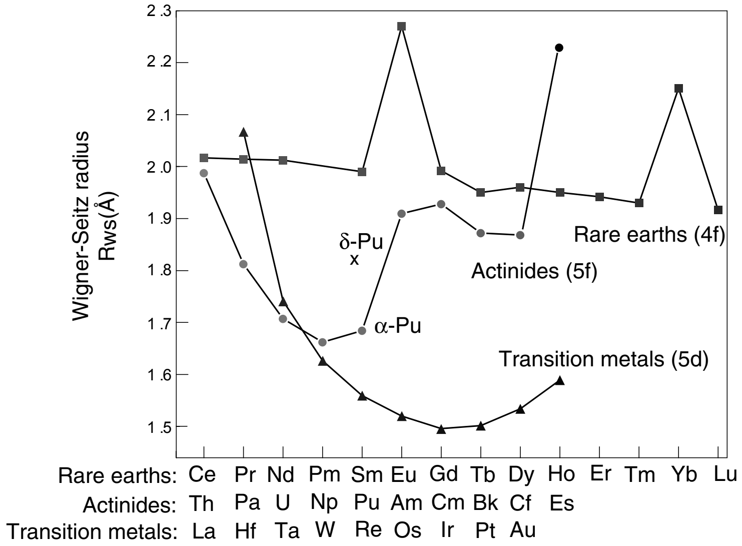

Fig. 7.39 *Wigner–Seitz radii for the actinides compared to the lanthanides and 5d transition metals. The actinides include the data for Es* (*Haire* et al., 2004), *which is divalent with a large volume, much like Eu in the lanthanides.*

Fig. 7.39, this behavior is similar to the lanthanides. The large jump in atomic volume at Es is due to divalent behavior similar to that for Eu and Yb for the lanthanides. The pattern of local moments, another strong indicator of what the electrons are doing, confirms this general picture. The light actinides show no local moments, as expected if all the valence electrons are in the conduction band, whereas the heavy actinides and the lanthanides generally exhibit local moments.

In the α phase, the 5f electrons appear to be bonding (although Savrasov *et al.* (2001) claim that the f-electrons are already strongly correlated in the α phase), whereas in americium the 5f electrons are clearly localized. It is interesting to note here that americium was found to be an ordinary superconductor with no hint of a magnetic moment although it is on the 'magnetic' side of the diagonal in Fig. 7.38 (Smith and Haire, 1978). This is a consequence of the $5f^6$ electronic configuration resulting in a total angular momentum $J = 0$, so that no moment is present even in the free ion limit. As shown by the atomic volumes in Fig. 7.39, the δ phase in pure plutonium falls between the plutonium α phase and the americium dhcp phase. The plutonium δ phase is a state that appears to be unique among the elements. Before addressing the δ phase, we will first consider the α phase ground state.

First-principles total-energy calculations based on density-functional theory (DFT) successfully predict electronic structure and bonding properties of simple metals and the transition metals (Skriver, 1985). With the advent of high-performance computing, it has become possible during the past 10 to 15 years to extend such calculations to the actinides by incorporating low-symmetry crystal structures, relativistic effects, and electron–electron correlations. The complicated electron–electron exchange term arising from the Pauli exclusion principle and electron–electron electrostatic interactions are incorporated through a local density approximation (LDA) or a generalized gradient approximation (GGA), which incorporates the local electron density and the density gradient. Wills and Eriksson (2000), who summarized their efforts and those of their colleagues, successfully predicted the structures and volumes of the low-symmetry ground states of the light actinides, including plutonium. These calculations show that in α plutonium all eight valence electrons are in the conduction band. However, the 5f bands are very narrow – that is, each 5f electron is nearly localized on an atomic site and, hence, spends a long time near this site before it jumps to the next site. Because the bands are narrow, they exhibit a very high DOS. As the number of 5f electrons populating the band increases across the actinide series, the specific properties of the band begin to dominate the bonding properties of the metal.

Wills and Eriksson demonstrated that the α phase is the stable ground state of plutonium because special conditions favor lattice distortions. Specifically, the very narrow band of the 5f electrons with a high DOS at or very near the Fermi energy split the band in certain regions, thereby lowering the total energy through a Jahn–Teller/Peierls-like distortion. We recall that in iron the degeneracy of the d-conduction band is lifted by the electron spins causing the d-band to split spontaneously into spin-up and spin-down bands. In plutonium the degeneracy of the f-band is lifted by a lattice distortion leading to lower energy. Also, because the narrow 5f band overlaps the s, p, and d bands, a number of electronic configurations have nearly equal energy, leading to multiple allotropes in the light actinides and to their great sensitivity to external influences such as temperature, pressure, and chemical additions. Before the insight gained from the calculations of Wills and Eriksson, the low-symmetry ground state in metallic plutonium was attributed to directional or covalent-like bonding, resulting from the angular characteristics of f-electron orbitals (somewhat analogous to molecular bonding, see Section 7.9.3) (Boring and Smith, 2000; Hecker, 2000). Although total-energy electronic structure calculations apply only at zero temperature, they have been remarkably successful in predicting the ground-state properties of the actinides, both at ambient and elevated pressures. In addition, energy differences for various structures can be calculated to give an indication of whether these are thermally accessible. Wills and Eriksson (2000) point out that including temperature effects is not a simple task. One possibility is to integrate existing molecular dynamics or Monte Carlo simulations with electronic structure calculations. It may also be possible that accurate calculations of the phonon spectra of different allotropes may enable reliable calculations of the free energy as a function of temperature.

We now turn to the fcc δ phase, which is the most desirable from an engineering standpoint but the least understood from a physics standpoint. As shown in Fig. 7.39, the volume (the Wigner–Seitz radius is actually plotted) of the δ phase falls between that of α plutonium and americium. The 5f electrons appear to be in some mixed state, neither fully itinerant nor fully localized. Above, we pointed out that the δ phase has other unusual properties, such as a negative thermal expansion coefficient and an unusually large low-temperature electronic specific heat. Unfortunately, even the best calculations based on standard DFT with some LDA do not adequately predict the δ-phase volume or elastic constants in unalloyed plutonium. This failure has spawned numerous attempts to go beyond the LDA. Wills and Eriksson (2000) found that they had to 'constrain' their calculations by localizing four of the five 5f electrons in the δ phase to predict the correct atomic volume using the same formalism as for the ground state of the light actinides. The constrained 5f electrons cannot hop from site to site and do not hybridize with other electrons. In essence, the constrained calculations combine knowledge of DFT and atomic theory. Hecker *et al.* (2004) review other recent attempts to explain the peculiarities of the δ phase. However, none of them currently provide an adequate explanation. The approach of Wills and Eriksson provides the best current guidance for understanding the δ phase and the alloying behavior of plutonium. This is clearly an area where we can expect significant advances in our understanding over the coming decade.

(a) Alloy theory and modeling

Before discussing the alloying behavior, it is instructive to view the behavior of plutonium in context of the other actinides. Fig. 7.40 shows the connected binary alloy phase diagrams of the actinides through curium. At the beginning of the actinides, there is little f-electron influence and, hence, one finds typical metallic crystal structures, few allotropes, and high melting points. As more f-electrons are added (up to plutonium) and participate in bonding (that is, they are itinerant), the crystal structures become less symmetric, the number of allotropes increases, and the melting points decrease. At americium and beyond, crystal structures typical of metals return, the number of allotropes decrease, and the melting points rise – all indications of the f-electrons becoming localized or inert. So we see that the peculiar properties of plutonium are not a single anomaly, but rather the culmination of a systematic trend across the actinides. And, the transition occurs not between plutonium and americium, but right at plutonium – between the ground-state α phase and the elevated-temperature δ phase.

To predict plutonium alloy phase diagrams, we need to know the Gibbs free energy of all the phases and compounds as a function of alloy concentration and temperature. We must calculate the internal energy and the entropy (electronic, vibrational, and configurational). To predict δ-phase stability, we must be able

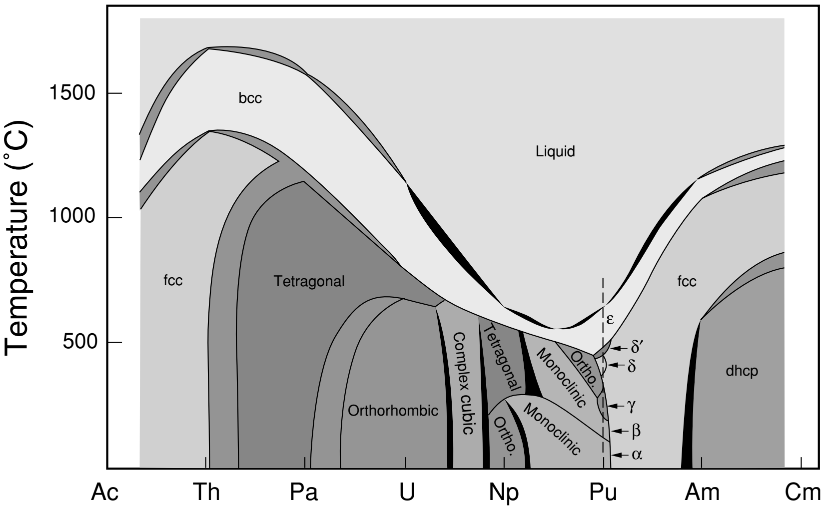

Fig. 7.40 *The experimentally determined, connected binary alloy phase diagram of adjacent actinide elements* (*Smith and Kmetko,* 1983).

to calculate the internal energy of a random substitutional alloy from first principles, which is an immense challenge. So, it is not surprising that semiempirical and phenomenological approaches have guided metallurgical practitioners for many decades. The Hume–Rothery rules, recently reviewed by Massalski (1996) and Gschneidner (1980), relate limits of solid solubility as well as the stability and extent of transition element intermediate phases to three factors:

1. If the atomic size differences of A and B are greater than 15%, solid solubility will be restricted. Significant experimental data support this rule. From a theoretical point of view, large size differences result in large elastic strain energies. The atomic size rule is primarily a ‘negative’ rule stressing that size differences will restrict solid solution formation. Within favorable size ranges, size differences become only of secondary importance.
2. High chemical affinity of A for B (usually denoted by large differences in electronegativity) helps promote intermetallic compounds and, therefore, limits solid solubility.
3. The relative valence rule stresses the importance of electron concentration, which is typically taken as the ratio of all valence electrons to the number of atoms (*e*/*a*).

Darken and Gurry (1953) developed a map that predicts solubility for size differences less than 15% and electronegativity differences of less than 0.4.

Gschneidner (1980) achieved best overall agreement on a large number of known binary alloys by relating solubility to size and similar electronic structures (for which he used the crystal structure as a first approximation) of the constituents. The Darken and Gurry maps for plutonium alloys have been discussed by Blank (1977).

We have not found any of these approaches, or the more sophisticated methods developed by Pettifor (1996) (using tight-binding approximation models) or by Miedema and coworkers (Miedema, 1973, 1976) (using a two-parameter model based on the work function, which is closely related to electronegativity, and on electron density) helpful in predicting solid solubility in δ-phase plutonium. Given the complex electronic structure of plutonium, especially the δ phase, this is not surprising. It is difficult to imagine that these simple approaches would capture the essence of how the electronic structure of plutonium changes with the addition of other elements. However, the Hume–Rothery size rule appears to set a reasonable upper limit on solubility.

Brewer (1965, 2000) developed models based on chemical binding insight to relate phase stability primarily to the total number of valence electrons per atom. Ferro and Cacciamani (2002) recently reviewed the work of Brewer and colleagues on the classification and mapping of alloying patterns. Brewer (1970, 1983) provided some useful insights and general guidance on solubility, melting points, and thermodynamic properties of plutonium and the actinides. For example, he predicted little mutual solubility between plutonium and the alkali metals, the alkaline-earth metals from calcium through radium, and europium and ytterbium. Also, he predicted little solubility of the 4d and 5d transition metals in plutonium, but somewhat greater solubility of the 3d transition metals. He also offered an explanation of the low melting point of plutonium based on the unusually stable liquid phase. He pointed out that plutonium exhibits four or more electronic configurations of comparable energy in the metal. Consequently, atoms of plutonium have different sizes that are readily accommodated in the liquid and pack to very high density. The strain energy resulting from trying to accommodate different-sized atoms into structures such as bcc and fcc with equivalent atom sites destabilizes these structures compared to the liquid. The stability of the liquid, according to Brewer, results from the increased entropy of mixed valence in the liquid state.

A more quantitative, phenomenological approach to predicting phase diagrams was developed by Kaufman and coworkers (Kaufman and Bernstein, 1970; Chang *et al.*, 2002; Kaufman, 2002). The success of CALPHAD (calculation of phase diagrams), a computational thermodynamics approach to predicting phase diagrams of multicomponent alloy systems based on the work of Kaufman and coworkers, was recently reviewed by Turchi *et al.* (2002). Applications of computational thermodynamic modeling to plutonium and its alloys is being developed, but is limited by the lack of good thermodynamic data on plutonium, its alloys, and its compounds. Adler (1991) assessed the Pu–Ga diagram with a calculation using FACT (Facility for the Analysis of Chemical

Thermodynamics, A. Pelton) and retrieved the excess free energy consistent with the Russian phase diagram. Turchi *et al.* (2004) applied the CALPHAD methodology to study the stability and the kinetics of phase transformation and evolution in plutonium-based alloys. They report very good agreement with the thermodynamic properties of pure, unalloyed plutonium. They also predict eutectoid decompositions for both the Pu–Ga and Pu–Al alloy systems.

This brings us back to the first-principles calculations for random alloy systems. In pure materials and perfectly ordered systems, the solution of the many-body Schrödinger equation is simplified by Bloch's theorem that allows us to solve the equation for one cell and use translational symmetry. Random substitutional alloys are disordered by definition and, hence, require some short-range order approximation, typically using an Ising-like cluster expansion. Colinet (2002) recently reviewed the state of the art of deriving phase diagrams by combining quantum mechanics and statistical thermodynamics contributions. Local chemistry affects both the internal energy and the configurational entropy. Statistical treatments of short- or long-range order in solid solutions can use the cluster variation method (CVM) or Monte Carlo simulations. The cluster interactions are either derived experimentally or from first-principles calculations. Local relaxations around the solute atoms are important but also difficult to treat theoretically (Zunger *et al.*, 1990; Abrikosov *et al.*, 1998). Although significant progress has been made in some of the well-studied alloy systems, first-principles calculations of phase stability or phase diagrams are still beyond our grasp. For plutonium, the difficulty is exacerbated by the fact that the parent δ phase is not well understood theoretically and key experimental measurements are sparse.

Baskes (2000) recently extended his semiempirical atomistic embedded-atom method (which is based on DFT) to plutonium. He found reasonable agreement of the calculated energetics and volumes of the phases of plutonium with experimental data. With this method, it is possible to calculate the properties of perfect and defect-containing bulk metal as a function of temperature and pressure. Baskes *et al.* (2003) extended the modified embedded-atom method to model the Pu–Ga phase diagram. They found that a subregular solid solution model is required to describe the properties of the δ phase. They were able to predict the eutectoid decomposition of the δ phase, in qualitative agreement with the Russian phase diagram. However, the accuracy of the calculated temperature and composition of the eutectoid point is limited by inadequate thermodynamic data on Pu_3Ga.

For now, the calculations of Wills and Eriksson (2000) provide good insight into δ-phase stability and alloying. They demonstrated that the low-symmetry ground states in plutonium and the other light actinides require the special conditions of narrow bands and high DOS at or very near the Fermi energy (a natural consequence of the oddity of an f-electron conduction band). It seems reasonable then that anything that destroys these special conditions favors the retention of high-symmetry structures. Their calculations show that energy can be gained (that is, the total energy lowered) either through bonding energy gained from a structural distortion, or through correlation energy gained by localization of the electrons. Plutonium is exactly at that position in the periodic table where either process leads to about the same energy gain. However, alloying or defects disturb the coherence of the 5f bands, thus reducing the bonding energy and leading to at least partial localization of the 5f electrons. Hence, we believe that the fcc δ phase is favored at high temperature in unalloyed plutonium because of 'bond stretching' (in addition to entropy considerations) and in alloys because of 'bond breaking.' Hence, we may expect any alloy addition without bonding 5f electrons to favor the δ phase, assuming it can be dissolved in plutonium. Likewise, defects such as vacancies, vacancy clusters, dislocations, and grain boundaries may favor the retention of the δ phase locally.

Sadigh and Wolfer (2005) recently suggested another mechanism based on their DFT calculations, which showed that the volume decrease that occurs with gallium additions to the δ phase is primarily the result of the reduction in size of the plutonium host atoms. This reduction accounts for roughly two-thirds of the experimentally measured value. The other third is split between the misfit of the gallium in the δ-phase lattice and the elastic strains. The large volume reduction of the plutonium is accompanied by a negative heat of mixing. Their calculations showed that the enthalpy of transformation from the δ→α phase at absolute zero decreases substantially with the addition of gallium solutes. They conclude this reduction accounts for the retention of the δ phase. Clearly one must then invoke a different mechanism for the existence of the δ phase in unalloyed plutonium at high temperature. For example, it could be a combination of entropy effects and possible changes in electronic structure, such as those observed by Manley *et al.* (2001) for uranium. The calculations of Sadigh and Wolfer (as those of Söderlind (2001)) require large local spin moments in the δ phase to get the volume correct.

Considerable debate still exists over these calculational techniques because no local moments have been found experimentally (as recently reviewed by Lashley (2005). The search for magnetic moments has been so elusive, Söderlind explains, because his calculations predict a near zero-ordered moment as the spin and orbital moments are close in magnitude but antiparallel. However, Shick *et al.* (2005), using the *around-the-mean-field* version of the LDA+U method, predict a nonmagnetic ground state for the δ phase. They claim the nonmagnetic character results from $S = 0$ and $L = 0$, rather than the cancellation of spin and orbital parts of the momentum. They claim good agreement with experimental measurements of δ-phase plutonium properties. Shorikov *et al.* (2005) used the LDA+U+SO method to predict nonmagnetic ground states with zero values of spin, orbital, and total moments in both δ-phase and α-phase plutonium. We look forward to future advances in electronic structure theory that provide satisfactory explanations to the enigma surrounding plutonium.

(b) Lattice effects and local structure

We now examine in greater detail some of the interesting electronic structure effects observed in binary plutonium alloys. Binary alloys of plutonium with Am, Ce, Ga, and Al solutes were studied recently by Dormeval *et al.* (2003). Fig. 7.41 shows the approximate range of the δ-phase fields at room temperature for these solutes and the variation in the δ-phase plutonium lattice parameters. The addition of americium or cerium expands the plutonium lattice, whereas gallium and aluminum shrink it. All of them show some deviation from the ideal solution behavior described by Vegard's law, which is not surprising considering the complex electronic interactions expected in plutonium alloys.

In americium, the 5f electrons are completely localized. Substituting large americium atoms into the smaller δ-phase lattice expands the plutonium lattice and causes the 5f electrons in plutonium to become more localized, thereby stabilizing the δ phase over the entire range of americium concentrations. Also,

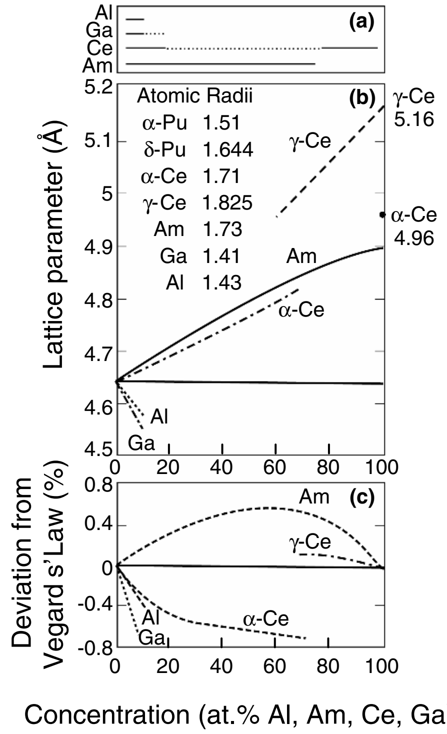

Fig. 7.41 (*a*) *Approximate solubility ranges at room temperature for the δ phase alloyed with Al, Ga, Ce, and Am.* (*b*) *Lattice parameters for these alloys.* (*c*) *Deviation from Vegard's Law* (*Dormeval,* 2001*; Hecker* et al., 2004).

the increased localization of the 5f electrons in plutonium causes the plutonium atoms themselves to increase in size, resulting in a positive deviation from Vegard's law. If a transition from itinerant (bonding) 5f electrons to localized 5f electrons were to suddenly occur in plutonium atoms as the americium concentration is increased, then we would expect a sudden increase in lattice parameter. As seen in Fig. 7.41, no discontinuities in lattice parameters are observed across the entire americium concentration range. This behavior demonstrates that the limited stability of the δ phase in unalloyed plutonium is just the tip of the iceberg for δ-phase stability upon alloying. This is shown most convincingly by looking more closely at the connected binary Np–Pu–Am phase diagrams shown in Fig. 7.42.

In contrast to additions of americium, neptunium stabilizes the α phase of plutonium. In fact, the Pu–Np phase diagram looks strikingly like the plutonium temperature–pressure phase diagram also shown for comparison in Fig. 7.42. Hence, adding neptunium has the same effect as applying pressure to the plutonium lattice, whereas adding americium is equivalent to applying hydrostatic tension.

As shown in Fig. 7.41, the addition of cerium also expands the δ-phase plutonium lattice. The range of stability for the fcc phase was extended across the entire concentration range of cerium by splat cooling (as indicated by the

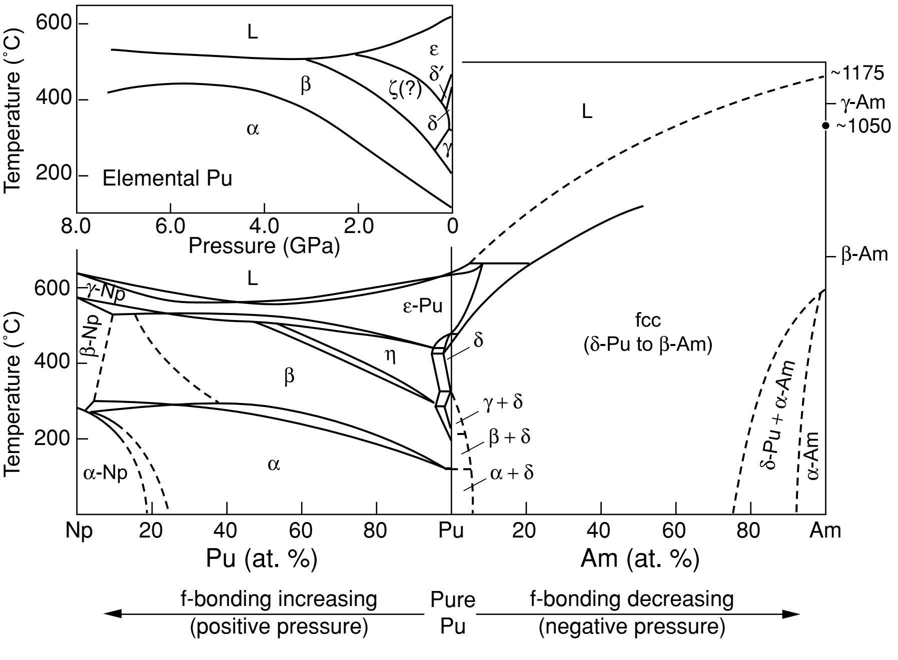

Fig. 7.42 *Plutonium pressure–temperature phase diagram compared to connected Np–Pu–Am binary ambient-pressure phase diagrams* (*Hecker,* 2004).

dotted lines in Fig. 7.41a). In addition to retaining the stable fcc phases of δ plutonium and γ cerium, Giessen *et al.* (1975) were able to retain the metastable fcc α-cerium phase at intermediate concentrations. Unlike americium, which behaves as a rigid sphere because the 5f electrons are well-localized, cerium is a 'soft' sphere, whose diameter adapts to its surroundings. When squeezed into the smaller δ-phase plutonium lattice at the plutonium-rich end, cerium's 4f electrons become delocalized and it takes on the α-phase radius ($r = 1.71$ Å). At 75 at.% Ce, an abrupt transition is observed to γ-cerium (with $r = 1.825$ Å). When viewed from the cerium end, the smaller plutonium atoms substitute in the γ-cerium lattice, until at 25 at.% Pu the pressure is sufficient to collapse the unstable cerium atom to its α-phase radius. Using EXAFS spectroscopy, Conradson (2003) showed that the cerium solute atom was accommodating in the plutonium lattices. It readily adapted its size to fit either into the δ-phase lattice or the even smaller α-plutonium lattice (when trapped in the α lattice under metastable conditions).

Dormeval *et al.* (2003) calculated the deviation of lattice constants from Vegard's law by considering two different limits in the law. As a result of the pressure imposed by the δ-plutonium lattice, cerium is α-like at concentrations below 75 at.% Ce and γ-like above that level. Hence, on the cerium end, there are two different limits corresponding to α-cerium and γ-cerium extrapolated to room temperature and pressure. Following this approach, Dormeval *et al.* found the deviation from Vegard's law to be negative on the plutonium-rich end, while slightly positive at the cerium-rich end as shown in Fig. 7.41c. Based on measurements of lattice constants, electrical resistivity, and magnetic susceptibility, Dormeval *et al.* suggested that the principal cause of the complex alloying behavior of cerium in plutonium is not the plutonium itself but the unstable nature of the cerium atom.

The addition of aluminum or gallium shrinks the δ-phase plutonium lattice (Fig. 7.41). Both show negative deviations from Vegard's law, with the gallium deviation being more than twice that of aluminum. As mentioned above, several investigators have probed the local structure of Pu–Ga alloys using EXAFS (Cox *et al.*, 1995; Faure *et al.*, 1996; Conradson, 2000; Allen *et al.*, 2002). These EXAFS results show that the first-neighbor Pu–Ga bond is 0.13 Å, or 3.7% (the experimental measurements vary from 3.5 to 4%) shorter than the Pu–Pu bond in dilute alloys. Scheuer and Lengeler (1991) and Massalski (1996) pointed out that local distortions in substitutional alloys may bear little or no relation to macroscopic distortions of the unit cell. The local distortions can vary greatly in magnitude and in sign compared to the average change in lattice parameters. The contraction in Pu–Ga is at the upper end of that found in substitutional alloys. Scheuer and Lengeler reported that the change in the next-nearest-neighbor and more distant shells is typically small for substitutional alloys. Conradson (2000) found contractions in the second and third nearest-neighbor shells in Pu–Ga to be almost negligible (0.05 and 0.01 Å, respectively). He also reported a significant change in local order in Pu–Ga alloys as the gallium concentration increases beyond roughly 3.5 at.% Ga. He found the Pu–Ga distance to remain constant with gallium addition, whereas Faure *et al.* (1996) found it to first increase and then decrease. Resolution of the differences in local Pu–Ga arrangements must await additional experiments. However, Ravat *et al.* (2003) recently reported results similar to those of Conradson; that is, the first shell distance for the Pu–Ga bond is 0.1 Å shorter than the Pu–Pu bond, and the second shell bonds are close to the Pu–Pu bond length. We must also heed the caution expressed by Scheuer and Lengeler that alloy additions of roughly 2% or more typically cause complex local ordering effects.

A lattice contraction with the addition of gallium or aluminum to plutonium is expected from purely elastic considerations because the atomic radii of aluminum and gallium are considerably smaller than the radius of δ-phase plutonium. The atoms tend to relax toward their natural bond length rather than retain their average spacing. Harrison (2001) pointed out that each solute atom eliminates 12 f–f bonds in δ-phase plutonium. The f–f bond cutting should counter the elastic contraction of the solutes. However, Harrison's calculations for Pu–Ga alloys showed that the experimentally observed negative deviation from Vegard's law results from a coupling between the core d-states in gallium and the unoccupied d-states in plutonium. Faure *et al.* (1996) suggested that negative deviation to Vegard's law is proof of delocalization. They assume that this negative deviation results from the f–p bonding between Pu 5f and Ga 4p electrons. Thus, in the Pu–Ga alloys the solutes delocalize some of the 5f electrons in alloyed δ plutonium compared to the pure δ plutonium, which, in turn, promotes more bonding and smaller atomic volumes. As pointed out above, using DFT (with spin polarization for the δ phase), Sadigh and Wolfer (2005) predicted that the δ-lattice volume decrease results primarily from the reduction in size of the plutonium host atoms. All of these analyses indicate that electronic effects play a major role in determining the alloying characteristics of plutonium.

Another interesting electronic effect in plutonium is the behavior of alloying elements such as gallium and aluminum in α-phase plutonium. Ellinger *et al.* (1968b) showed that there is no measurable equilibrium solubility of these elements in the α phase. However, as pointed out by Hecker *et al.* (2004), lean δ-phase Pu–Ga and Pu–Al alloys transform to the α phase upon cooling below 0°C or with hydrostatic pressure at ambient temperature and below. Adler *et al.* (1986) and Olson and Adler (1984) concluded that the temperature-induced δ→α transformations are martensitic. Zukas *et al.* (1981) concluded that the pressure-induced δ→α transformations are also martensitic – that is, displacive with no compositional change. Hence, the solute atoms are trapped in the monoclinic α lattice. The crystal structure, as shown in Fig. 7.22, has 16 atoms per unit cell, with eight unique lattice sites and with variable bond lengths.

Hecker *et al.* (2004) reported that XRD measurements and immersion-density measurements of the transformed α phase clearly showed that the gallium is in substitutional lattice positions in the monoclinic lattice, but that it expanded the α lattice (the expanded lattice is called the α′ phase). All three-crystal axes expand, whereas the monoclinic angle remains nearly constant. The volume expansions in the α′ phase with the addition of gallium or aluminum are shown in Fig. 7.43 and contrasted with the volume contractions in the δ phase with alloying additions. With the addition of gallium, the α-phase volume expands ~0.9% per at.% Ga, whereas the δ-phase volume decreases by ~0.6% per at.% Ga.

These results are a most interesting manifestation of the peculiar electronic effects in plutonium. As explained above, the gallium atom, which is 14.2% smaller than the δ-plutonium atom, contracts the lattice significantly more than expected because it is believed to make the plutonium atoms contract in its presence. In other words, the addition of gallium causes more of the 5f electrons in plutonium to bond. This result is conceptually consistent with the calculations of Wills and Eriksson (2000), which indicated that only one of the five 5f electrons appears to be bonding in the unalloyed δ phase. Also, Sadigh and Wolfer (2005) predict the decrease in the size of the plutonium atoms quantitatively.

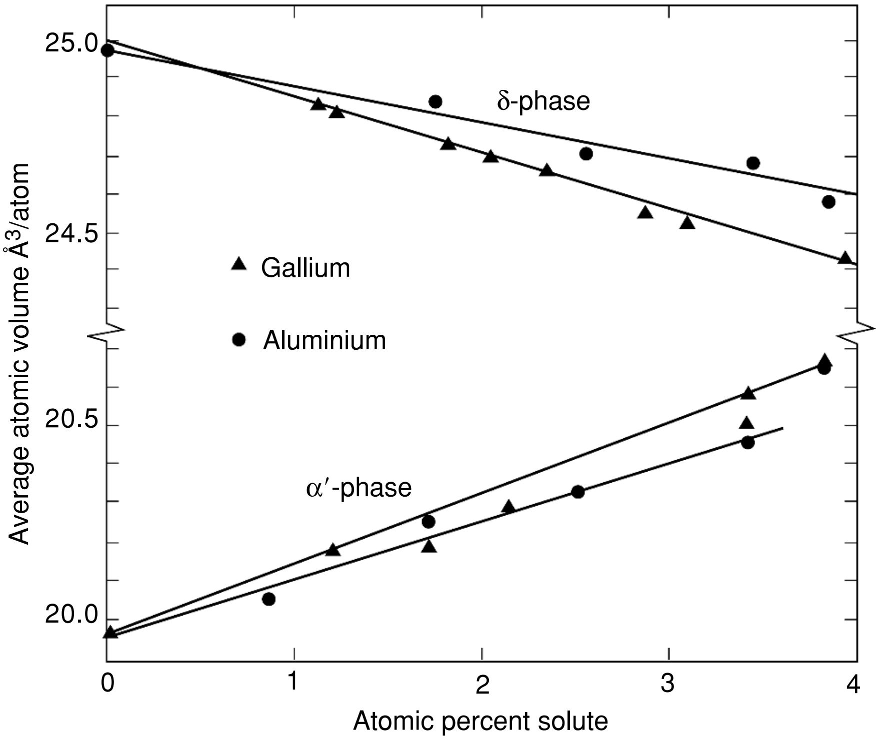

Fig. 7.43 *Atomic volumes of Pu–Ga and Pu–Al alloys in the δ and α′ phases.*

On the other hand, the gallium atom, although 7% smaller than the α-plutonium atom, expands the α lattice, indicating that in the α phase the presence of gallium localizes more of the 5f electrons. The calculations of Wills and Eriksson (2000) showed that all five 5f electrons bond in the α phase, hence it is quite likely that the solute additions disrupt the bonding, causing the volume to expand. Hecker *et al.* (2004) also showed that the lattice expansion in the α′ phase disappears slowly with time at ambient temperature and quite rapidly at slightly elevated temperatures. During the martensitic transformation, the solute atoms are trapped randomly in the α′ lattice, causing it to expand.

However, the eight different lattice sites have different bond lengths as shown in Fig. 7.22. Hecker *et al.* (2004) suggested that there is a strong driving force to rearrange the solute atoms into preferred sites, namely lattice site 8, because it has the fewest number of short bonds (Table 7.10). Based on their recent calculations, Sadigh and Wolfer (2005) showed that site 8 is by far the most favorable substitutional position for gallium. Furthermore, they found that the unit cell of the α phase is not expanded when gallium occupies site 8, while significant expansions are exhibited when gallium is substituted in other sites, with the largest expansion for site 1 occupancy. The energies for gallium substitution correlate with this volume expansion, with a maximum difference of 1.5 eV between site 1 and site 8, confirming the suggestion of Hecker *et al.* (2004) that gallium entrapped in sites other than site 8 will tend to order to this site and in the process contract the unit cell of the α′ phase.

These results demonstrate that plutonium atoms, like cerium atoms, readily change their electronic configurations and adjust their size as their lattice environment changes. It is no surprise then that alloying of plutonium is so complex.

7.7.6 Physical and thermodynamic properties

The physical and thermodynamic properties of plutonium are of great practical interest and present significant engineering challenges; they also represent some of the most puzzling features of solid-state behavior.

(a) Densities and lattice parameters

The densities of the six solid plutonium allotropes and liquid plutonium are summarized in Table 7.18. Of particular note is the fact that the density of liquid plutonium exceeds that of the three high-temperature allotropes and that the δ phase, which is also the closest-packed crystal structure, exhibits a particularly low density compared to the other allotropes. As pointed out above, full density is difficult to achieve in the α phase of unalloyed plutonium because of the propensity for microcracking during cooling and the retention

of lower-density phases during processing. Merz (1974) achieved exceptionally high density (19.82 g cm^{-3}) in α-phase plutonium by extrusion and concurrent recrystallization, which resulted in very fine grain size (on the order of micrometers). Alpha phase plutonium samples with densities >19.7 g cm^{-3} are typically considered as sound samples.

Alloying plutonium with elements such as aluminum and gallium, which promote δ-phase retention to room temperature, yields densities close to that of the unalloyed high-temperature δ phase. The densities of some δ-phase alloys are also compared to that of the plutonium allotropes and common plutonium compounds in Table 7.18. The densities reported in the middle column were calculated by the authors from the lattice parameters measured by XRD by a number of investigators. Experimental densities are typically measured by liquid immersion techniques. The experimental densities for the δ-phase alloys are usually lower than the calculated densities from X-ray measurements because of impurities and inclusions. Experimental densities higher than X-ray densities are almost always the result of transforming the surfaces of test samples from the δ phase to the α phase during sample preparation (such as punching, machining, filing, or polishing). The compounds Pu_6Fe, PuO_2, PuC, and PuN are common inclusions found in plutonium metal and alloys of typical purity. PuO_2, PuC, and PuN have also been considered for reactor fuels. The compound Pu_3Ga is the most plutonium-rich compound in the Pu–Ga system. Figs. 7.41 and 7.43 show how the lattice parameters of δ-phase plutonium alloys decrease with increasing alloy content.

(b) Thermal expansion

Thermal expansion of the unalloyed α, β, and γ phases of plutonium is large and positive. Thermal expansion of these allotropes is also anisotropic because of their low-symmetry crystal structures. Table 7.19 lists the coefficients of thermal expansion for all allotropes, including coefficients for different lattice directions for the low-symmetry allotropes. The values shown in Table 7.19 were taken primarily from X-ray measurements because of the variability of dilatometric results. Schonfeld and Tate (1996) recently reviewed available thermal expansion results for unalloyed plutonium. We have chosen to present their best fits to the available dilatometric data, as shown in Fig. 7.19. The low-temperature behavior of α-phase plutonium is quite nonlinear, as reported by Cramer *et al.* (1961) and Lallement (1963). On page 37 of the *Plutonium Handbook*, Miner and Schonfeld (1980) show an inflection in thermal expansion near 60 K. However, more recently, Schonfeld and Tate (1996) argued convincingly that the slight lattice expansion in α-phase plutonium reported below 60 K results from self-irradiation damage. Schonfeld and Tate replotted all available thermal expansion data for α-phase plutonium, as shown in Fig. 7.44. They list the average thermal expansion coefficient between 0 and 393 K as 37.8×10^{-6} K^{-1} and that between 294 and 377 K as 53.8×10^{-6} K^{-1} (by dilatometry) and 54×10^{-6} K^{-1}

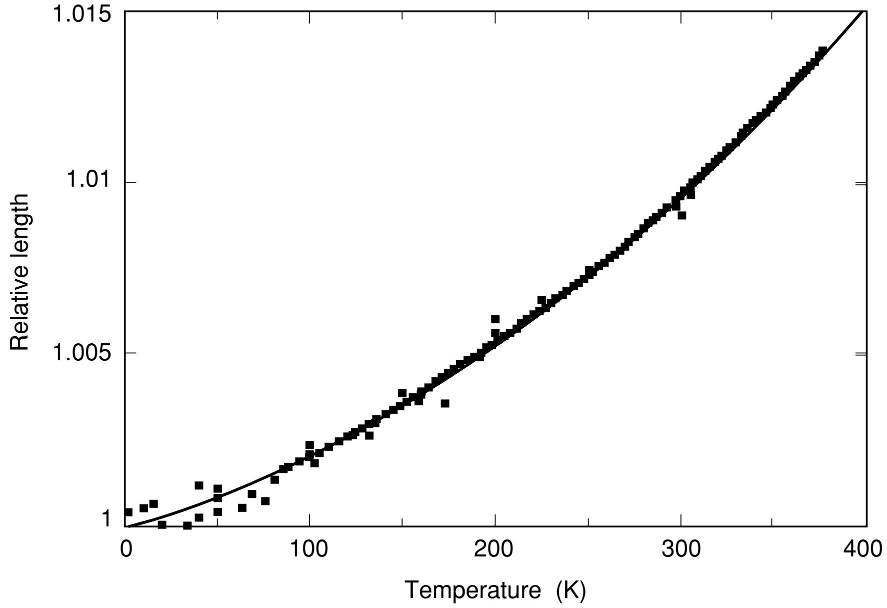

Fig. 7.44 *Thermal expansion of unalloyed α-phase plutonium over most of its temperature region of stability. The curve is a composite generated by Schonfeld and Tate* (1996) *based on data from several references* (*Sandenaw,* 1960*b*; *Cramer* et al., 1961; *Lee* et al., 1965*a*; *Lallement and Solente,* 1967; *Miner and Schonfeld,* 1980; *Lawson* et al., 1994).

(by X-ray measurements). The low-temperature results of Schonfeld and Tate are incorporated into the overall thermal expansion curve shown in Fig. 7.19.

The expansion of the high-temperature δ and ε phases is isotropic. However, the δ and δ′ phases exhibit negative thermal expansion. Thermal expansion of the δ′ phase is also highly anisotropic. The explanation of this unusual behavior has been a contentious issue since the late 1950s. In δ-phase alloys, the thermal expansion coefficient varies from slightly negative to positive, depending on the amount of alloying addition. A graphic example of this behavior is shown for Pu–Ga alloys in Fig. 7.45 (Goldberg *et al.*, 1970). We also show the thermal expansion behavior of various δ-phase plutonium alloys in Fig. 7.46 (taken mostly from the work of Elliott *et al.* (1960) and Lawson *et al.* (2002)). All alloying additions move the coefficient of thermal expansion to more positive values from that of the unalloyed δ phase; that is, alloying results in thermal expansion behavior closer to that observed in normal metals. As shown in Fig. 7.46, significantly less aluminum or gallium is required to increase the coefficient compared to cerium. The properties of Pu–Am alloys were estimated from the measurements of Shumakov *et al.* (1990).

The peculiar thermal expansion behavior of δ-phase plutonium alloys was reviewed by Lawson *et al.* (2002). A negative thermal expansion is associated

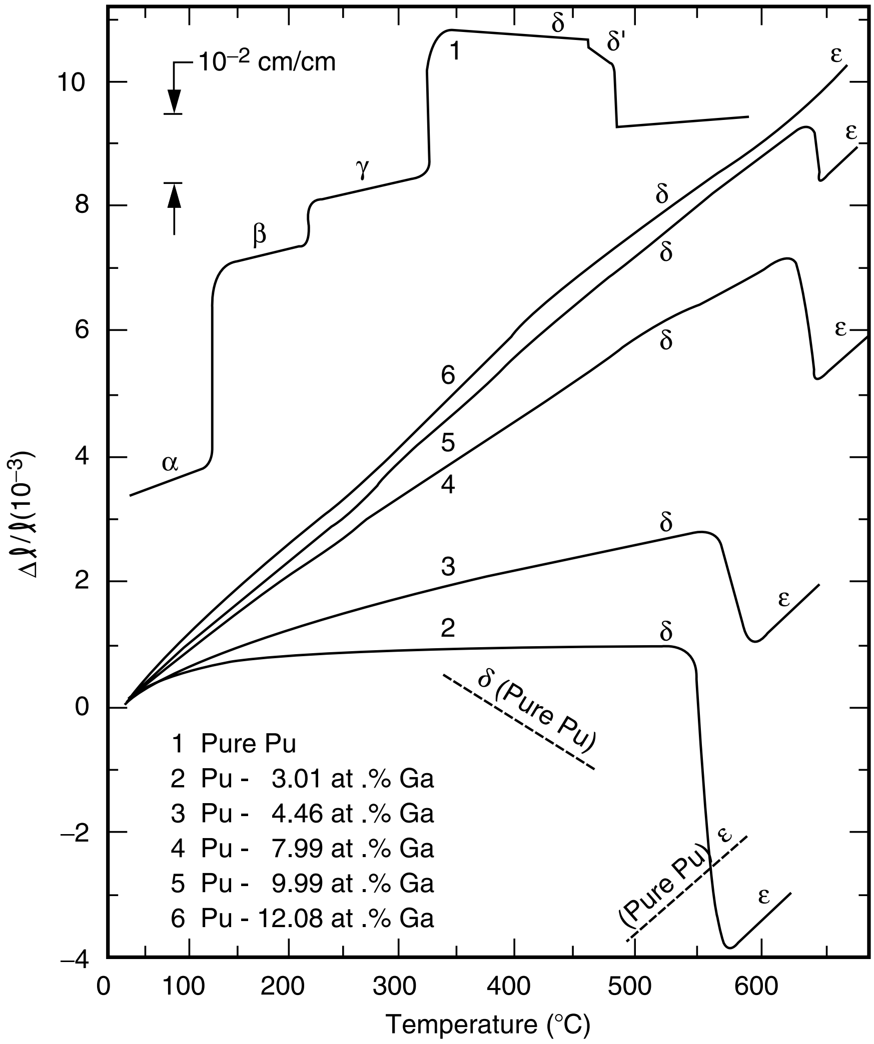

Fig. 7.45 *Corrected dilatometric heating curve* (*at* 4.5°C min^{-1}) *for a series of* δ*-phase Pu–Ga alloys. The curve for unalloyed* (*pure*) *plutonium is based on a scale of one-tenth* (*as shown in insert*) *that used for the alloys. with increasing disorder (higher entropy) at higher pressures according to the Maxwell relation $(\partial V/\partial T)_p = -(\partial S/\partial P)_T$, in contrast with the behavior found in ordinary metals. However, for some complex solids with negative thermal expansion, such as the recently discovered ZrW_2O_8, increasing pressure has

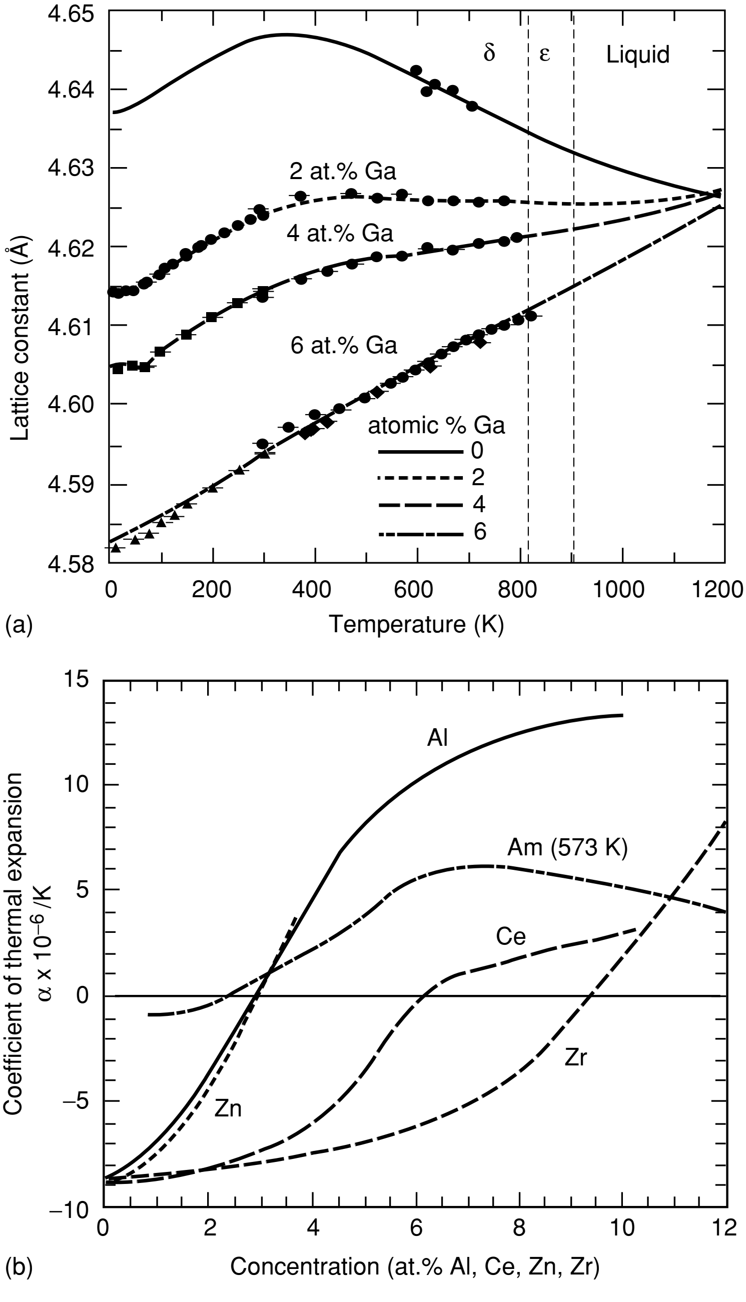

Fig. 7.46 (*a*) *Lattice constants of δ-phase Pu–Ga alloys measured by neutron diffraction by Lawson* et al. (2002). *The line through the data is a fit by the 'Invar' model proposed by Lawson* et al. (1990) *taken at* 573 K, *where the range of solid solution across the Pu–Am diagram is complete.*

been shown to increase the vibrational entropy of the molecular modes (Evans *et al.*, 1996; Mary *et al.*, 1996; Mittal *et al.*, 2001). For fcc δ plutonium there are no internal vibrational modes, so Lawson *et al.* looked for an electronic degree of freedom whose entropy variation with pressure determines the thermal expansion. They believe zero thermal expansion (Invar-like behavior) of some of the alloys results from a thermal transfer of plutonium atoms from a lower-energy, higher-volume δ_1 state to a higher-energy, lower-volume δ_2 state, comparable to the Weiss two-level model used to explain the Invar behavior in Fe–Ni alloys (Weiss, 1963).

For ordinary metals that follow Grüneisen's law, the thermal expansion behavior can be used to estimate the temperature dependence of the bulk modulus (or the sound speed or Debye temperature); namely, $\mathrm{d}B/\mathrm{d}T = -\gamma\beta B$, where B is the bulk modulus, γ the Grüneisen parameter, and β the volume thermal expansion. The δ-phase plutonium alloys, however, do not follow this relationship since the thermal expansion is small – or even negative – and $\mathrm{d}B/\mathrm{d}T$ is large. For these alloys it is necessary to assume that the elastic stiffness is intrinsically temperature dependent, independent of volume. For unalloyed α-phase plutonium, a recent review by Ledbetter (2004) and by Ledbetter and Migliori (2005) of Grüneisen parameters shows large variations from values of 3.1 to 7.0. They believe the best value is ~3.5. We also note that Hasbrouk and Burns (1965) provide additional listings of thermal expansion in various plutonium allotropes and in several alloys.

(c) Elastic constants and sound velocities

Early elastic constant measurements for unalloyed plutonium and several plutonium alloys by various investigators were compiled by Hasbrouk and Burns (1965). As pointed out by Fisher (1974) in a later compilation, reported elastic constant measurements (particularly the bulk modulus) exhibit significant scatter because of difficulties in fabricating quality samples. Acoustic measurements typically yield the most reliable elastic constants. Calder *et al.* (1981) reported elastic constants of α plutonium and δ-phase Pu–3.4 at.% Ga alloys at elevated temperatures. Migliori *et al.* (2004, 2006) and Ledbetter *et al.* (2004, 2005) recently performed the most accurate acoustic measurements to date on high-quality, high-purity, unalloyed plutonium (with a density >19.7 g cm^{-3}), and Pu–Ga alloys using the resonant ultrasound technique (Migliori *et al.*, 2000). Their room-temperature results are summarized in Table 7.20. Unalloyed α plutonium is soft elastically – its bulk modulus is nearly 50% less than that of α uranium. As shown in Table 7.20, the δ-phase Pu–Ga alloys exhibit substantially reduced elastic constants compared to α plutonium. Typical sound velocities are also listed in Table 7.20.

The temperature dependence of the elastic modulus (Young's modulus), the shear modulus, bulk modulus, and Poisson's ratio is shown for unalloyed plutonium in Fig. 7.47. All but Poisson's ratio are quite sensitive to temperature. The ratio of the bulk modulus at 0 K to the bulk modulus at 300 K for α plutonium is 1.303, compared to 1.104 for lead, 1.03 for iron, and 1.075 for aluminum. There are no single-crystal elastic constant measurements in the literature for α plutonium because of the difficulty of making single crystals of unalloyed plutonium. In addition, making elastic constant measurements of the monoclinic structure of the α phase with 13 independent elastic constants is a daunting task. Moment (2000) and Lashley *et al.* (2000) describe techniques used to prepare single crystals of δ-phase plutonium alloys. Ledbetter and Moment (1976) reported elastic constant measurements on a single crystal δ-phase Pu–3.4 at.% Ga alloy. As shown in Fig. 7.48, the elastic constants are highly anisotropic. The single crystals are stiff in tension and compression and soft in shear in the [111] direction and vice versa in the [100] direction. In fact, the Zener anisotropy ($Z = 2c_{44}/c_{11}-c_{12}$), where c_{ij} are the typical elastic constants is 7.03; whereas lead, the next elastically most anisotropic fcc metal, is roughly 4 and aluminum is nearly isotropic at slightly over 1.0. The elastic constants for a polycrystalline δ-phase Pu–3.35 at.% Ga alloy reported by Calder *et al.* (1981) and shown in Fig. 7.49, exhibit a greater reduction in elastic constants with temperature than that for unalloyed α plutonium. Poisson's ratio for the δ-phase alloy increases monotonically with temperature as is typical for fcc metals.

In addition to providing stiffness data, elastic constants also play an important role in determining the overall mechanical response of materials (Hecker and Stevens, 2000). The Debye temperature at 0 K can be determined by correcting for the temperature dependence of the elastic constants. We will compare these results to the Debye temperatures from specific heat measurements in a subsequent section. Sound velocities provide a convenient way to determine elastic constants. They are also important in dynamic and shock responses of materials. The sound velocities for α plutonium and Pu–Ga alloys are presented in Table 7.20. We also note that Rosen *et al.* (1969) measured elastic properties ultrasonically at low temperatures and found no discontinuities in the elastic constants at low temperature (at the time they were looking for a possible magnetic transition) for α plutonium, and δ-phase Pu–Al and Pu–Ce alloys. However, they observed a sharp peak in the longitudinal wave attenuation accompanied by a normal temperature dependence of the transverse attenuation. Cornet and Bouchet (1968) measured the elastic properties of unalloyed plutonium with temperature, including the bcc ϵ phase (the room-temperature density was 19.1 g cm^{-3}, indicating that the samples contained many microcracks). They reported detailed results for Young's modulus for the δ, δ′, and ϵ phases. They found the ϵ phase to exhibit a large compressibility (0.16 GPa^{-1} at 758 K) and a low Young's modulus (11 GPa at 703 K). As indicated above, however, the sample quality was questionable because of its low density.

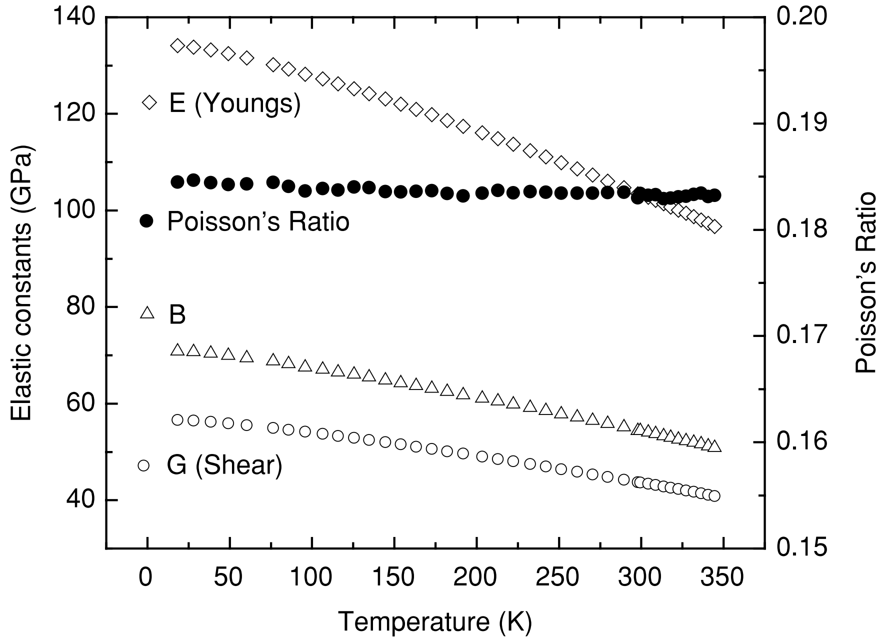

Fig. 7.47 *Elastic moduli of a high-purity, unalloyed α-plutonium polycrystal. Error bars are much smaller than the data points. The primary error is in the determination of density, computed from the dimensions and mass. E denotes Young's modulus, G, the shear modulus, and B, the bulk modulus (data from Ledbetter* et al., 2004; *Migliori* et al., 2004).

(d) Heat capacity

In 1976, Oetting *et al.* (1976) reviewed the early heat capacity measurements on plutonium. Low-temperature measurements of the heat capacity in ^{239}Pu, the most readily available plutonium isotope, have been plagued by self-heating (typically 2.2×10^{-3} W g^{-1} for ^{239}Pu) and by self-irradiation damage, which is especially pronounced at low temperatures where little if any healing of lattice damage occurs (Hecker and Martz, 2001). Although several investigators (Sandenaw and Gibney, 1971; Gordon *et al.*, 1976) minimized the effects of self-irradiation damage by using ^{242}Pu, they still had difficulty in obtaining sufficiently low temperatures to accurately measure the electronic specific heat. Lashley *et al.* (2003b) also reviewed previous low-temperature measurements and extended the measurements to ~2 K on ^{242}Pu using a thermal relaxation method and a specially designed sample mount (Lashley, 2003).

Lashley *et al.* demonstrated conclusively that previously reported anomalies in the heat capacity of plutonium resulted from the effects of self-irradiation damage. They also showed that anomalies in some of the δ-phase plutonium

alloys at low temperatures resulted from martensitic transformations incurred in such samples when cooled to cryogenic temperatures. The results of Lashley *et al.* for very pure, zone-refined α-phase ^{242}Pu (<200 ppm impurities) are shown in Fig. 7.50 and compared to those reported by Gordon *et al.* (1976).

The electronic contribution to the specific heat can be measured at low temperatures where the phonon contribution is small. It is represented by equation (7.25)

$$(C_p/T) = \gamma + \alpha T^2 + \delta T^4 + \ldots \tag{7.25}$$

where γT and $\alpha T^3 = (12\pi^4 R T^3)/(5\theta_D{}^3)$ are the electronic and phonon contributions to C_p and θ_D is the Debye temperature. The results of Lashley *et al.* (2003b) for low-temperature heat capacity measurements on high-purity ^{242}Pu and a ^{242}Pu–5 at.% Ga alloy are shown in Fig. 7.51. The intercept at $T = 0$, γ, is a measure of the electronic DOS. The low-temperature fit yields $\gamma = (17 \pm 1)$ mJ K^{-2} mol^{-1}, which is within the range of 16 to 23 reported by Gordon *et al.* (1976), but less than the values of 22 to 25 reported by Stewart and Elliott (1981).

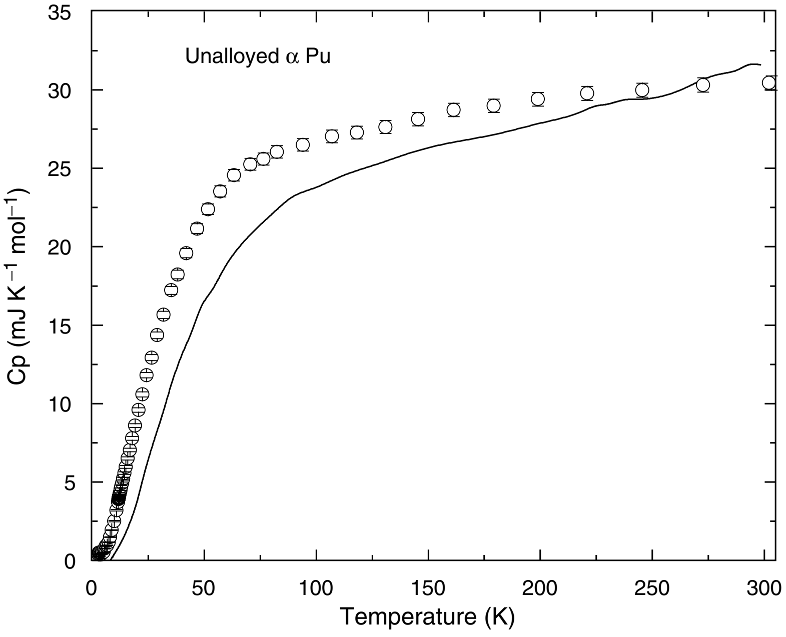

Fig. 7.50 *Heat capacity of unalloyed* ^{242}*Pu* (*solid line from Gordon* et al., 1976) *and high-purity, unalloyed* ^{239}*Pu (symbols) from Lashley* et al. (2003*b*) *who took extraordinary care to avoid self-irradiation damage at low temperatures.*

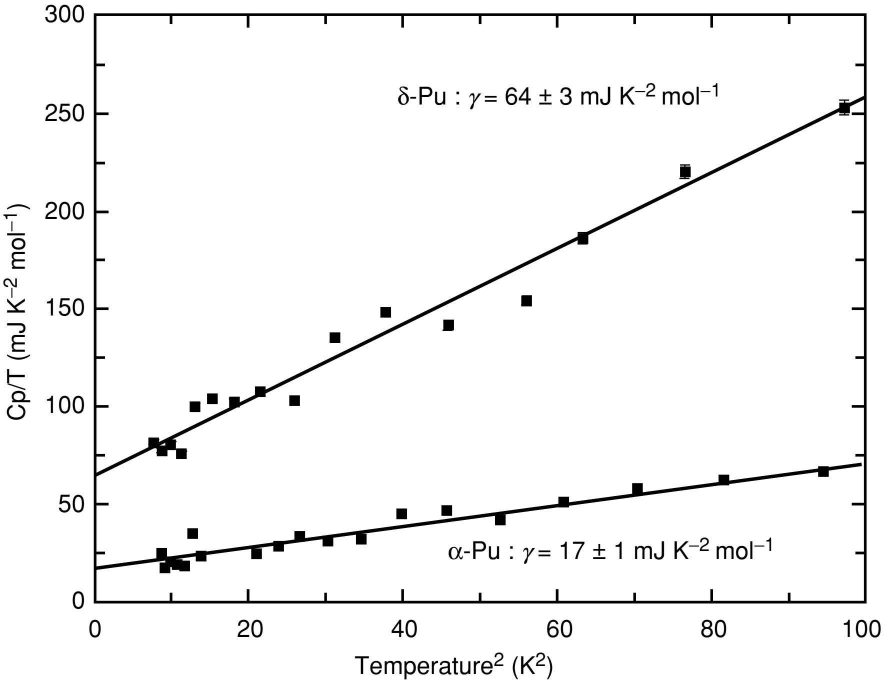

Fig. 7.51 *The low-temperature specific heat of unalloyed* α *plutonium and a* δ*-phase Pu-*5.1 at. *% Al alloy. These data represent the lowest temperature specific heat measurements reported on plutonium* (*after Lashley* et al., 2003*a,b*).

Since Lashley *et al.* reached the lowest temperatures, it is likely that their values are the most accurate. In any case, γ for plutonium is larger than that of any other element (Kittel and Kroemer, 1980). The δ-phase Pu–Al alloy has an even more remarkable γ of (64 ± 3) mJ K^{-2} mol^{-1}. Stewart and Elliott measured γ for Pu–Al alloys of varying aluminum concentration and found γ to vary from 44 to 63 mJ K^{-2} mol^{-1}. Extrapolation of the alloy data to zero alloy content yields $\gamma = 53$ mJ K^{-2} mol^{-1} for pure plutonium in the δ phase. Hence, the δ phase of plutonium, which is known to have less participation by the 5f electrons in bonding than the α phase, nevertheless has three times the electronic DOS at the Fermi energy.

Lashley *et al.* (2003b) calculated a Debye temperature, θ_D, of 153 K for α plutonium. On the other hand, Migliori *et al.* (2004, 2005) report the Debye temperature ($T = 0$ K) as 205 K based on the extrapolation of their elastic constant measurements to absolute zero. This method typically yields more accurate estimates of the Debye temperatures because it is less susceptible to the effects of self-irradiation damage. The literature values for α plutonium as determined from heat capacity, elastic constant, EXAFS, and neutron scattering Debye–Waller measurements (Sandenaw, 1961, 1962; Taylor *et al.*, 1965; Lee *et al.*, 1965b; Gordon *et al.*, 1976; Stewart and Elliott, 1981; Lawson *et al.*, 1994; Lashley *et al.*, 2003b) vary from 118 to 205 K. On the other hand, the Debye temperature for the δ-phase plutonium alloys are reported to vary much less; namely, from 100 to 130 K (Ledbetter and Moment, 1976; Stewart and Elliott, 1981; Lashley *et al.*, 2003b).

Heat capacity measurements below and above room temperature as reported by Oetting and Adams (1983), Taylor *et al.* (1968), and Lashley (2005) for unalloyed plutonium, and by Lashley *et al.* (2003a), Lashley (2005), and Rose *et al.* (1970) are shown in Table 7.21. The heat capacity measurements above room temperature are not affected by self-irradiation damage because defects are sufficiently mobile to heal the damage. As pointed out by Oetting *et al.* (1976) and others, no anomalies in the paramagnetic susceptibility with temperature have been observed, thus the magnetic contribution to heat capacity is negligible, as confirmed by Lashley (2005).

Oetting and coworkers (Oetting *et al.*, 1976) present a comprehensive listing of the thermodynamic functions – enthalpy and entropy – along with the enthalpies of transformation between the various plutonium allotropes. The heat capacity of unalloyed plutonium as a function of temperature taken from Lashley *et al.* (2003b) and Kay and Loasby (1964) is shown in Fig. 7.52. The enthalpies and entropies of transformation are listed for unalloyed plutonium in Table 7.16.

(e) Magnetic behavior

Fig. 7.53 shows the molar magnetic susceptibilities of unalloyed plutonium and a Pu–6 at.% Ga alloy as a function of temperature. The plots are taken from Lashley (2005). The data for unalloyed plutonium above 300 K are those of Comstock, published by Sandenaw (1961) with additional details provided by Olsen *et al.* (1992). These data were obtained by the Gouy method on large samples of ^{239}Pu with a purity of 99.9%. The low-temperature data for the unalloyed α plutonium and all of the data for the alloy is that of Méot-Reymond and Fournier (1996). Their plutonium alloy samples were of high purity, electrorefined, with ferromagnetic impurities constituting <10 ppm. In the plot shown in Fig. 7.53, Lashley *et al.* align Méot-Reymond and Fournier's high- and low-temperature alloy data at 300 K because of the concerns expressed by Méot-Reymond and Fournier about their high-temperature technique.

We note that the susceptibilities of unalloyed plutonium and the alloy are similar – both are quite large, similar to the magnetic susceptibility of manganese. Unlike manganese, which orders antiferromagnetically at 95 K, plutonium shows no anomaly in its susceptibility at low temperatures. Magnetic susceptibilities on the order of those exhibited by plutonium are characteristic of metals with relatively strong paramagnetism caused by electronic band magnetism (such as that for palladium). Lashley *et al.* (2004) recently concluded that a

thorough review of experimental data for plutonium (both in the unalloyed α phase and in the alloyed δ phase) provides no evidence for localized magnetic moments. They concluded that neither temperature nor magnetic-field dependencies of measured susceptibilities show evidence for ordered or disordered moments. They reinforce their conclusions with the results of other experimental probes, such as specific heat and NMR.

Magnetic moments and atomic volume are indicators of what the electrons are doing. As shown in Fig. 7.39, the atomic volumes of the actinides exhibit a huge expansion right at plutonium (between the α and δ phases, with an additional expansion at americium). In their review of actinide theory related to magnetic behavior, Lashley *et al.* (2004) show that the consensus among theorists is that a localization of the 5f electrons is required to explain the large volume expansion between the α phase and the δ phase, which leads inexorably

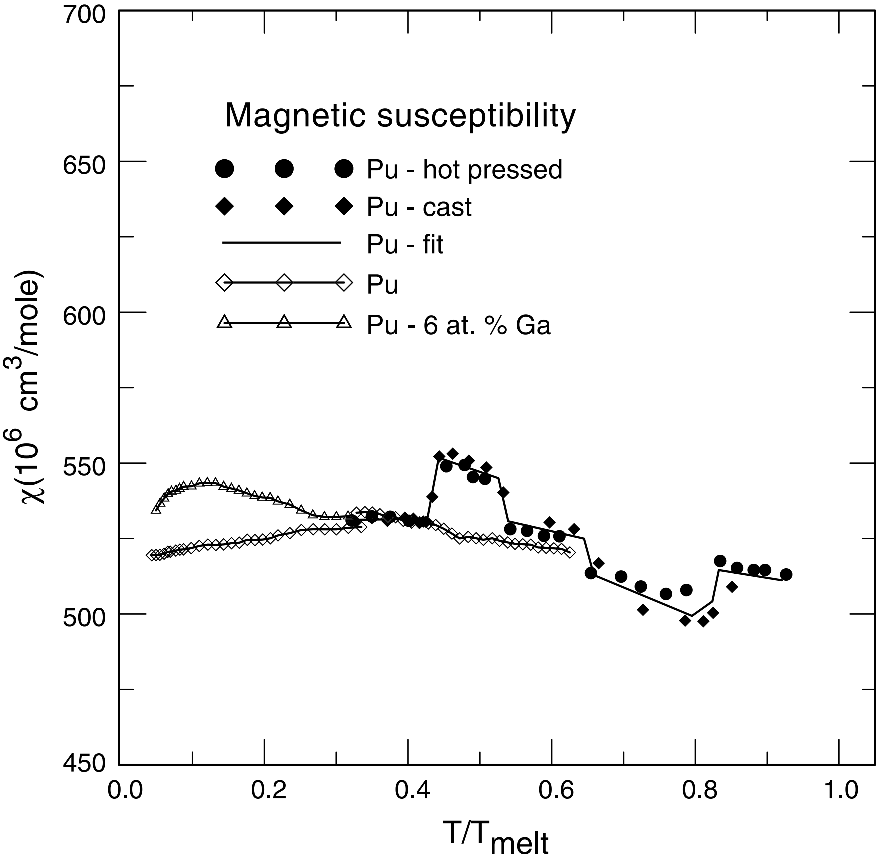

Fig. 7.53 *Molar susceptibility of unalloyed plutonium and δ-phase Pu*-6 at. *% Al alloy plotted as a function of temperature scaled by the melting point* (*from Lashley* et al., 2004). *See text for details of data.*

to magnetic ordering in the δ phase. Some theorists also predict magnetic order in the α phase. The magnetic moments are predicted to be large in both cases. Some of the theoretical treatments have suggested a partial cancellation between the spin and the orbital parts of the moments. However, even with such cancellation, magnetic moments of the order of 1 to $2\mu_B$ are predicted. Yet, the experimental evidence points overwhelmingly to the conclusion reached by Lashley *et al.* namely, neither ordered nor disordered local moments exist. Recent theoretical treatments by Shick *et al.* (2005) and Shorikov *et al.* (2005) predict reasonable volumes without any magnetic moments.

The reader is referred to the *Plutonium Handbook* (Miner and Schonfeld, 1980) and the *Gmelin Handbook of Inorganic Chemistry* (Lesser and Peterson, 1976; Blank, 1977) for additional references to magnetic susceptibility measurements and to the Hall effect in plutonium and its alloys. Recent magnetic susceptibility measurements on plutonium alloys, including Pu–Am and Pu–Ce, are also reported by Dormeval (2001) and Dormeval *et al.* (2000, 2003).

(f) Electrical resistivity, thermal conductivity, thermal diffusivity, and thermoelectric power

The unusual electrical resistivity of unalloyed plutonium is shown in Fig. 7.54 from Sandenaw and Gibney (1958). Unlike most normal metals that exhibit a linear decrease in resistivity at low temperatures, plutonium exhibits an increase and a maximum in resistivity at ~105 K. This low-temperature anomaly was initially believed to result from antiferromagnetic ordering. However, as pointed out above, no magnetic ordering has been found in plutonium or its alloys. Méot-Reymond and Fournier (1996) and Dormeval *et al.* (2000) suggest that the resistivity maximum is an indication of a Kondo effect in plutonium and its alloys. Boring and Smith (2000) make a convincing argument that the resistivity behavior along with other properties (such as the enhanced low-temperature specific heat) is an indication of strong electron–electron correlations involving spin and charge interactions. The resistivity maximum in plutonium is at the level of 150 μΩ cm, which means that an electron is scattered by roughly every atom in the lattice. As pointed out by Boring and Smith (2000), this type of scattering is considered the highest possible simple resistance that a

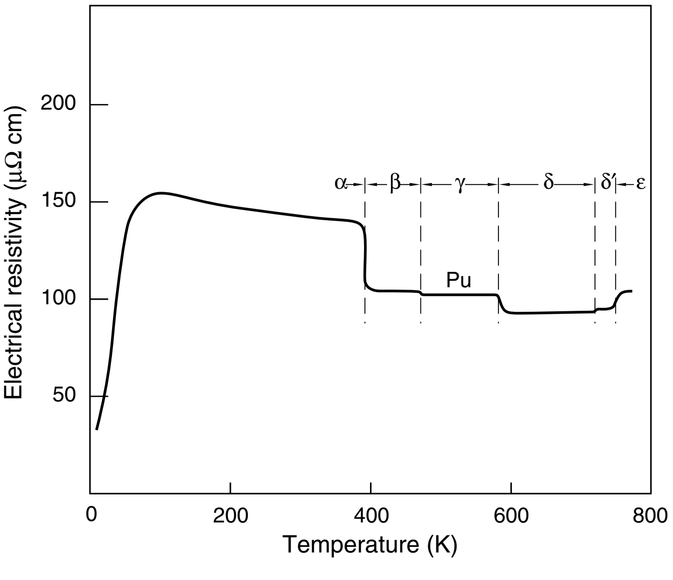

Fig. 7.54 *Electrical resistivity of unalloyed plutonium (from Sandenaw and Gibney,* 1958).

simple metal can exhibit; it is called the unitary limit. We also note that Lee *et al.* (1961) and Smith (1980) showed that plutonium does not become superconducting down to 0.75 K. Boivineau (2001) has extended resistivity measurements into the liquid phase using very high heating rates. He found the resistivity to remain nearly constant over the whole liquid range at a value of approximately 108 μΩ cm.

The resistivity of the δ-phase alloys has been measured by a number of investigators. The room-temperature values typically fall between 105 and 125 μΩ cm, depending on the alloying element and concentration. Extensive measurements have been reported on Pu–Ce alloys (Elliott *et al.*, 1962), Pu–Al alloys (Sandenaw, 1960a; Lee *et al.*, 1961; Elliott *et al.*, 1962), and Pu–Ga alloys (Joel *et al.*, 1971). The low-temperature results of Joel *et al.* (1971) for Pu–Ga alloys with gallium concentrations from 3 to 10 at.% are shown in Fig. 7.55. The results of Elliott *et al.* for Pu–Al alloys are very similar. We do not show the results for Pu–Ga alloys with gallium concentrations <3 at.% because they transform to the α′ phase upon cooling. The resistivities of all alloys are lower than that for unalloyed plutonium shown in Fig. 7.54. They also increase with decreasing temperature and exhibit a broad maximum. Increasing gallium concentration moves the maximum to lower temperatures and leads to higher

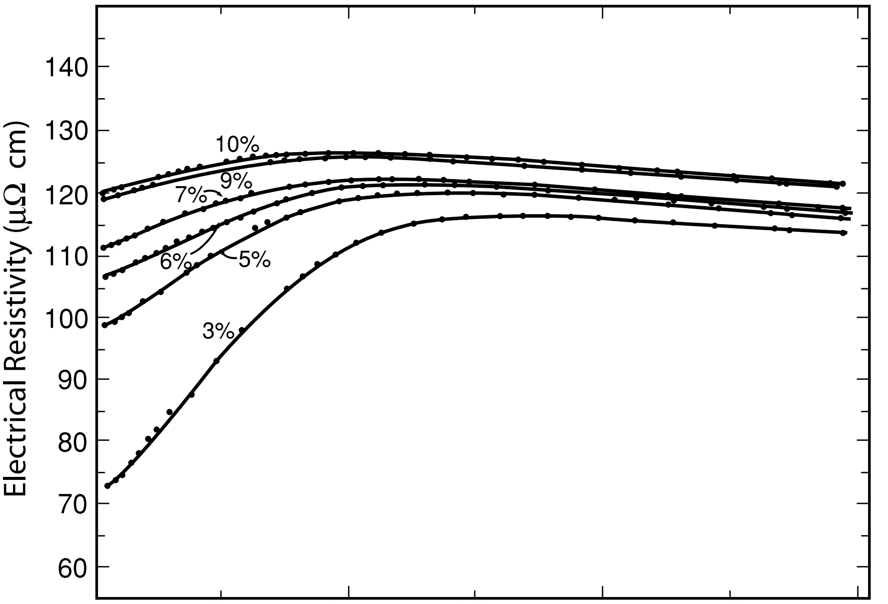

Fig. 7.55 *Electrical resistivity of various δ-phase Pu–Ga alloys (after Joel* et al., 1971).

resistivity. However, the increase with alloy concentration is less than what is typically observed for other metals. The low- and high-temperature regimes are shown together in Fig. 7.56 (taken from Blank (1977) and based on the work of Gibney and Sandenaw (1954)).

Gomez Marin (1997) and Dormeval (2001) recently measured resistivities of Pu–Am alloys across the entire range of δ-phase solubility at low temperatures. The resistivities for the entire range of alloys were considerably higher than any other plutonium alloy system. For example, the values for a Pu–15 at.% Am alloy was reported by Dormeval to be 370 μΩ cm at 293 K and 170 μΩ cm at 4 K. This alloy exhibited a slight maximum at 200 K. Alloys with higher americium contents were shown by Gomez Marin to decrease monotonically although not as rapidly as pure americium. Dormeval also reported resistivities of Pu–Ce alloys and of a number of ternary Pu–Ce–Ga and Pu–Am–Ga alloys. Blank (1977) reported the results of Mortimer and Adamson on Pu_3Al and Pu_6Fe. The resistivities at room temperature were 150 and 140 μΩ cm, respectively, and showed a maximum at lower temperatures. The resistivity for Pu_3Al remained unusually high (142 μΩ cm) at 4 K.

The literature shows large variations in low-temperature electrical resistivities measured in unalloyed plutonium. Much of this problem was a result of impurities. In addition, low-temperature measurements in plutonium are plagued by self-irradiation damage (see Section 7.7.9), which increases the resistivity

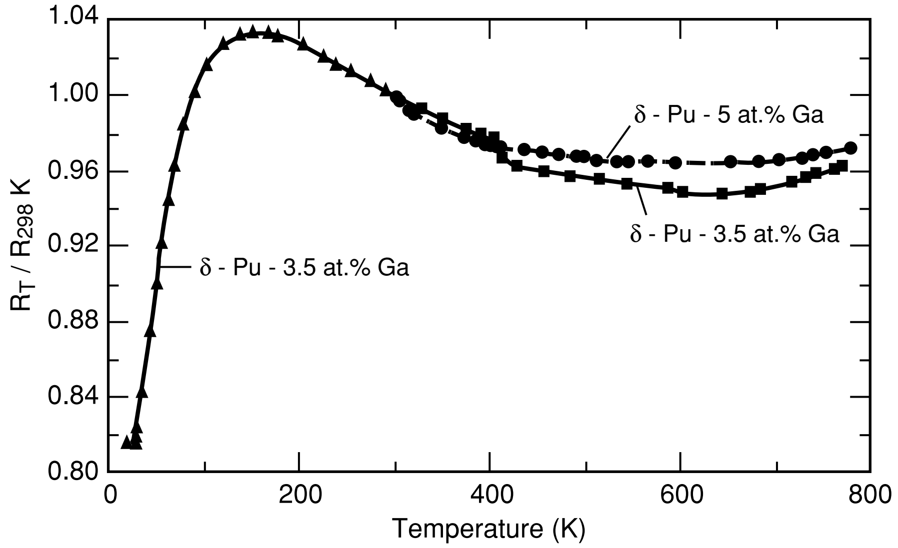

Fig. 7.56 *Electrical resistivity of a δ-phase Pu-*3.5 at. *% Ga alloy between* 25 *and* 750 K *and a δ-phase Pu-*5 at. *% Ga alloy between* 298 *and* 750 K. *The curves were normalized at* 298 K (*taken from Blank,* 1977 *with reference to Gibney and Sandenaw,* 1954).

because there is insufficient mobility of the defects generated to move and heal the lattice (Hecker and Martz, 2001). Olsen and Elliott (1962) reported some of the earliest measurements on the effects of impurities and self-irradiation on the resistivity of α-phase plutonium at low temperatures.

Thermal conductivity measurements on unalloyed plutonium were reported by Sandenaw and Gibney (1958), Lee and Mardon (1961), and Powell (1960). Andrew (1967) measured thermal conductivity of high-purity (99.98%) plutonium, chill-cast to minimize microcracking (density of 19.77 g cm^{-3}), and of preferentially oriented α-phase plutonium (by cooling from the β phase under pressure). The thermal conductivity decreases smoothly from a value of 0.0155 cal s^{-1} cm^{-1} K^{-1} at 300 K to 0.0075 cal s^{-1} cm^{-1} K^{-1} at 80 K for the chill-cast sample. Hence, the mechanisms that cause the increase in electrical resistivity and resistivity maximum at ~100 K do not seem to play a role in the thermal conductivity. Andrew found the thermal conductivity perpendicular to the [020] planes to be about 3 mW cm^{-1} K^{-1} higher than the thermal conductivity parallel to the [020] planes. He also reported a Lorenz number of 3.11×10^{-8} WΩ K^{-2} at 300 K and 5.95×10^{-8} WΩ K^{-2} at 80 K.

Andrew (1969) also reported thermal conductivities for high-purity, well-homogenized δ-phase Pu alloys. The conductivity of the Pu–3.35 at.% Ga alloy varied smoothly from 0.022 cal s^{-1} cm^{-1} K^{-1} at 300 K to 0.0098 cal s^{-1} cm^{-1} K^{-1} at 80 K. The conductivities of a Pu–7 at.% Ga alloy was approximately 10% lower and that of a Pu–10 at.% Ce alloy, approximately 20% higher. As was the case for the unalloyed plutonium, the thermal conductivities do not exhibit the anomalous low-temperature behavior found in resistivity measurements. Lewis *et al.* (1976) reported thermal conductivities calculated from thermal diffusivity measurements on high-purity Pu–3.35 at.% Ga alloys at high temperatures. Their calculated room-temperature value of 0.0205 cal s^{-1} cm^{-1} K^{-1} at 300 K increased to 0.04 cal s^{-1} cm^{-1} K^{-1} at 673 K.

Lewis *et al.* (1976) reported that the thermal diffusivity of high-purity plutonium (<200 ppm impurities) increased approximately linearly from about 0.011 cm^2 s^{-1} at 293 K (α phase) to 0.057 cm^2 s^{-1} at 843 K (ϵ phase). The thermal diffusivities of the δ-phase Pu–3.35 at.% Ga alloy increased smoothly from 0.04 cm^2 s^{-1} at 293 K to 0.065 cm^2 s^{-1} at 673 K.

The thermoelectric power of plutonium at room temperature is large and positive, and it decreases after each allotropic transformation as the temperature is increased, except for the δ′ to ϵ transformation, which shows an increase. The average value and ranges measured are shown in Table 7.22, taken from Wick (1980) and based on the work of Lee and Hall (1959), Costa (1960), Meadon and Lee (1962), and Lallement (1963). The thermoelectric power decreases rapidly at low temperatures with a slight rise at 80 K before falling very rapidly to 4 K. Blank (1977) reviewed thermoelectric power measurements for plutonium alloys. Lee *et al.* (1961) and Brodsky (1961) showed that the thermoelectric power in Pu–Al alloys exhibited an increase with decreasing temperature with a maximum at ~80 K for a δ-phase Pu–6 at.% Al alloy.

Table 7.22 *Thermoelectric power of plutonium* (*Wick*, 1980).

Phase	*Temperature* (K)	*Thermoelectric power, averaged values* (μV K^{-1})	μV K^{-1}, *range*
α	~20	1.75	~1.5–~2
	~80	10.1	8.6–11.6
	~100	9.8	8.2–11.5
	~293	~13	11.2–15.6
	300	11.5	7–15.5
β	400	9.1	7–10.7
γ	500	8.4	7.4–9.4
δ	600	3.0	2.3–3.7
δ'	725	2.32	–
ϵ	800	3.5	3.2–3.8

The value of the thermoelectric power at room temperature was approximately 4 μV K^{-1}, about one third the value of unalloyed plutonium in the α phase.

(g) Diffusion

Diffusion rates in solids depend principally on crystal structure and homologous temperature (T/T_m), that is, how close the temperature is to the melting point (Sherby and Simnad, 1961). Plutonium, of course, has multiple allotropes and a very low melting point. Sherby and Simnad (1961) showed that the Arrhenius-like rate equation for self-diffusion, $D = D_0\exp(-Q/k_BT)$, where D_0 is a constant and Q is the activation energy for self-diffusion (vacancy formation and migration), fits the diffusion data for most solids. The activation energy, Q, was found to depend primarily on the homologous temperature and the crystal structure. Experimental data for plutonium are summarized by Lesser and Peterson (1976), Blank (1977), and Deloffre (1997). The diffusion data presented in Table 7.23 are based on Deloffre's summary (1997) of the work of Tate and coworkers (Tate and Cramer, 1964; Tate and Edwards, 1966), Johnson (1964), Edwards *et al.* (1968), Rafalski and coworkers (Rafalski *et al.*, 1967; Harvey *et al.*, 1971), Dupuy and Calais (1968), Wade (1971), and Wade *et al.* (1978).

The data presented in Table 7.23 contrast self-diffusion rates in the various phases of plutonium. There are no data available for α-phase plutonium because it is stable only below 395 K where diffusion rates are extremely slow. Wade *et al.* (1978) showed that the large variations in diffusion rates in the β and γ phases were a result of short-circuit diffusion along paths such as dislocations or grain boundaries. The diffusion rates in ϵ plutonium are anomalously high even for the open bcc crystal structure. In fact, Cornet (1971) showed that the rate of self-diffusion decreased under pressure, similar to what was previously found for white phosphorus (Nachtrieb and Lawson, 1955). He calculated the

activation volume to be –4.9 cm^3, which is one-third of the molar volume of plutonium. He suggested an interstitial diffusion mechanism instead of the vacancy mechanism typically associated with lattice diffusion. Hill and Kmetko (1976) agreed with the proposed interstitial mechanism and suggested that the high self-diffusivity in the ϵ phase results from the nature of the 5f electron bonding in plutonium.

As shown in Table 7.23, the frequency factor, D_0, in plutonium is higher for self-diffusion than for interdiffusion. This behavior is shown graphically by the work of Edwards *et al.* (1968) in Fig. 7.57. It also agrees with the general observation that diffusion rates decrease with the addition of elements that raise the melting point of the host metal (Shewmon, 1963). Hilliard *et al.* (1959) showed that diffusion rates decrease significantly with increasing solute concentrations in typical alloy systems. Dupuy and Calais (1968) and Wade (1971) reported decreases in D_0 with additional solute additions. However, as reported by Mitchell *et al.* (2001), Edwards *et al.* (1968), and Rafalski *et al.* (1967) all concluded that the interdiffusion of gallium in plutonium did not vary with concentration over the range studied. Likewise, Tate and Edwards (1966) found no concentration dependence of diffusion rates in a series of δ-phase Pu–Al alloys. They reported values of $D_0 = 2.25 \times 10^{-4}$ and $Q = 106{,}690\ \mathrm{J\ mol^{-1}}$ in the range of 623 to 790 K.

The large differences in interdiffusion rates of gallium between the δ and ϵ phases are particularly important because they lead to microsegregation of gallium in δ-phase plutonium alloys, as discussed in Section 7.7.4. The diffusion data for such alloys were recently summarized by Mitchell *et al.* (2001). Hecker *et al.* (2004) showed that interdiffusion of gallium in the α' phase of plutonium (an expanded α phase resulting from the entrapment of gallium atoms in a martensitically transformed δ-phase plutonium alloy) appears to be quite rapid even at room temperature.

Irradiation enhances both self-diffusion and interdiffusion rates in solids and can lead to phase instability or radiation-enhanced segregation. Such effects are particularly important in plutonium since the radiation is self-induced. Smirnov and Shmakov (1999) provide experimental and theoretical results for the actinides including plutonium and also present a rich Russian literature on this topic.

(h) Liquid plutonium, surface tension, viscosity, and vapor pressure

Liquid plutonium is highly corrosive and easily oxidized. Early measurements of its properties, including compatibility with container materials, were made as part of the LAMPRE program. Comstock (1952) reported some of the first direct measurements on liquid plutonium. There is general agreement today that the melting point of plutonium is (913 ± 2) K. The low melting point (with respect to its position in the periodic table) has many consequences on the practical properties of plutonium. In addition to restricting the temperature

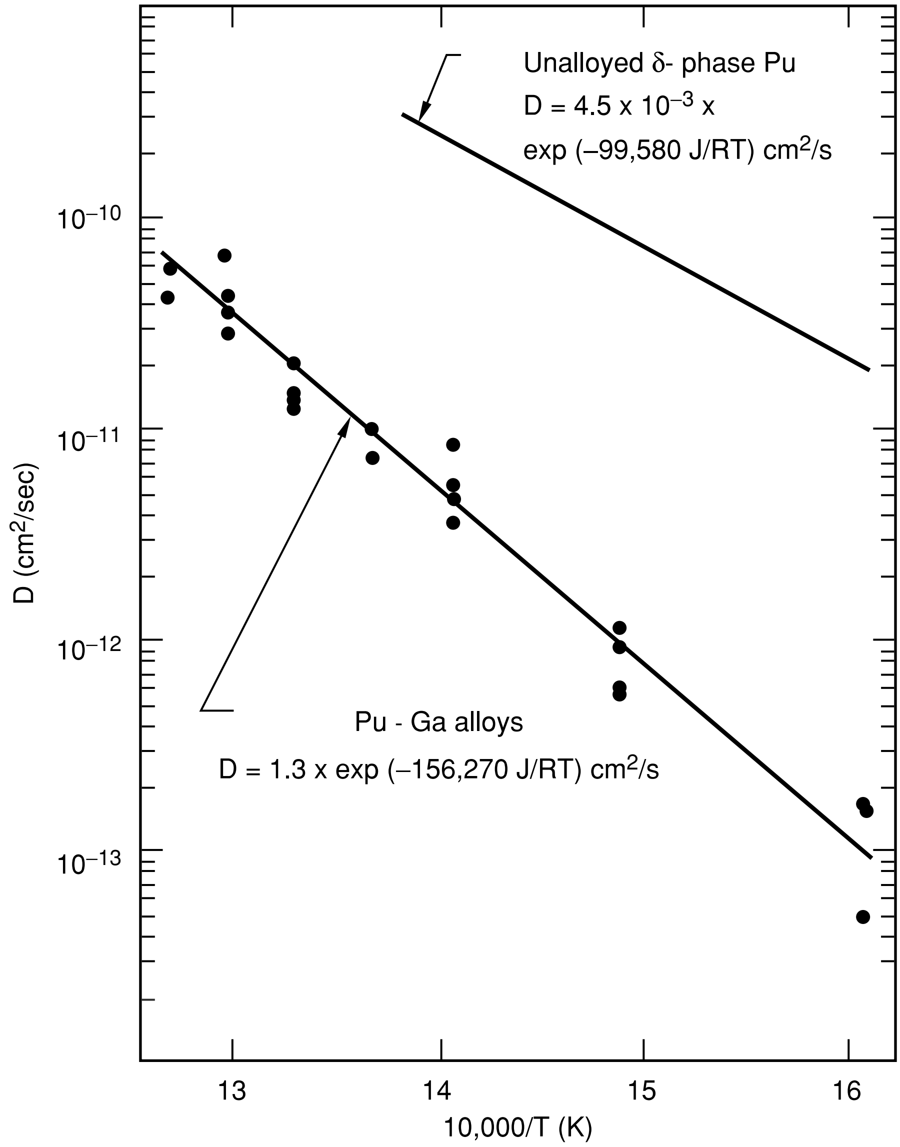

Fig. 7.57 *Diffusion coefficient, D, as a function of temperature for unalloyed plutonium and a δ-phase Pu-*3 at. *% Ga alloy plotted on a customary Arrhenius plot* (*Edwards* et al., 1968).

range of applications, it also affects all thermally activated processes, which scale with the melting point (Hecker, 2000). For example, room temperature represents a homologous temperature of 0.33, a temperature at which many defects become quite mobile. In addition, as pointed out by Nelson *et al.* (1965), the effective melting point of the α phase is significantly lower than that of the ϵ phase, increasing the homologous temperature at room temperature to 0.53 for the α phase (see Hecker *et al.* (2004) for a discussion of the metallurgical consequences).

Liquid plutonium has many peculiarities, including a density greater than the last three solid allotropes, and its heat of fusion ($\sim$2800 J mol^{-1} as shown in Table 7.16) is unusually small. The stability of liquid plutonium has been attributed to the nature of 5f electron bonding in plutonium by Hill and Kmetko (1976) and Brewer (1983). Its melting point decreases with increasing pressure up to 3 GPa (Liptai and Friddle, 1967; Morgan, 1970) consistent with the volume contraction on melting. Other materials such as gallium, bismuth, antimony, germanium, silicon, tellurium, and water show similar behavior. Merz *et al.* (1974) and Boivineau (2001) also reported an increase in sound speed in liquid plutonium with increasing temperature, with a slope of 0.08 to 0.1 m s^{-1} K^{-1}. Using a rapid heating technique, Boivineau showed that the sound speed increases to 2000 K before undergoing a rapid change in slope to a negative value from 2000 to 3600 K. Similar results have been reported for cerium (McAlister and Crozier, 1981), in which 4f electrons also play a role in bonding under pressure. Lawson *et al.* (2000) and Lawson (2001) modified Lindemann's rule for melting to include the temperature dependence of the elastic properties. Lawson *et al.* explain the anomalously low melting point of plutonium and the trend across the light actinides by temperature-induced elastic softening.

The viscosity of liquid plutonium was measured by Wittenberg and coworkers at the Mound Laboratory (Eichelsberger, 1961; Jones *et al.*, 1962; Wittenberg, 1963; Ofte and Rohr, 1965; Ofte *et al.*, 1966). Jones *et al.* (1962) reported the viscosity of liquid plutonium to follow the relation:

$$\log \eta = 672/T + 0.037 \text{ (in centipoise)} \tag{7.26}$$

which yields a viscosity of 6 cP at the melting point. This is one of the highest viscosities measured for metals and is similar to the melting point viscosity of 6.53 cP for uranium (Wittenberg, 1975) and 5.8 cP for iron (Ofte *et al.*, 1966). Ofte *et al.* pointed out that the viscosity of plutonium and its fluid flow properties place it in a class of metals whose melting points are substantially higher than that of plutonium. However, if one accounts for its high mass and low Debye temperature, then plutonium falls only somewhat above the correlation established by Iida *et al.* (1988) for most liquid metals.

Blank (1977) reviewed the measurements of viscosity on liquid Pu–Fe alloys by Ofte and coworkers (Wittenberg *et al.*, 1960; Ofte and Wittenberg, 1964; Wittenberg *et al.*, 1968). The Pu–Fe system is of practical importance because it forms the low-melting eutectic compound, Pu_6Fe. The viscosities of Pu–Fe alloys were uniformly high. That of a Pu–9.5 at.% Fe eutectic alloy (near the compound Pu_6Fe) was a remarkable 25.2 cP at 684 K (and decreased to 6.14 cP at 1081 K). Blank (1977) provides great detail in his summary of the Pu–Fe system. Wittenberg *et al.* (1960) found the activation energy for viscous flow for the eutectic alloy to be 21.9 kJ mol^{-1}. Ofte *et al.* (1966) reported viscosities for Pu–Ce and Pu–Ce–Co alloys in excess of that for plutonium. The viscosity of Pu–28.4 at.% Ce–23.7 at.% Co was reported as 23 cP at its melting point, nearly matching the viscosity of the Pu–Fe eutectic alloy. The Debye temperatures for these alloys are not available, so it is not possible to check if the viscosities fit the correlation established by Iida *et al.* (1988).

The accepted value for the surface tension of unalloyed liquid plutonium is that reported by Spriet (1963), namely 0.55 N m^{-1}. Wittenberg (1975) also reported 0.55 N m^{-1} for plutonium and 1.5 N m^{-1} for uranium. The value for plutonium fits the correlation of surface tension with melting point and molar volume proposed by Iida *et al.* (1988) for most elements in the periodic table. That of uranium appears to be anomalously high.

The optical properties and normal spectral emissivity of liquid Pu–3.4 at.% Ga at 632.8 nm were measured over the temperature range of 2016 to 2189 K using rotating analyzer ellipsometry by Sheldon *et al.* (2001). The temperature dependence of three optical properties ϵ_λ (emissivity), n_λ (index of refraction), and k_λ (extinction coefficient) were reported as:

$$\varepsilon_\lambda = 5.38 \times 10^{-5} + 0.250$$

$$n_\lambda = -1.29 \times 10^{-4}\ \mathrm{T} + 3.82$$

$$k_\lambda = -7.04 \times 10^{-4} + 5.77$$

The value for ϵ_λ is almost a third higher than that measured for uranium by Krishnan *et al.* (1993), demonstrating that the light actinides exhibit significant variations in emissivity.

Phipps *et al.* (1955) reported the vapor pressure of liquid plutonium. Subsequently, Mulford (1965), Kent and Leary (1968), and Kent (1969) added to these measurements, and reported the vapor pressure to be described by the following equation with T in K and P in atmospheres:

$$\log P = (4.924 \pm 0.120) - (17,420 \pm 184)/T \tag{7.27}$$

This relationship extrapolates to a boiling point of (3573 ± 100) K. Hence, the boiling point is quite high, in keeping with the position of plutonium in the periodic table. The combination of a high boiling point and a low melting point results in a wide range of liquid stability. Kent and Leary (1968) also reported the standard enthalpy of vaporization (H°_{298}) as (347.7 ± 2.1) kJ mol^{-1} and the standard entropy of vaporization (S°_{298}) as 123.2 J mol^{-1} K^{-1}. Oetting *et al.* (1976) reviewed the available data and recommended the best average for the enthalpy of vaporization as (345.2 ± 0.4) kJ mol^{-1}. A detailed listing of the thermodynamic properties of plutonium gas is given in Oetting *et al.* The data for the Pu_6Fe intermetallic reported by Sandenaw and Harbur (1973) were summarized by Blank (1977).

(i) New tools, new measurements of physical properties

Arko *et al.* (2006) reviewed the properties of actinides in the metallic state in Chapter 21 of this work. Their emphasis is on those properties that are unique or predominantly found in the metallic solid state. Such properties include magnetism, superconductivity, enhanced mass, spin, and charge density waves as well as quantum critical points. We refer the reader to this chapter for discussion of how plutonium fits into the trends across the actinides. They also provide detailed results of photoemission spectroscopy measurements on plutonium and its alloys.

There has been a revival of experimental work (along with a great increase in theoretical activity) in plutonium over the past 5 years. Some of the modern tools of materials science developed during the past couple of decades are being used to make measurements on plutonium and its alloys. We summarize a few salient ones in this section. One of the key barriers to many of the techniques remains the difficulty in synthesizing single crystals of the various phases of plutonium. No single crystals of α plutonium have been fabricated since the pioneering work in the 1960s by Liptai *et al.* (1967), who grew very large grains by a high-pressure technique. However, Lashley *et al.* (2000, 2001) have refined the strain-anneal technique developed in the 1960s by Moment (1968) to grow large grains of δ-phase plutonium alloys, which are suitable for many of the single-crystal measurements. These large-grained, very high-purity plutonium samples have been used for many recent physics experiments.

Zocco and Schwartz (2003) provide a history of the development of TEM techniques and their application to plutonium and its alloys. This technique is an essential tool for metallurgical studies, first demonstrated for plutonium around 1980 and revived in 2000. Zocco and Schwartz show examples of how TEM has helped answer key questions about phase transformations in plutonium alloys, as well as study the effects of self-irradiation damage. Boehlert *et al.* (2001) demonstrated how electron backscattered diffraction can be used to examine the grain structures in Pu–Ga alloys.

Ledbetter and Moment (1976) raised interest in the phonon spectrum of plutonium with their results nearly 30 years ago on the unusual elastic anisotropy of δ-phase plutonium. In a pioneering paper, Wong *et al.* (2003b) recently reported the first complete phonon dispersion curves of plutonium using inelastic X-ray scattering from a third-generation synchrotron facility (the European Synchrotron Radiation Facility in Grenoble, France). Their results are shown in Fig. 7.58 for a Pu–2 at.% Ga δ-phase alloy large-grained polycrystal grown by the techniques developed by Lashley *et al.* (2001). Wong *et al.* confirmed the large elastic anisotropy found by Ledbetter and Moment. They also found a small shear elastic modulus, C', a Kohn-like anomaly in the T_1 [011] branch, and a pronounced softening of the [111] transverse modes. They relate these findings to a strong coupling between the lattice structure and the 5f valence instabilities in plutonium. Dai *et al.* (2003) predicted the phonon dispersion

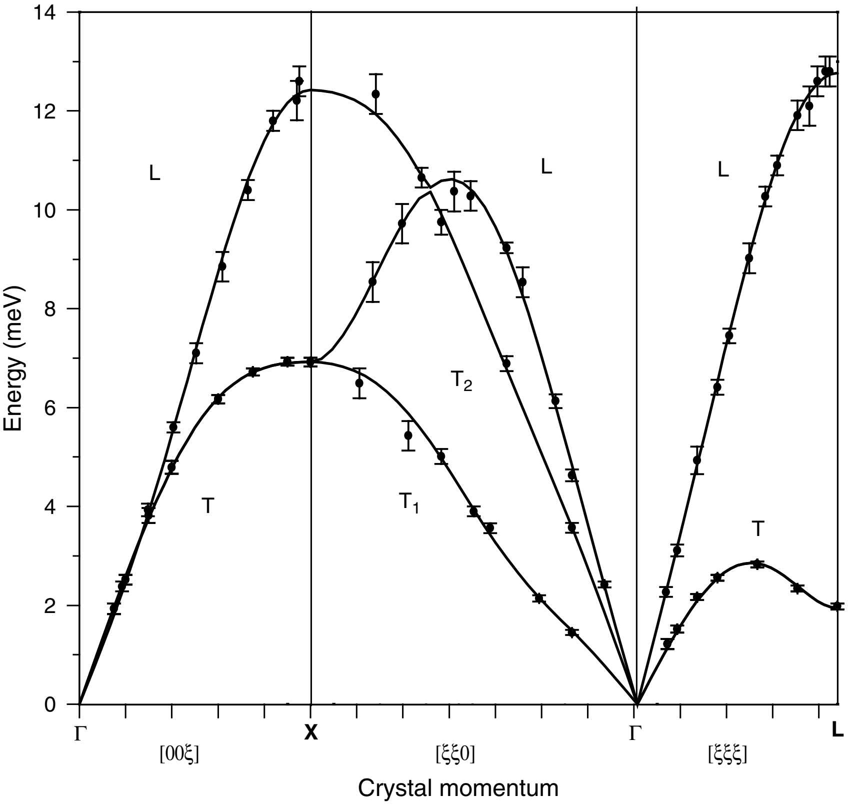

Fig. 7.58 *Phonon dispersion along high-symmetry directions in δ-phase Pu-*2 at. *% Ga alloy. The longitudinal and transverse modes are denoted L and T, respectively. The experimental data are shown with error bars. Along the* [0ξξ] *direction, there are two transverse branches,* [011]<011>(T_1) *and* [011]<100>(T_2)*. The softening of the TA* (*transverse acoustic*) [111] *branch toward the L point is apparent. The curves represent the fourth-nearest neighbor Born–von Kármán model fit* (*Wong* et al., 2003*b*).

curves using dynamical mean-field theory (DMFT), which includes electron correlations that are so important in plutonium. Wong *et al.* point out that although the qualitative agreement between theory and experiment is quite good, there are important quantitative differences. Wong *et al.* (2003a) also developed a thermal diffuse scattering technique to complement their inelastic scattering technique.

McQueeney *et al.* (2004) reported the temperature dependence of the phonon spectrum, as observed from measurements of the phonon DOS and sound velocities as shown in Fig. 7.59. The DOS was measured with inelastic neutron scattering on a polycrystalline ^{242}Pu–5 at.% Al δ-phase alloy. The ^{242}Pu isotope was used because the absorption of thermal neutrons is low compared to the

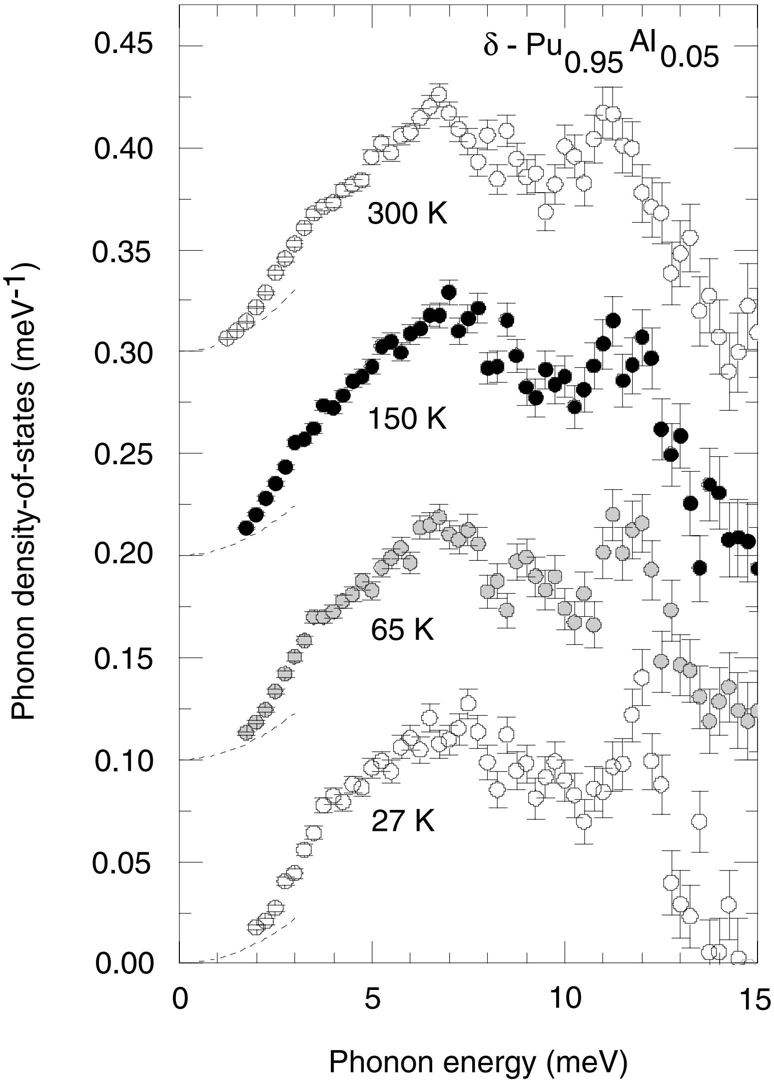

Fig. 7.59 *Phonon density of states of δ-phase Pu-*5 at. *% Al at four temperatures. The dashed line represents the quadratic part of the DOS at each temperature, as estimated by the average sound velocity obtained from resonant ultrasound measurements* (*from McQueeney* et al., 2004).

standard ^{239}Pu isotope. The phonon frequencies and sound velocities soften considerably with increasing temperature in spite of nearly zero thermal expansion over this temperature range. The frequency softening of the transverse branch along the [111] direction is anomalously large (~30%) and sensitive to alloy composition. Based on a comparison to the results of Wong *et al.*, McQueeney *et al.* concluded that the interatomic potential is extremely sensitive to alloy composition, pressure, and temperature, unlike any other metal. They suggest that this behavior may arise from an unusual temperature dependence of the electronic structure.

We referred to local structure measurements at the modern synchrotron sources earlier using EXAFS along with conventional XRD in Section 7.7.5. Allen *et al.* (2002) reported temperature-dependent EXAFS measurements over the temperature range of 20–300 K of the vibrational properties of a Pu–3.3 at. % Ga δ-phase alloy as a means of discerning differences in the vibrational character of the gallium and plutonium sites. They obtained pair-specific, correlated Debye temperatures, θ_{cD}, of (110.7 ± 1.7) K for the Pu–Pu pairs and (202.6 ± 3.7) K for the Pu–Ga pairs. Allen *et al.* concluded that these results indicate that Ga–Pu bonds are significantly stronger than the Pu–Pu bonds. Lynn *et al.* (1998) previously reported a Pu-specific value of $\theta_{\mathrm{D}} = 127$ K and a Ga-specific $\theta_{\mathrm{D}} = 255$ K using neutron-resonance Doppler spectroscopy on a Pu–3.6 at.% Ga alloy. Nelson *et al.* (2003a,b) reported EXAFS measurements on the vibrational properties of both the δ phase and the α′ phase of a Pu–1.9 at. % Ga alloy (in the δ-phase and mixed, α′ + δ, phase conditions). They found a bond-length contraction for the Pu–Ga bond of 0.11 Å in the δ phase, but only 0.03 Å in the α′ phase. They reported correlated Debye temperatures of θ_{cD} (δ) = (120.4 ± 2.6) K and θ_{cD} (α′) = 159.1 ± 12.5 K.

Moore *et al.* (2003) used high-energy electron energy loss spectroscopy (HE-EELS) in a TEM and synchrotron-radiation-based X-ray absorption spectroscopy to determine phase-specific electronic structure information on plutonium. The sample was a dilute Pu–Ga alloy treated to produce a mixture of the α + δ phases. The TEM examination allowed individual grains of each phase to be examined. Moore *et al.* conclude that Russell–Saunders coupling fails for the 5f states of plutonium, and that only the use of JJ or intermediate coupling is appropriate. In addition, they conclude that their results confirm calculations that there is considerable spin–orbit splitting of the occupied and unoccupied 5f states of plutonium, indicating that spin–orbit splitting cannot be neglected in the Hamiltonian for the 5f states of plutonium.

Superconductivity has recently been discovered above 18 K in a plutonium-based nearly magnetic compound, $\mathrm{PuCoGa_5}$ by Sarrao *et al.* (2002, 2003a,b). At the same temperature, this compound exhibits a step-like transition in heat capacity, from which they inferred the electronic specific heat, γ, to be 77 mJ $\mathrm{mol^{-1}\ K^{-2}}$, which points to strong electron–electron correlations. In addition, field-dependent resistivity data gave an upper critical field of 74 T, a surprisingly large value. Other actinide-based superconductors have transition temperatures below a few K. The cerium-based isostructural compounds $\mathrm{CeCoIn_5}$ and $\mathrm{CeIrIn_5}$ are also superconducting but only in the 1-K range, and for $\mathrm{CeRhIn_5}$ only under pressure. The T_{c} of $\mathrm{PuCoGa_5}$ can be further enhanced to about 22 K by applying pressure (Griveau *et al.*, 2004). $\mathrm{PuRhGa_5}$ is superconducting, as well, with $T_c = 8.6$ K (Bauer *et al.*, 2004). The properties of these plutonium-based superconductors are indicative of an unconventional, most likely magnetically mediated, superconductivity (Sarrao *et al.*, 2003b).

7.7.7 Mechanical properties of plutonium metal and alloys

Mechanical properties of metals and alloys depend to first order on their crystal structure and melting point, which indirectly affects all thermally activated processes. The multiple allotropes of plutonium lead to a rich spectrum of mechanical properties as reviewed recently by Hecker and Stevens (2000). The low melting point allows for relatively easy mobility of defects near and above room temperature. Consequently, the mechanical properties of plutonium are especially sensitive to temperature and strain rate. They are also sensitive to chemistry (both intentional alloying and unintentional impurities) and processing, which, in turn, control the microstructure (phases present, their structure and distribution, and the nature and number of defects). Therefore, it is necessary to know the chemistry and the processing history to compare the properties of plutonium.

Gardner (1980) presented the most comprehensive review of the mechanical properties of plutonium and its alloys. His results for the yield and ultimate tensile strengths of unalloyed plutonium (for a range of purities and processing histories) are summarized in Fig. 7.60. These data demonstrate the dramatic temperature and crystal-structure dependence of the strength properties of plutonium. As reported by Gardner, the monoclinic crystal structure of plutonium (the only element in the periodic table with this low-symmetry structure) precludes the necessary conditions for plastic slip (by dislocation glide) in polycrystalline material for extended plastic flow. Consequently, the α phase of plutonium is brittle at and near room temperature. As shown in Fig. 7.60, it is quite strong. However, the tendency for α plutonium to microcrack during typical processing causes significant scatter in the properties. Moreover, certain impurities lead to the retention of second phases (typically the δ or β phases) or the presence of inclusions (such as oxides, nitrides, carbides, or the eutectic intermetallic, Pu_6Fe), which can have a significant effect on the mechanical properties.

Another important variable in determining the mechanical behavior of α plutonium is the grain size. Merz (1970, 1971) demonstrated that in α plutonium with decreasing grain size the mechanism for plastic flow changes. He fabricated very fine-grained α plutonium (1–3 μm) by extrusion and concurrent recrystallization of electrorefined, high-purity plutonium. He demonstrated that the strength decreased substantially with grain size and the ductility increased. At room temperature, he found surprising plastic elongation of 8% at low strain rates. On the high-temperature end of α-phase stability, he found extended plasticity, that is, elongations in excess of 100% (Merz and Allen, 1973;

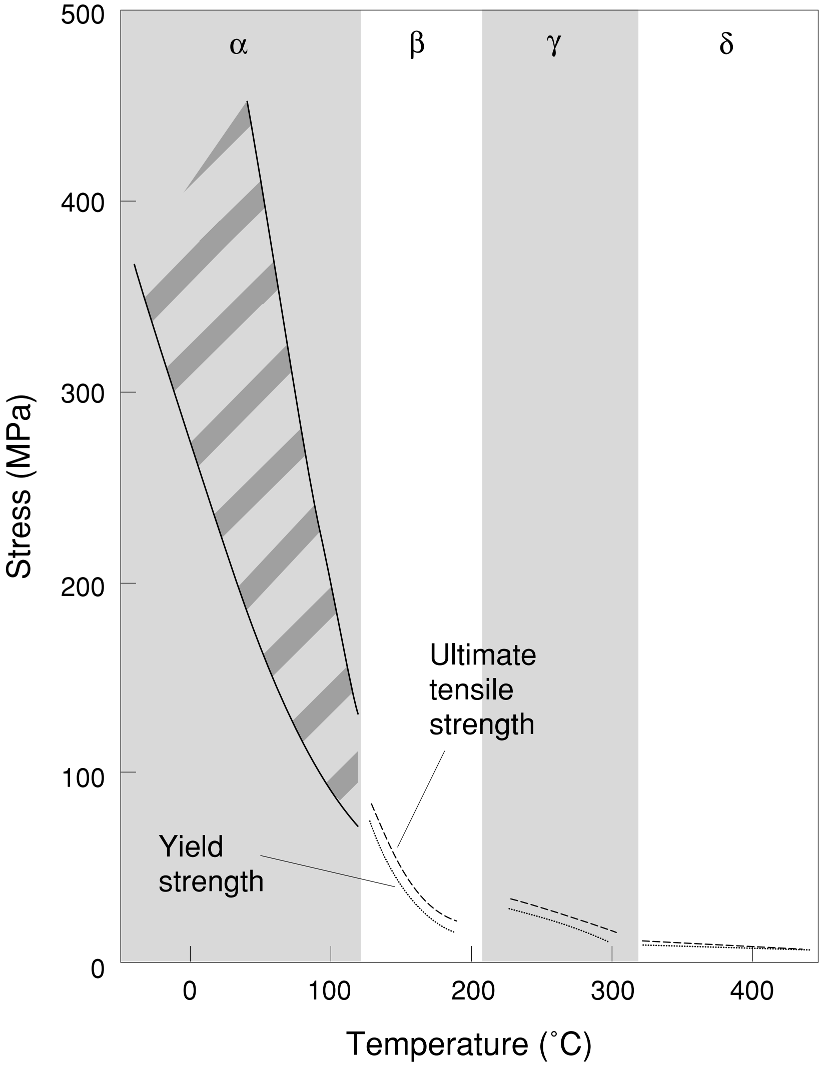

Fig. 7.60 *Strength as a function of temperature for unalloyed plutonium tested in uniaxial tension at nominal strain rates of* 10^{-3} s^{-1} (*after Gardner,* 1980).

Merz, 1974). In the β phase, he found the fine-grained plutonium to exhibit classical superplasticity with several 100% elongation. He explained that the deformation mechanism changed from dislocation glide to grain boundary sliding because of the small grain size and the high homologous temperature of 0.53 at room temperature for the α phase of plutonium. Fig. 7.61 shows the change in Vickers Microhardness with temperature for several grain sizes in α plutonium (Merz and Nelson, 1970). Hecker and Morgan (1976) found that the strength of coarse-grained α plutonium increased moderately at intermediate strain rates. Hecker and Stevens (2000) pointed out several other interesting features about the mechanical behavior of α plutonium in their review.

As shown in Fig. 7.60, the other phases of unalloyed plutonium are relatively weak compared to the α phase. Gardner shows no data for the ε phase. Cornet and Bouchet (1968) showed that the elastic moduli of the ε phase is approximately two-thirds that of the δ phase, and we also expect its strength properties to be lower. The other phases of plutonium are also considerably more ductile than the α phase. As pointed out earlier, a few atom percent of alloying

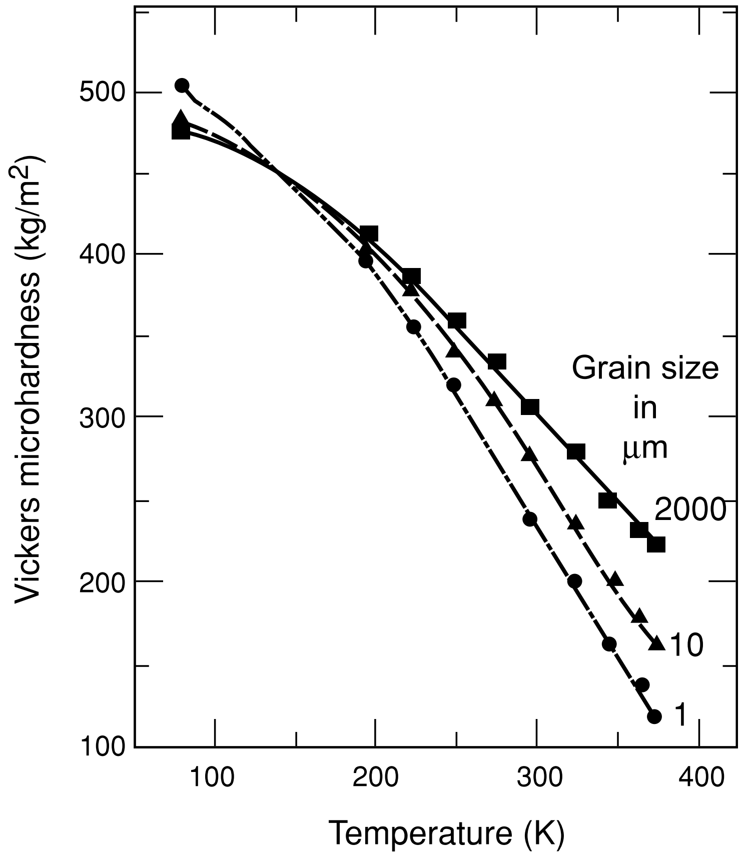

Fig. 7.61 *Vickers microhardness as a function of temperature for unalloyed α plutonium at various grain sizes (after Merz and Nelson,* 1970).

additions of elements such as gallium or aluminum retain the fcc δ phase to room temperature. As expected the δ phase alloys are considerably more ductile than the monoclinic α phase. A comparison of room temperature mechanical behavior is shown in Fig. 7.62 (Hecker and Stevens, 2000). The α phase is shown to be strong and brittle (like cast iron), whereas the δ-phase Pu–Ga alloy is weak and ductile (like commercially pure aluminum). Processing of the δ-phase alloys strongly influences the mechanical properties. Particularly important are gallium segregation, which can be minimized by elevated-temperature annealing treatments and thermo-mechanical treatments (see Fig. 7.33). Robbins (2004) recently reported an extensive compilation of the mechanical properties of Pu–3.4 at.% Ga δ-phase alloys. The compression behavior of a typical, well-homogenized alloy is shown in Fig. 7.63 (from the work of Barmore and Uribe (1970)). We should note that the mechanical properties of δ-phase Pu–Al alloys are similar to Pu–Ga alloys with similar atomic concentrations of the alloying element.

Detailed mechanical properties of plutonium and various alloys, including strength, hardness, ductility, creep, impact strength, and fatigue strength are presented by Gardner (1980), by Lesser and Peterson (1976) for unalloyed

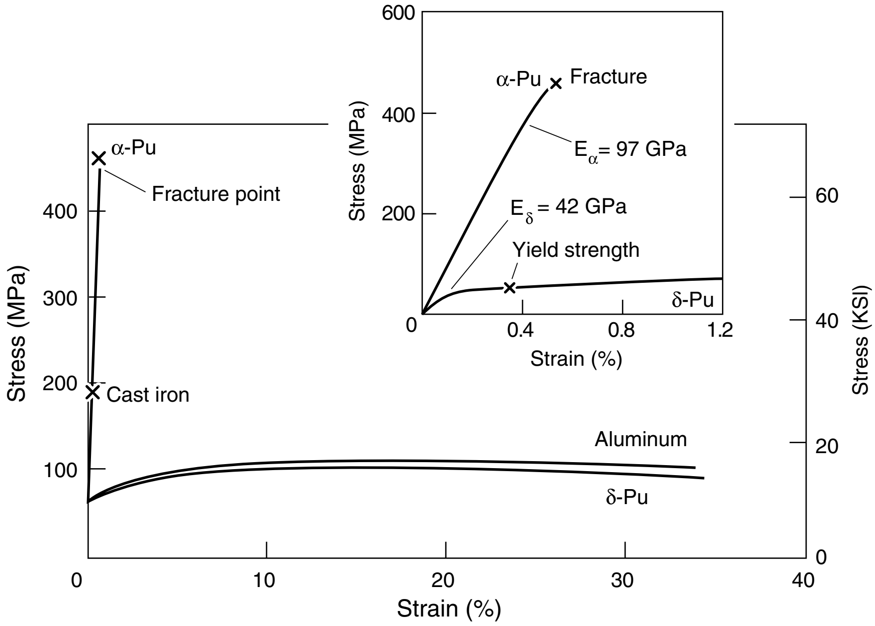

Fig. 7.62 *Typical uniaxial tensile stress–strain curves for unalloyed α plutonium compared to a δ-phase Pu–Ga alloy at a nominal strain rate of* 10^{-3} s^{-1}. *The insert shows the initial stress–strain curve at higher resolution* (*after Hecker and Stevens,* 2000).

plutonium (on pp. 29–33 of their review), and by Blank (1977) for Pu–Al alloys (pp. 180–183) and for Pu–Ga alloys (pp. 221–232). Blank (1976, 1977) also provides mechanical properties for additional alloy systems, with a particularly extensive discussion of the Pu–Fe system (Blank, 1976). Care must be taken during low-temperature experiments on δ-phase alloys to avoid transformation of the retained δ phase to the α′ phase. Since the α′ phase is so much harder than the δ phase, even small amounts of α′ result in significant strengthening.

There are few theoretical treatments of mechanical behavior of plutonium in the literature. The principal problem stems from the fact that the mechanical properties are controlled by microstructure and defects, which are still beyond the reach of *ab initio* calculations for all practical metals. Stout *et al.* (2002) developed a physically based constitutive model to predict the mechanical behavior of fcc δ-phase plutonium alloys. The input to the model was based on previous work with other fcc metals and the published test results on Pu–Ga alloys referenced above. The model is able to predict the temperature and strain-rate effects on the yield and ultimate strengths of Pu–Ga alloys. It also allowed the authors to isolate the effects of microstructural variables such as grain size, alloy content, and impurity content. The effect of gallium solutes has the largest strengthening effect. The yield strength increases by 50% with an increase in gallium from 1 to 6 atomic percent. The grain size effect follows the classical Hall–Petch relationship:

$$\sigma_y = \sigma_0 + \kappa/\sqrt{d} \tag{7.28}$$

where σ_y is the yield strength for a grain diameter d in μm, and σ_0 and κ are measured constants. Hence, decreasing grain size leads to increased strength in the deformation regime controlled by dislocation glide. (We note that in the deformation regime dominated by grain boundary sliding, the relationship is inverted – small grain size leads to lower strength.) The parameters for Pu–Ga alloys are given by Stout *et al.* (2002). The model allowed them to demonstrate that the typical impurities (such as C, O, N, and Fe form hard inclusions of μm to tens of μm in diameter) in these alloys have little effect on strength values at ambient temperature. However, the fracture behavior will be affected negatively by higher impurity contents. In addition, Beitscher (1970) showed that iron impurities at the level >300 ppm lead to dramatic high-temperature embrittlement (at 683 K and low strain rates) because the Pu_6Fe intermetallic inclusions melt and lead to brittle behavior known as 'hot shortness.'

7.7.8 Oxidation and corrosion in plutonium metal and alloys

Degradation of plutonium surfaces under various atmospheric conditions is of concern during handling and for all considerations that require storage of plutonium, its alloys, or its compounds. Although plutonium is a reactive metal as suggested by a standard reduction potential of –2.02 V for the Pu^{3+}/Pu^0 couple (see Fig. 7.116a), its oxidation rate in very dry air (<0.5 ppm H_2O) is a minuscule 20 pm h^{-1} (Haschke *et al.*, 1996). Clean plutonium surfaces have a silvery, metallic sheen, similar to clean iron or nickel. Plutonium loses its metallic sheen quite rapidly in most atmospheres. It takes on a darker appearance and exhibits interference colors before it begins to develop a loose, olive-green powder of PuO_2 'rust' (see Section 7.8.5.a). Although this process occurs quite slowly in most of the protective atmospheres in which plutonium is handled, experience over the years has yielded many surprises, including pyrophoric behavior and anomalous corrosion rates catalyzed under complex atmospheric conditions of hydrogen or moist air that can increase surface corrosion rates by a staggering 13 orders of magnitude. The enhanced oxidation rates in the presence of moisture were already discovered at Los Alamos during the Manhattan Project by Covert and Kolodney (1945). Uncontrolled surface reactions are one of the greatest risks during storage or use of plutonium metal. Not only do these reactions change the geometry of the material, they typically result in finely powdered forms that are more readily dispersed, and hence, increase the health risk of inadvertent release and uptake of plutonium, a safety hazard of paramount importance for long-term plutonium storage (Haschke *et al.*, 1998).

Waber (1980) summarized the available knowledge on corrosion and oxidation of plutonium up to 1964. Subsequent results to 1976 were summarized by Lesser and Peterson (1976). More recently, Haschke *et al.* (2000a) presented a current understanding of corrosion and oxidation, and Hecker and Martz (2001) summarized current understanding and presented practical examples of plutonium corrosion problems. Much of the discussion here is based on the report of Hecker and Martz. We refer the reader to Lesser and Peterson (1976) for a description of the reaction of plutonium with other gases such as nitrogen and ammonia at higher temperatures as well as surface reactions of plutonium with acids and other solvents.

(a) Oxidation in air

Corrosion rates depend greatly on plutonium surface chemistry. Hence, it is crucial to understand the specific surface chemistry for different plutonium substrates and for different atmospheric conditions. In dry air, the reactive plutonium metal surface is passivated by a layer of protective $PuO_{2\pm x}$ that forms rapidly over the entire surface. In the Pu–O system, Pu(IV) is a stable oxidation state and forms a classic fluorite-type crystal structure, with four plutonium cations per unit cell arranged in an fcc lattice, and eight oxygen anions at the tetrahedral interstices in a simple cubic packing (as discussed in Section 7.8.5.a, and shown in Fig. 7.90).

The oxidation rate is controlled by the diffusion of oxygen through the oxide surface to the oxide–metal interface, yielding classic parabolic growth rates. Significant stresses build up at the interface because the density of the oxide is 11.46 g cm^{-3} compared to pure α plutonium at 19.86 g cm^{-3}. The oxide layer reaches a steady-state thickness of 4 to 5 μm because at this thickness the oxide begins to spall, leading to a balance between spalling of the oxide and re-oxidation of the surface (Martz *et al.*, 1994). A constant isothermal oxidation rate is maintained by diffusion of oxygen through an oxide layer of constant average thickness. Fig. 7.64 also shows that corrosion rates depend strongly on temperature and atmospheric conditions. The details of this behavior are presented by Haschke *et al.* (1998) and discussed by Hecker and Martz (2001). Activation energies of oxidation in unalloyed plutonium are reported by Blank (1977), based on the work of Thompson (1965), to be 96.2 kJ mol^{-1} for the α phase, 50.2 kJ mol^{-1} for the β phase, and 58.6 kJ mol^{-1} for the γ phase, each in their temperature range of phase stability. However, Blank points out that significantly different results have been cited by other authors because of the substantial influence of microcracks, impurities, and crystallographic textures. The reader is referred to Haschke *et al.* (1998) for a more detailed discussion of the thermodynamics and kinetics of the oxidation process.

(b) Moisture-enhanced oxidation

Corrosion of plutonium metal in moist air occurs at a rate 200 times greater than in dry air at room temperature and five orders of magnitude greater at 100°C. The mechanisms of water-catalyzed corrosion of plutonium have only recently been elucidated (Haschke *et al.*, 1996). It had been generally accepted that the greatest oxygen concentration possible in plutonium oxide was in the

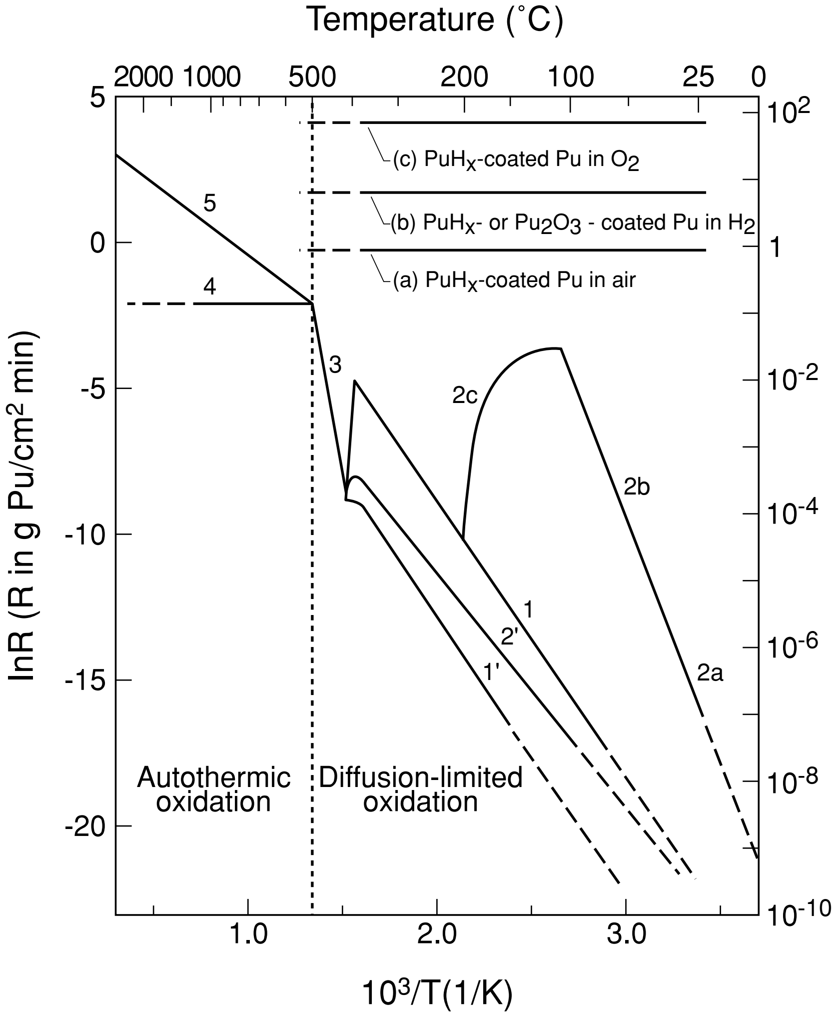

Fig. 7.64 *Oxidation rates of plutonium vs temperature. Curve* 1 *shows the oxidation rate for pure plutonium exposed to dry air or oxygen at an* O_2 *pressure of* 21.3 kPa. *Curve* 2*a presents the oxidation rate when the same, dry Pu samples are exposed to water vapor at the same pressure* (21.3 kPa). *Note the increase of four orders of magnitude in oxidation rate. Curves* 2*b and* 2*c extend the water-exposed oxidation rate to the temperature ranges of* 61–110°C *and* 110–200°C, *respectively. The drop in oxidation rate at higher temperatures is not fully understood, but may be related to the lack of spallation of product oxide at higher temperatures. Curves* 1′ *and* 2′ *present oxidation data for Ga-stabilized* δ *Pu in dry and moist air, respectively. Distinctions in oxidation rates for various alloys and conditions disappear at high temperatures as shown by curve* 3. *Curve* 4 *shows the constant oxidation rate observed under static conditions, while curve* 5 *shows recent data extrapolated from ignited Pu droplets oxidizing during free-fall in air. The reactions of hydride-coated Pu are shown in curves a–c. Curve a shows the constant reaction rate for hydride-coated Pu exposed to dry air. This represents an increase in reaction rate of over* 10^9 *compared to pure Pu. Curve c shows the same material exposed to pure oxygen. This reaction is* 10^{13} *times faster than pure Pu exposed to* O_2. *Finally, curve b shows the constant reaction rate of either hydride- or cubic sesquioxide-coated Pu to hydrogen* (*at* 101 kPa) (*Martz and Haschke,* 1998*; Haschke* et al., 2000*a*).

dioxide, namely $PuO_{2.0}$. However, Stakebake *et al.* (1993) and Haschke *et al.* (2000a, 2001) demonstrated that hyperstoichiometric plutonium oxide, PuO_{2+x}, forms in the presence of either gaseous or liquid water. The largest value they measured for x was 0.26. Rapid oxidation by adsorbed water produces hydrogen at the gas–solid interface and forms a higher oxide as Pu(IV) cations in PuO_2 are replaced by Pu(V) and an equal number of O^{2-} or OH^- ions in interstitial defect sites (see Section 7.8.5). In moist air, product hydrogen combines with disassociatively adsorbed oxygen to reform water on the surface. A water-catalyzed cycle is propagated as Pu and O_2 are transformed into oxide at the rapid rate characteristic of the metal–water reaction. This change in the composition of the oxide is also accompanied by a dull yellow to a khaki-to-green color change.

(c) Oxidation behavior of plutonium alloys

The overall rate of oxidation is less for alloyed plutonium in the fcc δ phase than it is for unalloyed plutonium (shown in Fig. 7.64) because the lowered stresses upon oxide formation (the δ-phase density is 15.8 g cm^{-3} compared to 19.86 g cm^{-3} for the α phase). Haschke (1999) has also speculated that gallium is not incorporated in the PuO_2 lattice and resides in octahedral sites of the fluorite structure. Consequently, since oxygen diffusion occurs via these sites, he suggested transport of oxygen through the oxide layer may be inhibited. Blank (1977) summarized the work of Raynor and Sakman (1965) and Waber (1980) on oxidation of plutonium δ-phase alloys. Pu–Ga alloys were found to oxidize at a lower rate than unalloyed plutonium at all temperatures in moist air. The oxidation rates were found to be greater in moist argon. However, the protection afforded by alloying was less for the case of moist argon than for moist air. Blank (1977) also summarized oxidation results for Pu–Al alloys. A partial summary, presented in Table 7.24, shows that the addition of aluminum lowers the oxidation rate, but that the behavior depends strongly on temperature and relative humidity. As examples of actual weight gain through oxidation, Blank cites the results of Waber *et al.* (1961): 0.1 mg cm^{-2} for Pu–9 to 12 at.% Al alloys after 500 h at 75°C and 50% relative humidity and 0.5 mg cm^{-2} for Pu–8 at.% Al after 8700 h at 35°C and 20% relative humidity. Blank (1977) also provided a summary of the oxidation behavior of Pu–Fe and other alloys.

(d) Pyrophoricity of plutonium metal in air

Fig. 7.64 also shows that at elevated temperatures, plutonium exhibits an autothermic reaction, igniting spontaneously in air when the temperature reaches 500°C. Studies of pyrophoricity of plutonium by Martz *et al.* (1994) helped to elucidate the role of another oxide of plutonium, namely the cubic (bcc) sesquioxide, Pu_2O_3. The revised view of the plutonium–oxygen interface is shown in Fig. 7.65. Although the dioxide is the one observed when plutonium

Table 7.24 *The relative merit given by the merit ratio* (*MR*) *as defined by weight increase of unalloyed α-phase plutonium divided by the weight increase of a δ-phase Pu–Al alloy after the oxidation of the samples by water vapor as compiled by Blank* (1977).

metal is exposed to oxygen or air, there is always a layer of the cubic sesquioxide present at the metal-oxide interface. However, at room temperature, its thickness is small compared to that of the dioxide. The cubic sesquioxide acts as a layer that separates the oxide-rich surface from the plutonium-rich substrate, being simultaneously consumed and formed by competing reactions. The thickness of these various oxides depends upon a variety of factors including temperature and oxygen concentration. At temperatures exceeding 150°C and in oxygen-poor environments, the cubic sesquioxide becomes the predominant phase, appearing as a surface product under oxygen-free environments.

Martz *et al.* (1994) explained the apparent paradox that plutonium metal with low specific surface areas ignites at temperatures above 500°C, whereas metal with large specific surface areas (turnings, chips, and powder) spontaneously ignites in air at temperatures between 150 and 200°C. In such cases, Martz *et al.* concluded that heating metal to 150–200°C in air transforms a large fraction of the surface oxide to cubic sesquioxide. Rapid oxidation of the sesquioxide back to dioxide produces a thermal spike sufficient to heat high-surface-area chips and turnings to the autothermic reaction temperature of 500°C.

(e) Hydrogen- and hydride-catalyzed corrosion

Plutonium reacts readily with hydrogen at rates unprecedented for other metals. It forms an fcc solid solution of PuH_x hydrides with a fluorite structure similar to plutonium oxides (Haschke, 1991; Bartscher, 1996) as discussed in Section 7.8.1 and shown in Fig. 7.72. The hydrogen mole ratio, x, varies from 1.9 to 3.0. As the hydrogen content increases, the hydride exhibits a transition from metallic material near $x = 2$ to a semiconductor near $x = 3$. The electronic structure of the hydride is complex, with electrons apparently being removed from the conduction band and bound as H^- on octahedral sites as the hydrogen concentration is increased in the hydride.

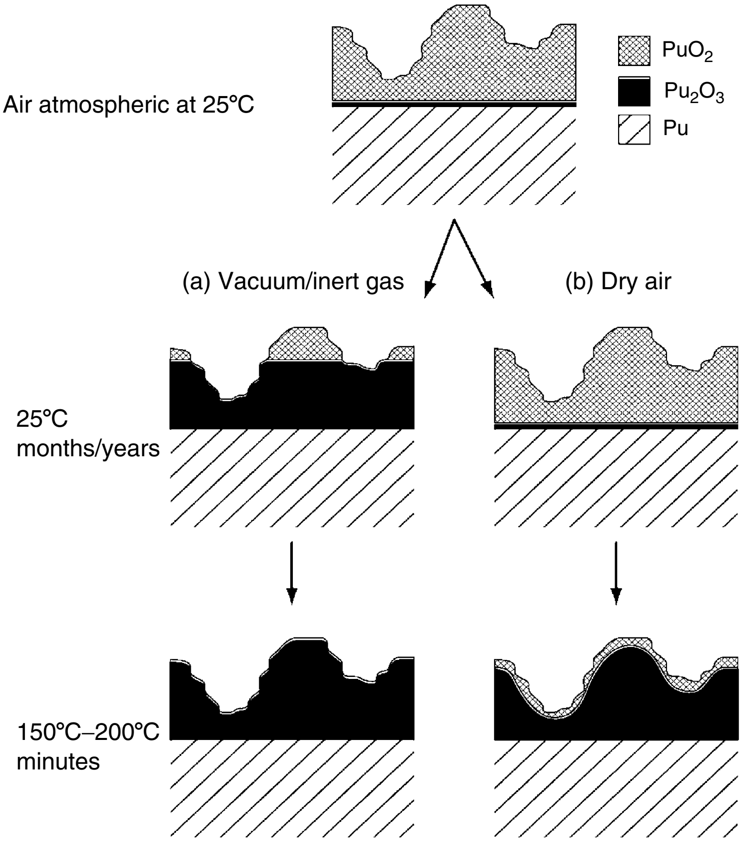

Fig. 7.65 *Evolution of the oxide layer on metallic plutonium. These simplified sketches present the structure of the oxide on Pu. In air, a constant thickness of* PuO_2 *is present on a thin layer of cubic* Pu_2O_3*. If this surface is exposed to inert conditions (vacuum or inert gas), the* PuO_2 *autoreduces to a thicker layer of* Pu_2O_3*. At elevated temperatures, the rate of the autoreduction reaction increases, increasing the thickness of the internal* Pu_2O_3 *layer under all conditions. Oxidation of this layer and its subsequent heat evolution is the attributed cause for the pyrophoric behavior of thin films and small particles (Martz* et al., 1994). *In addition, the growth of* Pu_2O_3 *under inert conditions at elevated temperatures will activate the surface to the hydride reaction, a fact exploited in the hydride–dehydride recovery process for metallic plutonium.*

Reactions of hydrogen on metallic plutonium are complicated by the ever-present layer of plutonium dioxide. Hydrogen gains access to the metal surface only after the dioxide layer is penetrated at cracks or spallation sites, making the nucleation of the hydride reaction heterogeneous. The hydriding rate increases exponentially as nucleation sites grow. Once the entire metal surface is covered with hydride, the reaction occurs very rapidly at rates of 20 cm h^{-1} linear penetration for H_2 at 1 bar compared to the rate of the oxidation reaction of 20 pm h^{-1} in dry air (10^{11} times faster). Haschke (1991) has suggested that this catastrophic enhancement occurs by one of two mechanisms. First, if PuH_x forms, it catalyzes the dissociation of adsorbed H_2 and promotes transport of atomic hydrogen to the hydride–metal interface. Or alternatively, if cubic Pu_2O_3 is exposed to H_2, then the hydride reaction begins instantaneously because Pu_2O_3 also catalyzes the dissociation of H_2 and becomes the medium for hydrogen transport. In either case, rapid dissociation of adsorbed H_2 results in a dramatic enhancement of the reaction rate. Further, the transport of anions in the fluorite structures of PuH_x or cubic Pu_2O_3 is potentially very rapid because in these anion-deficient fluorite structures both tetrahedral and octahedral sites may be vacant and able to participate in the transport of anions such as hydrogen and oxygen (see Sections 7.8.1 and 7.8.5). Another factor is the high self-diffusivity of oxygen in nonstoichiometric PuO_{2-x}, which increases dramatically from PuO_2 to Pu_2O_3.

If a hydride-coated plutonium surface is exposed to oxygen, it has been proposed that PuH_x will promote a dramatic catalytic enhancement of the corrosion rate (Haschke and Martz, 1998a). In this proposed mechanism, oxygen reacts with the pyrophoric plutonium hydride to produce heat and an oxide layer. The temperature is raised sufficiently that the cubic sesquioxide is preferentially formed. The hydrogen produced at the oxide–hydride interface moves through the PuH_x layer increasing the stoichiometry of the hydride. Excess hydrogen is continuously produced at the oxide–hydride interface and consumed at the hydride–metal interface. Thus, hydrogen is involved in a classic catalytic cycle to enhance the oxidation rate. This hydride-catalyzed reaction continues until all the metal is consumed. The rate for reaction of hydride-coated metal with pure oxygen (Fig. 7.64) is 10^{13} times greater than oxidation rates in dry air. Hydride-coated plutonium also reacts rapidly in air. However, the rate is 100 times slower than that in oxygen, apparently due to additional steps involving reaction or transport of nitrogen in air (Haschke, 1991). These fast reactions generate large amounts of heat (approximately 836.8 kJ mol^{-1} of plutonium), which can produce thermal hazards as well. Of additional concern is the possibility of plutonium nitride formation when the temperature exceeds 200–250°C and hydride is exposed to the nitrogen in air. This reaction results in a consumption of all of the major gases in air, preventing the formation of an inert nitrogen 'blanket' and allowing the reaction to proceed to completion within many storage environments. Hecker and Martz (2001) describe some of the practical consequences of enhanced corrosion problems in the storage of plutonium.

7.7.9 Aging and self-irradiation damage in plutonium

The aging of plutonium and its alloys has received increased attention during the past decade because of interest in extending the lifetimes of plutonium components and in the long-term storage of excess weapons-grade plutonium.

Several reviews of the salient aging issues have been reported by Hecker and Martz (2000, 2001), Wolfer (2000), Martz and Schwartz (2003), and Wirth *et al.* (2001). The complexities of plutonium materials are compounded by changes that occur with age. Phase stability is of concern because the various allotropic phases of plutonium are very close in energy and, hence, sensitive to any changes, including kinetic changes, that can occur with time at temperatures close to ambient. The differences in U.S. and Russian phase diagrams for Pu–Ga (Fig. 7.29) demonstrate that we lack definitive information on some basic characteristics of plutonium alloys such as thermodynamic steady-state phase stability. In addition, the very reactive nature of plutonium just described makes it especially susceptible to surface-induced modifications resulting from different atmospheric environments. If that were not sufficient, the most perplexing change is caused by the radioactive decay of the plutonium nucleus in its various isotopic forms. Moreover, in most practical applications the effects of these three types of aging-induced changes occur simultaneously and in synergy causing significant changes in plutonium and its alloys over time. The phase stability and surface behavior were described in some detail above. We will provide additional details of the salient consequences of self-irradiation damage and transmutation resulting from radioactive decay in plutonium and its alloys.

The two primary consequences of plutonium radioactive decay are the displacement damage in the lattice induced by the self-irradiation, and the transmutation of plutonium into its decay products. Displacement damage can cause changes in lattice parameters, the accumulation of defects and, potentially, void swelling. Transmutation may upset the delicate balance of phase stability and lead to phase changes. One of the decay products, helium, is of particular concern because it can form helium bubbles if self-irradiation occurs at temperatures at which helium is mobile. Schwartz *et al.* (2005) provided an excellent overview of the effects of self-irradiation in plutonium. They identified three self-irradiation-related effects that could cause dimensional changes: lattice damage resulting in an initial transient, helium accumulation, and void swelling.

The unstable plutonium nucleus decays principally by α-particle decay. Two primary energetic nuclear particles are produced by α decay – an α particle and a recoil nucleus. These primary particles are created in much less than a femtosecond (10^{-15} s). The range of the 5 MeV α particle is approximately 10 μm within the crystal lattice. The α particle captures two electrons from the plutonium metal and comes to rest in the lattice as a helium atom. The light α particle loses nearly 99.9% of its energy to electrons, heating the plutonium lattice. Some atomic displacements occur near the end of range, producing $\sim$265 Frenkel pairs (vacancies and self-interstitial atoms). Wolfer (2000) calculated the helium generation to be $\sim$41 atomic ppm per year.

The 86 keV ^{235}U recoil nucleus has a range of $\sim$12 nm and creates roughly 2300 Frenkel pairs. Calculations by Wolfer (2000) showed that there are 3×10^{9} α events g^{-1} s^{-1} for a typical ^{239}Pu isotopic mix, resulting in a lattice displacement rate of roughly 0.1 displacements per atom (dpa) per year. Wolfer (2000) and Wirth *et al.* (2001) used molecular-dynamics simulations showing that in the first 200 ns, 90% of the Frenkel pairs return to their original lattice sites, whereas the other 10% remain as free interstitials and vacancies or interstitial/vacancy clusters. In reactor applications, it was shown that these types of microstructural changes ultimately result in property changes that include void swelling, mechanical hardening, and embrittlement. Wirth *et al.* pointed out that although the damage produced by the α particle and the uranium recoil atom are different, it is the eventual interaction and evolution of these spatially uncorrelated primary defects that may, over time, drive materials evolution and the aging process, thus producing microstructural changes over time scales as long as many decades.

(a) Self-irradiation lattice damage

Studies of self-irradiation lattice damage in plutonium at low temperatures (at which little or no annealing of nonequilibrium defect structures is expected) were reported as early as 1962 by American researchers (Olsen and Elliott, 1962) and British researchers (Lee *et al.*, 1962; Wigley, 1964, 1965), and in 1965 by French researchers (Lallement and Solente, 1967). However, more than 40 years later, we still understand little about the mechanisms of defect migration and agglomeration in plutonium. Few measurements and direct observations of the defect structures in plutonium have been made compared to the vast body of literature that exists for irradiation-induced defect structures in other metals and alloys; see Ehrhart *et al.* (1991) for an excellent review. The early work showed that plutonium undergoes substantial lattice damage as determined by increases in electrical resistivity and by length changes. As shown in Fig. 7.66, the α phase in unalloyed plutonium expands during self-irradiation at 4.2 K. Retained β-phase and retained δ-phase plutonium alloys contract. As discussed below, self-irradiation damage of δ-phase plutonium at room temperature results in a volume expansion. All three phases exhibit increases in electrical resistivity with self-irradiation at this temperature; see Hecker and Martz (2001) for more detailed discussions.

Marples and Hall found that if low-temperature irradiation was allowed to proceed sufficiently long, lattice expansion in the α phase saturated at approximately 10.5 vol %. In the δ-phase alloy, lattice contraction saturated at –15 vol %. Their results on all three phases examined are summarized in Table 7.25. Interestingly, all three phases appear to converge to the same density, 18.4 g cm^{-3}. These results may indicate that all three phases are becoming increasingly disordered, approaching an amorphous state. It would not be surprising to create local amorphous regions as a result of the collision cascades following α-decay events. At sufficiently low temperatures, in the absence of significant defect rearrangement, these regions could eventually consume the entire sample. However, the XRD work done at low temperatures showed that

β	18.2	18.4
δ	15.6	17.4 18.3 after correction for presence of 6 at.% Al

the initial crystal structures were retained, although significant line broadening was observed.

At ambient temperature, damage from self-irradiation of plutonium is partially annealed out by thermally activated recovery. Lattice damage created at low temperatures is also annealed out as the temperature is raised. Some of the early experiments of Wigley (1964, 1965) are summarized by Hecker and Martz (2001). Typical damage recovery (based on electrical resistivity measurements)

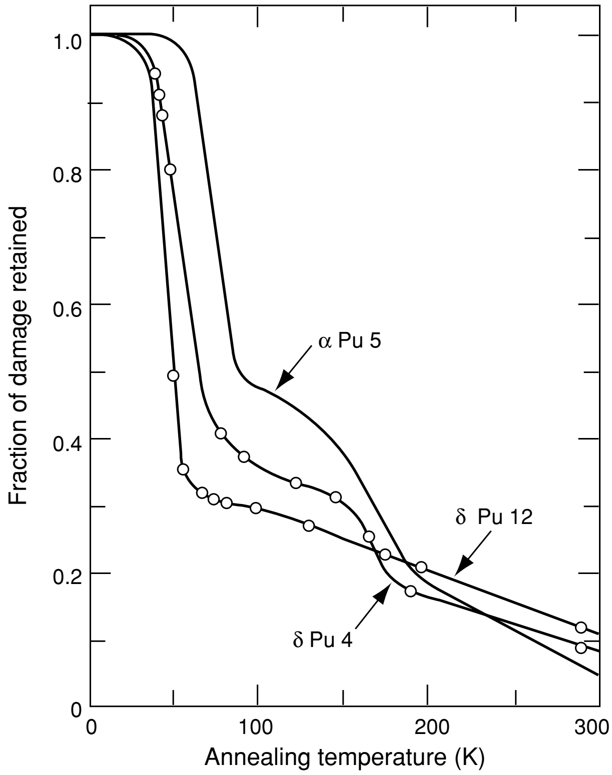

Fig. 7.67 *Damage recovery during isochronal annealing after self-irradiation at* 4.5 K. *δPu*4 *is for an alloy of Pu*-4 at. *% Al with* 920 h *at* 4.5 K. *δPu*12 *is for an alloy of* Pu-12 at. *% Al with* 665 h *at* 4.5 K. *The α-Pu sample, αPu*5, *was self-irradiated for* 640 h *at* 4.5 K (*from Hecker and Martz,* 2001 *based on original data from Wigley,* 1965*; King* et al., 1965).

during isochronal annealing of self-irradiated unalloyed plutonium and δ-phase Pu–Al alloys is shown in Fig. 7.67, based on the work of Wigley (1965) and King *et al.* (1965). Based on comparison to a vast literature of irradiation damage in metals (Ehrhart *et al.*, 1991), Hecker and Martz estimated the following temperatures for the key recovery stages in plutonium alloys: ~18 K for Stage I (recombination and migration of self-interstitials); ~180 K for Stage III (vacancy migration and annihilation); and 410 K for Stage V (thermal dissociation of vacancy and/or interstitial clusters). Unfortunately, the data on plutonium are limited and difficult to interpret quantitatively because of incomplete information about precise isotopic contents, purity levels, prior age, and processing conditions. Wirth *et al.* (2001) reported on recent self-irradiation and isochronal annealing experiments. They found the onset of Stage I to be diffuse and difficult to determine. Their best estimates for the temperatures for the onset of Stage III and Stage V were 190 K and slightly above 320 K. Hence, the defect mobility in plutonium alloys at ambient temperature is substantial. Although much of the damage is healed at room temperature, some of it remains.

For self-irradiation at ambient temperature, we would then expect lattice damage to compete with recovery resulting from the defect mobility. Chebotarev and Utkina (1975) reported a lattice expansion in δ-phase plutonium alloys. Wolfer (2000) showed that the initial transient results in the formation of dislocation loops that lead to expanded lattice parameters, which tend to saturate within approximately 2 years. Unlike at low temperatures, both the unalloyed α-phase plutonium and alloyed δ-phase plutonium exhibit lattice expansion with age. Ellinger *et al.* (1962a) reported that X-ray samples of typical plutonium in the δ phase (alloyed with 12.8 at.% Al) retained their fcc crystal structure with a 0.1% expansion of the lattice constant (0.3% volume change) after 10 years at ambient temperature. Chebotarev and Utkina (1975) also reported slight lattice expansion in δ-phase Pu–Al alloys, with the expansion increasing with increasing aluminum content. For aluminum contents slightly below 10 at.%, they found an expansion of the lattice parameter of 0.25% after 2.5 years at ambient temperature. They also reported that all changes were recovered after a long-term anneal at 423 K.

Morales *et al.* (2003) confirmed that δ-phase alloys expand at ambient temperature and possibly undergo an orthorhombic distortion at long aging times. In recent TEM studies of aged δ-phase plutonium alloys, Schwartz and coworkers observed nanometer-size helium bubbles (see Wirth *et al.*, 2001; Martz and Schwartz, 2003; Schwartz *et al.*, 2005). These will be discussed in greater detail below.

We report one additional important aspect of self-irradiation damage in plutonium described in recent presentations and abstracts by Russian researchers Gorbunov and Seleznev (2001). They studied unalloyed plutonium consisting mostly of ^{238}Pu, which increased the α-decay damage rate by a factor of 240 over the typical ^{239}Pu. They used thin films to keep the temperature close to room temperature. Starting with a sample of α-phase plutonium, their XRD measurements demonstrated that the sample experienced numerous crystallographic transformations over the period of 1 year (equivalent to 240 years of aging for the typical mix of isotopes in plutonium). Specifically, they claim to find evidence that all six phases of plutonium coexisted at 40 to 50 days of age, and that after roughly 1 year, the sample consisted mostly of the α and δ phases. They suggest that the vacancies and vacancy clusters resulting from the intense self-irradiation affect the delicate balance between bonding and localized 5f electrons and, hence, affect phase stability.

(b) Actinide transmutation products and radiogenic helium

In addition to the lattice damage described above, α decay also results in transmutation products. The decay products for plutonium isotopes and

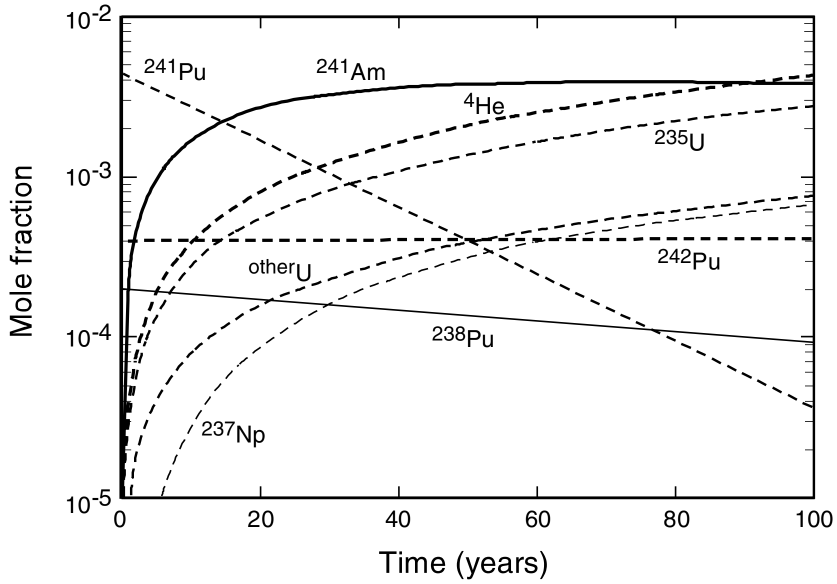

Fig. 7.68 *Transmutation products in typical* ^{239}*Pu metal* (*from Hecker and Martz,* 2001) *as a function of time. For typical* ^{239}*Pu,* 10 years *results in* 1 dpa.

its transmutation products are shown in Fig. 7.68. Helium grows in at the rate of 41.1 atomic ppm per year (based on the assumption made by Wolfer (2000) for typical plutonium). Hence, after 50 years of storage, approximately 2000 ppm helium, 3700 ppm americium, 1700 ppm uranium, and 300 ppm neptunium have grown into plutonium metal. After that length of time, a 1 kg piece of plutonium will contain nearly two-tenths of a liter of helium (measured at standard conditions). Several thousand ppm of americium should help to further stabilize δ-phase alloys. For pure plutonium it is conceivable that the in-growth of americium could stabilize microscopic regions of higher-temperature phases in the monoclinic α phase. However, in both cases, the nonequilibrium conditions that exist immediately following the decay event may further complicate the effects of the transmutation products. Under equilibrium conditions, uranium and neptunium reduce δ-phase stability. As in the case of americium, however, the effect of their presence associated with decay products under the nonequilibrium conditions is not well understood. Our best estimate is that the in-growth of actinides, other than americium, over a time frame of decades should have no major macroscopic effects, but their presence as atomic impurities may influence some microscopic processes. In addition, one must take account of the heat generated during the decay process. For the typical isotopic mixtures discussed above, the heat is a rather modest 2 W kg^{-1}, making kilogram quantities of plutonium warm to the touch. On the other hand, ^{238}Pu used in radioisotope heat sources is roughly 250 times more radioactive.

The accumulation of radiogenic helium, on the other hand, could potentially affect the properties of plutonium significantly. It is well known that less than 100 ppm of helium in fcc stainless steel can cause swelling or dramatic embrittlement. Once helium atoms are generated in the plutonium lattice, they quickly fill nearby vacancies and diffuse through the lattice as helium-filled vacancies (Howell *et al.*, 1999). Wirth *et al.* (2001) calculated that at relatively high helium generation rates, a critical helium bubble nucleus consists of just two helium atoms and one or two vacancies. Russian researchers (Filin *et al.*, 1989) used angle-resolved positron annihilation to study self-irradiation-induced defects in aged δ-phase Pu–3.6 at.% Ga with 800 ppm helium. They concluded that elementary complexes of helium and vacancies are energetically favorable. Their results showed that pores with radii of 0.4–0.8 nm and 17–23 nm formed at temperatures above 200°C. They concluded that the small pores are probably simple helium-vacancy complexes and the larger pores are complex helium-vacancy clusters, possibly also associated with solute atoms. They observed groups of small bubbles with diameters <1 μm by optical metallography after heating the aged plutonium alloy above 425°C. Using TEM, Zocco and Rohr (1988) observed helium bubbles of 3–7 nm and 10–15 nm in diameter in a 10-year-old δ-phase Pu–Ga alloy after annealing at 400°C. Decades-old plutonium will not only swell substantially after heating to such temperatures, but may also suffer major microstructural void damage under these conditions.

Schwartz and coworkers recently observed nanometer-sized helium bubbles using a Fresnel fringe imaging technique in TEM. Schwartz *et al.* (2005) examined Pu–Ga δ-phase alloys ranging in age from 6 months to 42 years. Their observations revealed that the dominant defects attributable to self-irradiation damage at ambient temperature are nanometer-sized, homogeneously distributed helium bubbles as shown in Fig. 7.69. They found no bubbles in the 6-month-old sample above their resolution limit of 0.7 nm. For samples 16–42 years old, they reported a number density of bubbles in the range of $0.6\text{–}2.0 \times 10^{17}$ cm^{-3}, which increases at a steady rate with time. The average diameter of the bubbles in this age range varies from 1.3 to 1.6 nm and is observed to change little with age beyond 16 years. The volume fraction of bubbles increased from roughly 0.01 to 0.03% within the age range of 16–42 years. Based on positron annihilation spectroscopy by Howell and Sterne (personal communications to Schwartz) (Howell and Sterne, 2002), Schwartz *et al.* concluded that helium bubbles containing two to three helium atoms per vacant site must already be present in 6-month old plutonium. Moreover, the characteristic positron lifetime of 180–190 ps remains remarkably constant for

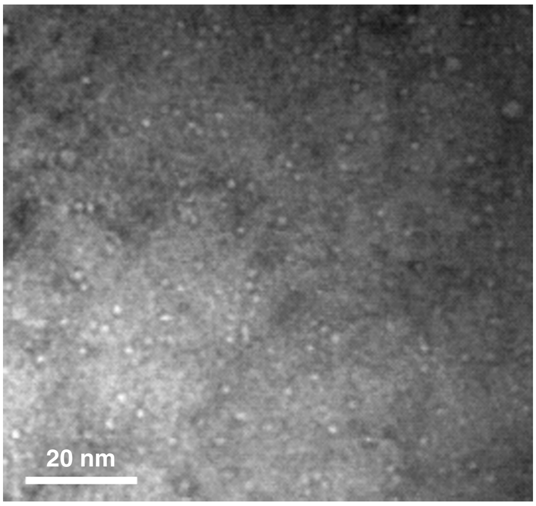

Fig. 7.69 *Transmission electron micrograph of nanometer-scale helium bubbles in a* 30+-year-*old δ-phase Pu*-3.4 at.% *Ga alloy* (*from Martz and Schwartz,* 2003; *Zocco and Schwartz,* 2003; *Schwartz* et al., 2005).

all aged material, implying a constant helium density within the bubbles of 2 to 3 helium atoms per vacant site.

The combination of irradiation-induced lattice damage and the presence of helium can cause void growth and bulk swelling at much lower temperatures without the presence of helium bubbles. Void growth is an obvious potential consequence of vacancy migration and clustering. Sustained void growth requires both the presence of biased defect sinks and the presence of neutral sinks. Wolfer (2000) estimated that for δ-phase plutonium alloys this may vary from 1 to 10 dpa (lifetimes from 10 to 100 years for typical ^{239}Pu). No experimental evidence for void swelling in plutonium has been found to date. In addition, our experience at Los Alamos shows that δ-phase plutonium aged at ambient temperature for 30–40 years retains structural integrity and exhibits no discernable microstructural changes. The influence of aging on the full range of plutonium properties remains to be assessed.

7.8 COMPOUNDS OF PLUTONIUM

From an historical perspective, the early study of plutonium compounds was plagued with difficulties. In addition to the fact that only very small amounts of plutonium were available for early experimentation, there were also special problems associated with the handling and manipulation due to radioactivity.

The problem of handling very small amounts of plutonium was overcome through the introduction of ultramicroscale experimental methods (Cunningham, 1949; Cefola, 1958; Fried *et al.*, 1958), and characterization of small quantities of compounds was masterfully performed by X-ray crystallography by Zachariasen (1954b), who made a major contributions to the structural chemistry of plutonium, almost entirely with Debye–Scherrer X-ray films of polycrystalline samples.

In more modern times, the available quantities of plutonium are large enough that the study of plutonium compounds can be conducted on the milligram and gram scale, and occasionally even on the multigram or kilogram scale. In the latter case, however, special safeguards to prevent criticality have to be taken (cf. Table 7.2) (Clayton, 1965; Thomas, 1969; Hunt and Boss, 1971; Hunt and Rothe, 1974; Paxton and Pruvost, 1987).

The evolution of modern techniques for handling plutonium has taken advantage of specialized high-efficiency particulate air (HEPA) filtered hoods, gloved boxes, and inert atmosphere dry boxes (Maraman *et al.*, 1975; Louwrier and Richter, 1976; Oi, 1995) that make it possible to work with plutonium with confidence, and the health and safety records of laboratories engaged in research with plutonium are very good. It cannot be denied, however, that laboratory work with plutonium and other actinide elements requires more than ordinary foresight and laboratory experience for the investigator. Laboratory safety guides (Peddicord *et al.*, 1998; *Health Physics Manual of Good Practices for Plutonium Facilities*, 1988) have been published that describe handling techniques and operational procedures in plutonium laboratories.

A considerable body of information on the compounds of plutonium has been amassed over the past 65 years, and the sheer volume of data is a testimony to the intense interest in the chemistry of plutonium. Several thorough monographs, conference proceedings, and reviews of the chemistry of plutonium before 1970 are available, and provide fascinating and often personal accounts of the many individual achievements that defined much of our current understanding in this field (Katzin, 1944; Thomas, 1944; Harvey *et al.*, 1947; Seaborg *et al.*, 1949b; Connick, 1954; Cunningham, 1954; Hindman, 1954; Seaborg, 1958; Grison *et al.*, 1960; Taube, 1964; Kay and Waldron, 1967; Miner, 1970; Blank and Lindner, 1976). Since 1970 there have been a number of comprehensive reviews (Keller, 1971; Cleveland, 1979; Wick, 1980; Carnall and Choppin, 1983; Hoffman, 2000) and finally, there are a series of modern reviews concerning a wide range of more specific topics such as chemistry in marine environments (Choppin and Wong, 1998), colloids in groundwater (Kim, 1991, 1994), bioinorganic chemistry in blood (Taylor, 1998), environmental behavior (Guillaumont and Adloff, 1992; Graf, 1994; Silva and Nitsche, 1995), behavior in carbonate media (Clark *et al.*, 1995), behavior in alkaline media (Shilov, 1998; Shilov and Yusov, 2002), actinide–lanthanide separations (Nash, 1993), synthetic methodologies for compounds (Meyer and Morss, 1991; Morss and Fuger, 1992), and a comprehensive compendium of XRD data for plutonium compounds (Roof, 1989).

7.8.1 Plutonium hydrides and deuterides

Plutonium hydrides were first observed in 1944 (Johns, 1944) when Johns found that elemental plutonium would react rapidly with H_2 to form a continuous solid solution of varying stoichiometry, PuH_x, with $1.9 \leq x \leq 3$ according to the equation:

$$Pu(s) + x/2H_2(g) \rightarrow PuH_x(s) \tag{7.29}$$

The reaction proceeds at a range of H_2 pressures. Heating is often required to initiate and sustain the process (Haschke, 1991). The chemical reaction is facile and reversible, making hydride–dehydride cycles a convenient route for preparing powdered plutonium metal samples. It is important to emphasize that stoichiometric compounds such as PuH_2 or PuH_3 do not exist as distinct phases apart from the PuH_x solid solution, though many authors describe reactions in terms of the stoichiometry PuH_2 or PuH_3 to facilitate the balancing of equations (Haschke, 1991).

Recent interest in plutonium hydrides has emerged due to considerations of long-term storage and safe handling of plutonium metal and compounds (Haschke and Allen, 2001) and the application of the plutonium–hydrogen reaction for pyrochemical processing of excess weapons plutonium (Flamm *et al.*, 1998; Mashirev *et al.*, 2001). Several excellent reviews have appeared on the synthesis and kinetics (Haschke, 1991), the thermodynamics (Flotow *et al.*, 1984; Lemire *et al.*, 2001), and the physicochemical characteristics of plutonium and other actinide hydrides (Flotow *et al.*, 1984; Ward, 1985; Ward *et al.*, 1992; Ward and Haschke, 1994; Bartscher, 1996; Haschke and Haire, 2000).

(a) Preparation and reactivity

The only practical method for preparing plutonium hydrides is the direct reaction of plutonium metal with gaseous H_2. In general, there are no good procedures for purification of PuH_x once it is formed, so purity is generally controlled through the use of high-purity metal and gaseous reagents. Plutonium metal must be cleaned to remove surface oxide and other impurities, and this is most conveniently conducted inside a secondary positive pressure chamber within an inert atmosphere gloved box to maintain proper H_2 partial pressures and temperatures. A Sieverts apparatus, and pressure–volume–temperature (PVT) relationships are commonly employed to determine the exact Pu–H stoichiometry, which is crucial because of the stoichiometric variability in the PuH_x product ($1.9 \leq x \leq 3$). Even when the stoichiometry is carefully controlled, differences in preparation or storage can result in differences in homogeneity, morphology, and even crystal structure (see below). Desorption of H_2 is a common problem encountered in working with plutonium hydrides, even under ambient conditions.

Plutonium hydrides are hard, typically black metallic-appearing materials that show different behaviors based on particle size and composition. The color ranges from silver near $x = 2$ to black at higher values of x. Small particles can be extremely reactive towards O_2 and H_2O, and powders near composition PuH_2 can be pyrophoric or ignite spontaneously in air (Flotow *et al.*, 1984; Haschke *et al.*, 1987; Haschke, 1991; Haschke and Allen, 2001). The hydrides can also react with N_2 and CO_2, although these reactions are quite slow. Hence all manipulations and storage should be carried out under inert atmospheres. An excellent and thorough discussion of the practical considerations necessary for preparing plutonium hydrides has appeared (Haschke, 1991).

The kinetics of the Pu–H_2 reaction have been well studied, and the highly complex reaction proceeds through induction, acceleration, parabolic, linear, and terminal stages. Detailed discussions of reaction rates and the role of catalysis are available (Haschke, 1991; Haschke and Allen, 2001). Moreover, hydride stoichiometry and composition changes induced by the addition or removal of H_2 from PuH_x are important in determining plutonium hydride reactivity.

(b) Stoichiometry and phase relationships

The PuH_x phase relationships are remarkably complex. A broad range of nonstoichiometric phases is exhibited that extends from $PuH_{1.9}$ to near stoichiometric PuH_3. Equilibrium data indicate that the hydride composition near the gas–surface interface may also vary from $PuH_{2.3}$ to $PuH_{2.7}$ while the composition at the plutonium metal–plutonium hydride interface remains close to $PuH_{1.95}$ (Ward and Haschke, 1994). The resulting stoichiometry and phase can differ between studies conducted at low temperatures and low pressures, or at high temperatures and high pressures. As a result, two notional phase diagrams, one for slow reaction at low pressure and one for rapid reaction at high pressure, have been proposed and discussed in detail by Haschke and coworkers (Haschke *et al.*, 1987) and by Bartscher (1996). These complex stoichiometry and phase relationships are best understood from consideration of the solid-state structures of the PuH_x system.

The phase relationships in the plutonium–hydrogen system are shown in the phase diagrams of Fig. 7.70 (slow reaction at low pressure) and Fig. 7.71 (rapid reaction at high pressure) (Flotow *et al.*, 1984). Hydrogen dissolves in solid and liquid plutonium (melting point 640°C) to form plutonium metal that is essentially saturated in hydrogen. This is denoted as PuH_s in the figures. Hydrogen-saturated plutonium (PuH_s) coexists with the cubic PuH_x solid solution up to composition $x \approx 1.9$. Between composition $PuH_{1.9}$ and PuH_3, a continuous solid solution forms. The exact value of x is highly dependent upon the

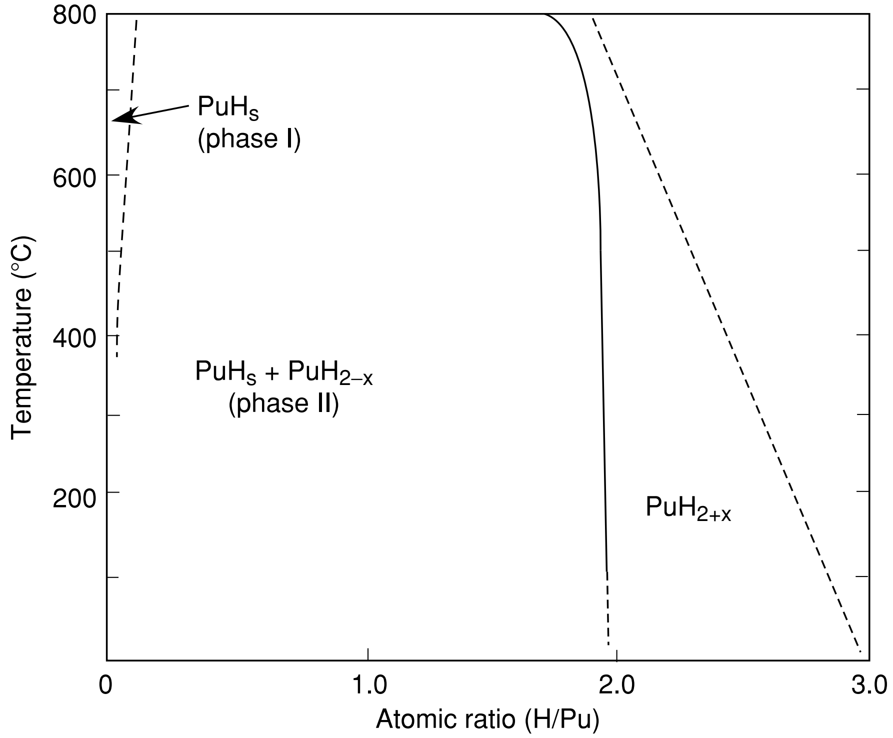

Fig. 7.70 *A plutonium–hydrogen phase diagram depicting equilibrium relationships based on Wick* (1980) *and Flotow* et al. (1984).

conditions of formation (Haschke *et al.*, 1987). The variable composition arises because the hydride reacts reversibly with H_2 between 25 and 500°C and pressures less than 1 bar (Johns, 1944; Haschke *et al.*, 1987). Extrapolation of 25°C data suggests that at 1 bar H_2 pressure, a composition $PuH_{2.93}$ is attained, while at 25 bar H_2, composition PuH_3 is attained. These observations are consistent with the phase diagram for slow reaction at low pressure shown in Fig. 7.70. An alternative phase diagram based on data generated at high pressures and rapid reaction is shown in Fig. 7.71 (Haschke *et al.*, 1987). This diagram is based on measurement of partial molar free energy isotherms that suggest the existence of five hydride phases (indicated as II–VI in Fig. 7.71) in addition to PuH_s (phase I). These data suggest the coexistence of a cubic $PuH_{2.70}$ and a hexagonal $PuH_{2.88}$ in the III + IV two-phase region. Hexagonal phase IV is thought to have a structure similar to that of disordered tysonite (LaF_3), while phase V is thought to be similar to that of orthorhombic YF_3 with a composition near $PuH_{2.95}$. The properties of phase VI are unknown. For a detailed discussion of the plutonium–hydrogen phase equilibria, the reader is

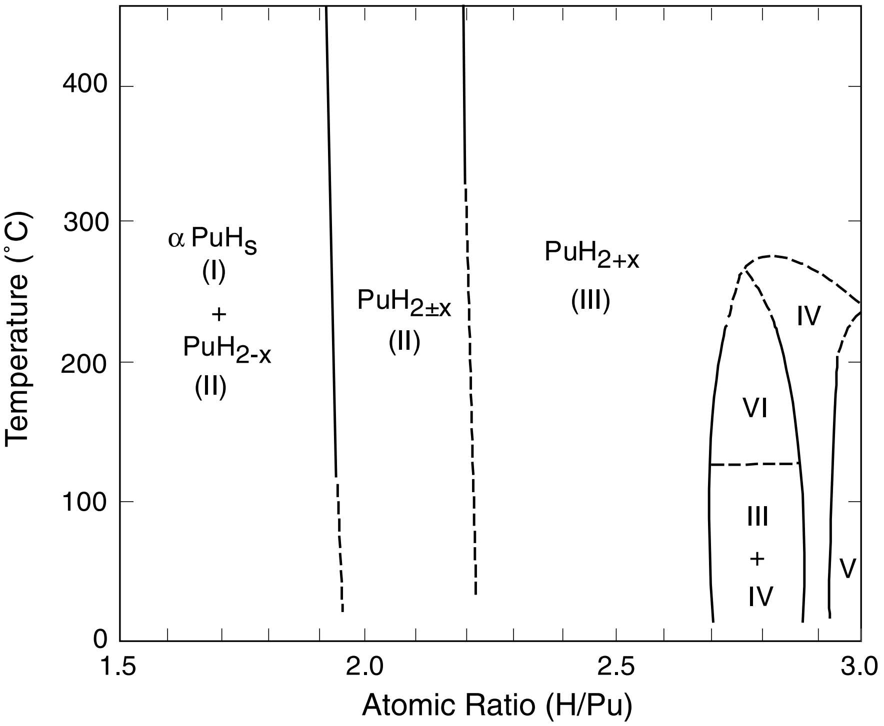

Fig. 7.71 *A plutonium–hydrogen phase diagram for rapid high-pressure reaction conditions, based on Haschke* et al. (1987).

referred to reviews by Flotow *et al.* (1984), Bartscher (1996), and Haschke and Haire (2000).

(c) Solid-state structures

The solid-state crystal structures of plutonium hydrides possess many similarities to those of the lanthanide hydrides, and Haschke and coworkers have suggested a similarity and analogy to the lanthanide trifluoride system (Haschke *et al.*, 1987). A summary of crystallographic data for plutonium hydrides is given in Table 7.26. Plutonium hydride forms a cubic fluorite-type phase over the composition range of PuH_x, where $1.9 < x < 2.7$, and a lanthanum trifluoride-related hexagonal phase beyond $x = 2.9$. The cubic fluorite-type structure based upon CaF_2 is illustrated in Fig. 7.72. As the composition of the fcc PuH_x varies between $1.9 < x < 2.7$, the lattice parameter decreases from 5.360(1) Å at $x = 1.9$ to 5.34(1) Å at $x = 2.7$. Within this fcc arrangement of plutonium metal cations are tetrahedral (*t*) and octahedral (*o*) interstices that may be occupied by the H^- ion. For an idealized PuH_2 structure with lattice

Table 7.26 *Crystal structure data for plutonium hydrides.*

Formula	*Symmetry*	*Space group*	*Lattice parameter* a_0 (Å)	c_0 (Å)	*Formula units per cell*	*Calculated density* (g cm^{-3})	*References*

PuH_3	hexagonal	P6$_3$/*mmc* or P$\bar{3}$*c1*	3.78(1)[b] 6.55(1)	6.76(1)	2	9.608	Ellinger (1961)

---

[a] The values of x between 2.15 and 2.70 are represented by the equation a_0 (Å) = 5.4337 – 0.003575 (H/Pu) (Bartscher, 1996).

[b] Hexagonal LaF_3 (tysonite) has space group P$\bar{3}$*c1*, which is the same as observed in hexagonal lanthanide hydrides, and is the likely space group for PuH_3. To transform from P6$_3$/*mmc* to P$\bar{3}$c*1*, one would use $a_0 = a'\sqrt{3}$, or $a_0 = 6.55$ (Å) for PuH_3.

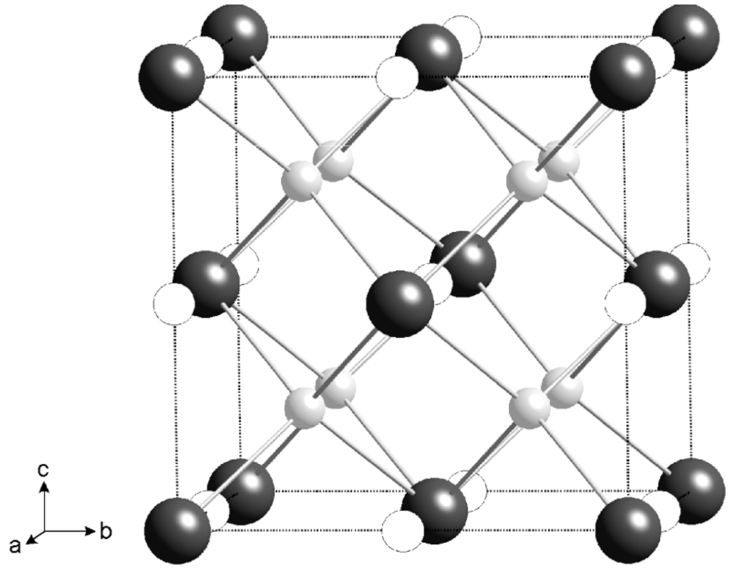

Fig. 7.72 *The cubic* (*Fm*3*m*) *fluorite-like solid-state structure of* PuH_x *showing the fcc arrangement of Pu atoms* (*black*) *with tetrahedral H atoms* (*gray*). *Octahedral vacancies are indicated with white circles, and the unit cell is indicated as a dashed line. For lattice parameter,* $a = 5.336$ Å, *Pu–H* = 2.31 Å, *Pu–Pu* = 3.77 Å, *and Pu-vacancy* = 2.67 Å (*Ellinger,* 1961).

parameter $a = 5.34$ Å, there is eight-fold (cubic) coordination of each plutonium atom by 8 hydrogen atoms, and four-fold tetrahedral (*t*) coordination of hydrogen atoms by 4 plutonium atoms with a Pu–H distance of 2.31 Å. The six-fold octahedral (*o*) sites in this model are vacant. Compositions of PuH_x, where $x < 2$, are likely formed by the creation of hydrogen atom vacancies in the normal *t* sites. At low temperatures, low pressures, and slow reaction times, an extended metastable cubic solid solution can exist all the way up to the PuH_3 phase boundary, and a simplistic model (see discussion below) would have additional hydrogen atoms randomly filling the *o* sites, with a concomitant decrease in lattice parameter.

The simple model of random occupancy of *o* sites in the fluorite lattice by additional hydrogen atoms when H–Pu is greater than two is overly simplistic. Since hydrogen mobility can occur at fairly low temperatures, the hydrogen atom can be disordered between *t* and *o* sites in the lattice (Muromura *et al.*, 1972; Flotow *et al.*, 1984; Haschke *et al.*, 1987; Ward and Haschke, 1994). Bartscher and coworkers employed elastic neutron scattering on deuterated samples of composition $PuD_{2.25}$, $PuD_{2.33}$, and $PuD_{2.65}$ and demonstrated a progressive depletion of *t* sites and occupation of *o* sites relative to PuD_2 (Bartscher *et al.*, 1985). Deuterium atoms in the *o* sites are displaced by 0.4 Å in the [111] direction (body diagonal) toward the *t* sites, in analogy with that observed in lanthanide systems (Ward and Haschke, 1994). In lanthanides, this low-temperature ordering of octahedral hydrogen atoms appears with a concomitant doubling of the *c*-axis of the unit cell. The 'freezing in' of the hydrogen atoms in this structure can be observed by NMR and by heat-capacity measurements (see below) (Cinader *et al.*, 1976; Flotow *et al.*, 1984). Haschke has proposed a conceptual model based on vacancy clusters for interpreting the relative *t*- and *o*-site occupancy factors in this structural model (Haschke *et al.*, 1987).

The structural behavior of the Pu–H system near the PuH_3 phase boundary is complex, and this region remains to be fully characterized. At low temperatures and for compositions above $PuH_{2.7}$, a cubic (fcc) form has been identified (Fig. 7.72). Under the appropriate conditions of rapid (high-temperature and high-pressure) reaction, both hexagonal and orthorhombic phases can also be formed near the PuH_3 boundary. In the range $PuH_{2.9}$–$PuH_{3.0}$, there is a hexagonal, nonstoichiometric phase in which the proposed structure is based on a disordered LaF_3 (tysonite) hexagonal structure ($P\bar{3}c1$), and an orthorhombic phase thought to be based on the YF_3 structure (Haschke *et al.*, 1987). The hexagonal phase was originally reported by Ellinger and assigned space group $P6_3/mmc$ (Ellinger, 1961), but more recent studies of the related lanthanide hydrides and fluorides reveal that trigonal space group $P\bar{3}c1$ is more likely the correct choice (Cheetham *et al.*, 1976). According to Haschke, the two-phase regions separating cubic (fcc) and hexagonal hydrides close in on themselves at 200–400°C, and only the cubic phases exist at higher temperatures (Haschke *et al.*, 1987). For more detailed discussion of these phase relationships, the reader is referred to the recent review by Haschke and Haire (2000).

(d) Physical properties and electronic structure

Trends in electronic properties as a function of x in PuH_x systems are crucial for understanding the nature of chemical bonding in plutonium hydrides. All data are consistent with the general description of cubic plutonium hydrides consisting of a localized 5f shell with a trivalent Pu(III) ion, best formulated as $Pu^{3+}(H^-)_x(e^-)_{3-x}$. Plutonium is trivalent for all compositions and exhibits 'rare-earth like' behavior. For nominal composition PuH_2, XPS shows a 4f intensity at the same 4f binding energy as a Pu(III) standard (Willis *et al.*, 1985). Neutron scattering data display an ordered magnetic moment of $0.71\mu_B$ per plutonium atom, which is the same as the trivalent free ion value (Bartscher *et al.*, 1985). Electrical conductivity decreases with increasing x, indicating that electrons are progressively removed from the conduction band and bound as H^- as the value of x increases (Willis *et al.*, 1985). Moreover, as the conductivity decreases, the hydride color changes from silver to black. Valence band XPS recorded on a (nominal composition) PuH_2 film reveal a large 5f peak consistent with a localized 5f shell, while core-level XPS on the same sample shows $4f^{5/2}$ and $4f^{7/2}$ peaks characteristic of Pu(III) (Ward *et al.*, 1992). Recent XPS data on a thin film of nominal composition PuH_3 shows the disappearance of the 5f peak (Gouder, 2005). Cinader and coworkers studied ^1H NMR spectroscopy on cubic PuH_x (where $x = 1.78$, 2.35, 2.65, and 2.78) between 77 and 300°C (Cinader *et al.*, 1976). Evaluation of line shapes, Knight shifts, and relaxation times are consistent with paramagnetic phases with localized 5f moments. Different line shapes and shifts were observed for *t* and *o* sites, and they were able to observe the 'freeze in' of the hydrogen atoms at low temperature. Enthalpies and entropies of formation for the extended cubic phase composition are given in Table 7.27.

(e) Applications

The hydriding reaction may be used to prepare plutonium metal powder. Compact pieces of plutonium metal can be converted to one of the hydrides and then powdered under an H_2 atmosphere by a magnet hammer. Subsequent

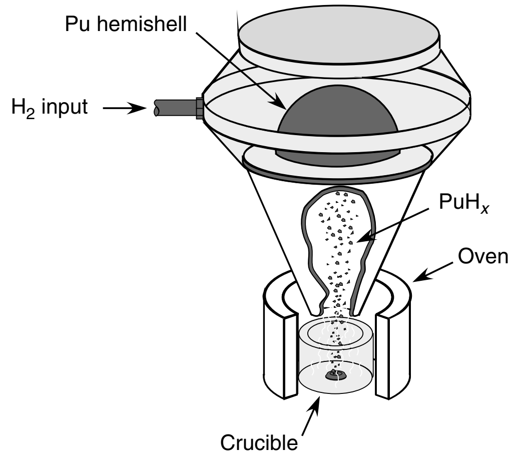

Fig. 7.73 *A schematic representation of the hydride–dehydride or hydride-oxidation chamber for conversion of surplus weapons plutonium. A weapon hemishell sits in the upper chamber, PuH_x spalls off and falls into the lower crucible, where it can be converted to the metal, a nitride or oxide* (*Toevs,* 1997).

decomposition *in vacuo* at more than 400°C leaves finely divided, highly reactive plutonium powder (Stiffler and Curtis, 1960). Both the U.S. and Russian technology for disassembly and conversion of excess plutonium from nuclear weapons employs a hydride–dehydride, or hydride–oxidation process for conversion into an unclassified form that can be examined by inspectors from other nations (Cremers *et al.*, 1995; Toevs, 1997; Nelson, 1998; Mashirev *et al.*, 2001). The U.S. process uses continuous H_2 recycle where the hydride falls into a crucible that is heated, driving off H_2 gas, leaving molten plutonium in the crucible. The H_2 refluxes to the top of the chamber, where it removes additional plutonium from the component. A schematic representation of the reaction chamber employed in this process is shown in Fig. 7.73. For conversion to an oxide, the crucible is not heated, and either O_2 is admitted and the hydride burned to release H_2 and leave an oxide powder, or N_2 is used and burned to a nitride powder. The nitride can then be converted to the oxide by burning with O_2. The three-step process of converting the hydride to the nitride and then the oxide avoids having an H_2–O_2 atmosphere in a glove box (Toevs, 1997). The hydride–dehydride approach to weapons conversion avoids the generation of large volumes of liquid waste from wet chemical methods.

7.8.2 Plutonium borides

Plutonium borides form at stoichiometric compositions PuB_2, PuB_4, PuB_6, PuB_{12}, and PuB_{66}, and at a very restricted solid solution of less than 0.5 at.% Pu in β-rhombohedral boron. These five compounds have high melting points, and with the exception of the preparation and identification of the compounds, very little experimental work is available. Recent detailed reviews describing the plutonium–boron system have appeared (Potter, 1991; Rogl and Potter, 1997).

Plutonium borides were first reported in 1960 (McDonald and Stuart, 1960), when the crystal structures of 'PuB,' PuB_2, PuB_4, and PuB_6 were described. Additional studies of the plutonium boron phase relationships were reported shortly thereafter (Skavdahl, 1963; Skavdahl and Chikalla, 1964; Skavdahl *et al.*, 1964; Weber *et al.*, 1964). Careful structural investigations employing XRD and metallography demonstrated that cubic samples of 'PuB' were contaminated with cubic PuN, and that 'PuB' was not actually a real phase in the Pu–B system (Eick, 1965; Chipaux *et al.*, 1989). Two additional compounds, plutonium dodecaboride, PuB_{12}, and the hectoboride, PuB_{66} were also discovered (Eick, 1965). The hectoboride was originally reported as having composition PuB_{100} (Eick, 1965), but based on analogy with rare-earth elements, which show a YB_{66}-type structure (Kasper, 1976), Rogl and Potter (1997) suggest that PuB_{66} represents a more-likely composition. Using the similarities between rare-earth and actinide boride systems, Rogl and Potter have provided a cautious assessment of the plutonium–boron phase diagram, shown in Fig. 7.74 (Rogl and Potter, 1997).

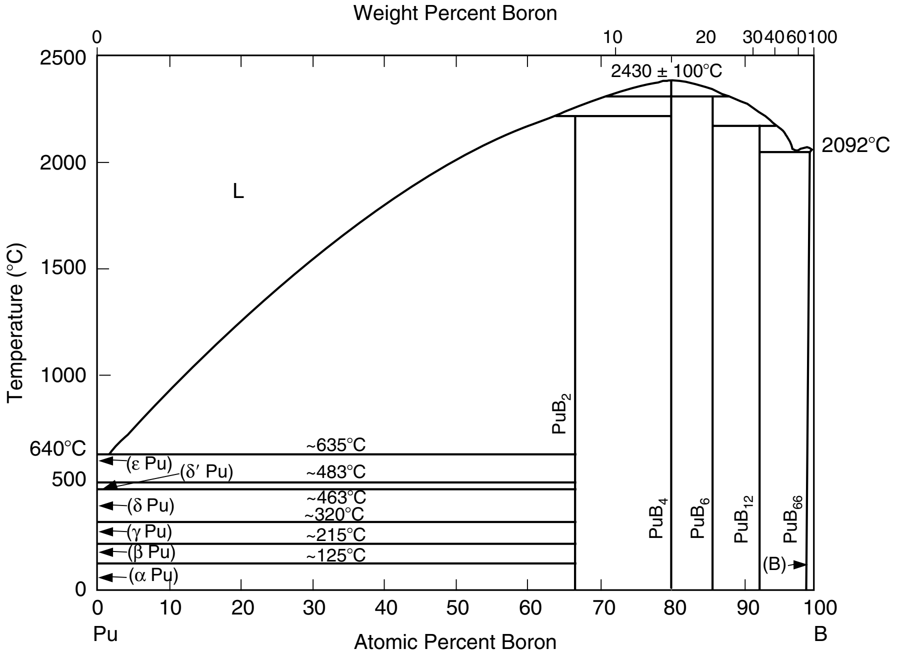

Fig. 7.74 *The plutonium–boron phase diagram* (*redrawn from Rogl and Potter,* 1997).

(a) Preparation

Plutonium borides can be prepared by a variety of methods: heating mixtures of pressed powders of elemental plutonium and boron under vacuum between 900 and 1200°C (McDonald and Stuart, 1960; Weber *et al.*, 1964), arc-melting pure plutonium with crystalline boron under a purified argon atmosphere followed by heat treatment (Eick, 1965), reaction of plutonium hydride with elemental boron at 900°C (Chipaux *et al.*, 1988, 1990), or reduction of PuO_2 by elemental boron and carbon (Skavdahl, 1963; Skavdahl and Chikalla, 1964; Skavdahl *et al.*, 1964; Larroque *et al.*, 1986). All of these reactions are carried out at high temperature (800–1500°C) under Ar or *in vacuo*. A comprehensive listing of preparative methods has been reported (Rogl and Potter, 1997). In view of the recent advances in the low-temperature synthesis of highly refractory materials (Rice, 1983; Wynne and Rice, 1984), and a possible application of actinide borides as an alternative storage form for actinide elements (Lupinetti *et al.*, 2002), it seems likely that this area will grow in interest and importance over the coming decades.

(b) Solid-state structures

The solid-state structures of plutonium borides (as in most metal borides) are dominated by B–B bonding, and the structures are made up of three-dimensional boron atom networks or clusters in which the plutonium atoms occupy otherwise vacant sites (Greenwood and Earnshaw, 1997). The B–B distances in all the plutonium borides are within the same range as those found in elemental boron and other boride complexes, and span 1.73–1.92 Å. The basic structural units in actinide borides, as in all metal borides, are readily described in terms of the B–B bonding configuration, followed by the actinide atom coordination (Potter, 1991; Greenwood and Earnshaw, 1997). Boron bonding units can be conveniently described as belonging to B_2-sp^2, B_6-octahedral, or B_{12}-cubeoctahedral boron atom cluster configurations as shown schematically in **1**, **2**, and **3** below (Potter, 1991; Greenwood and Earnshaw, 1997). To date, the structural characterization of plutonium borides has been performed exclusively by X-ray powder diffraction techniques, and a summary of crystallographic parameters of plutonium borides is given in Table 7.28. No single crystal diffraction studies have been reported.

[a] Calculated for ^{239}Pu.

Plutonium diboride (PuB_2) exhibits the hexagonal AlB_2 structure in space group *P*6/*mmm* containing one formula unit per unit cell (McDonald and Stuart, 1960; Eick, 1965). The AlB_2 structure is by far the most common phase displayed by metal borides (Spear, 1976). The solid-state structure (Fig. 7.75) consists of graphite-like hexagonal layers of catenated boron atoms with a close B–B contact of 1.84 Å. These hexagonal boron layers are separated by a hexagonal close packed (hcp) layer of plutonium atoms, positioned so that the centroid of a hexagonal ring of boron atoms lies directly above and below each plutonium atom. The closest Pu–B contact in this structure is 2.70 Å, with a closest Pu–Pu separation of 3.19 Å.

Plutonium tetraboride (PuB_4) has a tetragonal lattice (space group *P*4/*mbm*) formed by chains of B_6 octahedra along the *c*-axis and linked in the lateral direction by pairs of B_2 units in the *ab* plane (McDonald and Stuart, 1960;

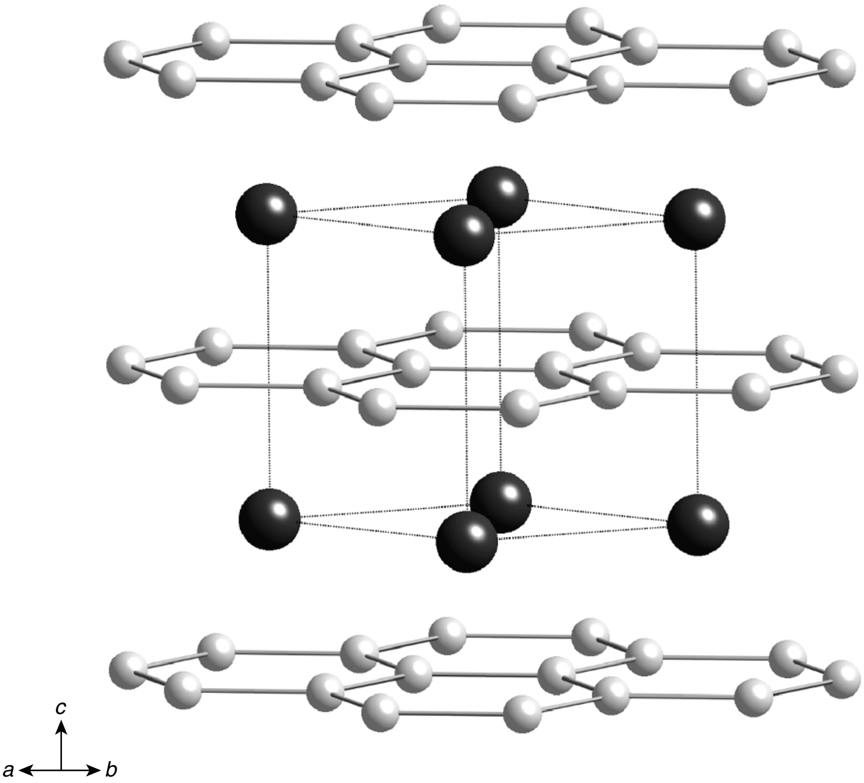

Fig. 7.75 *The solid-state structure of PuB_2 shown perpendicular to the c-axis, and emphasizing the hexagonal graphite-like layers of boron atoms (gray) separated by layers of plutonium atoms (black). The unit cell is indicated as dashed lines.*

Eick, 1965). This forms a three-dimensional network with channels along the *c*-axis that are filled by plutonium atoms. B–B contacts span a narrow range between 1.70 and 1.76 Å, with the shortest Pu–Pu contact of 3.66 Å between chains, and a longer contact of 4.00 Å along the chains. The closest Pu–B contact is 2.72 Å between Pu atoms and B_6 units. This structure type is shown in Fig. 7.76.

Plutonium hexaboride (PuB_6) has a cubic CsCl-type lattice (*Pm3m*) in which the plutonium atom and B_6 octahedra occupy the metal and halogen sites, respectively, as shown in Fig. 7.77(a) (McDonald and Stuart, 1960; Eick, 1965). In this structure, the B_6 octahedra are linked together in all six orthogonal directions. Within this framework, plutonium atoms occupy the corner

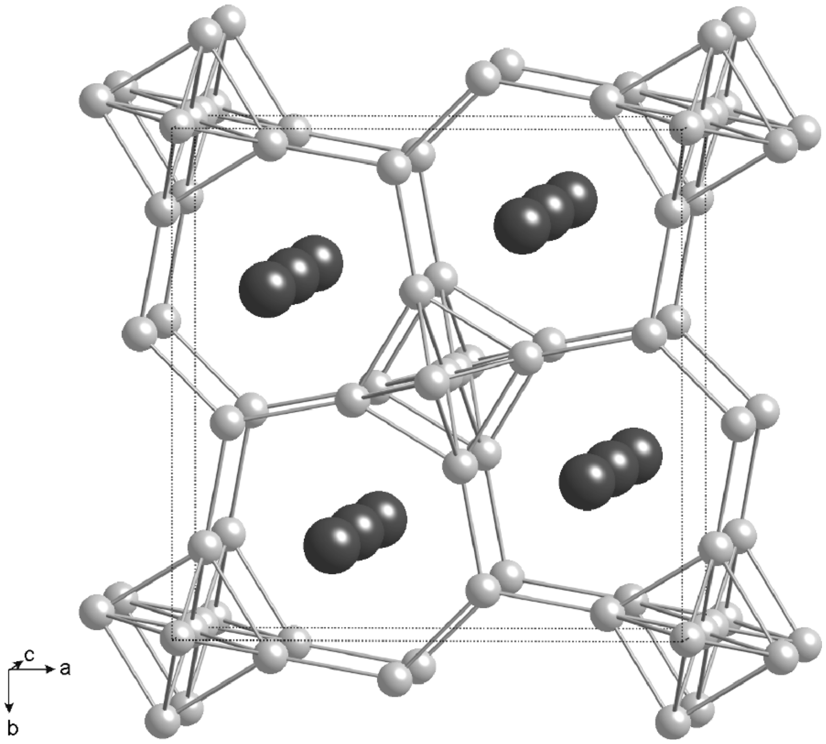

Fig. 7.76 *The solid-state structure of PuB_4 shown looking down the c-axis and emphasizing the open channels filled with plutonium ions (black). Boron atoms (gray) comprise octahedral B_6 units linked by bridging B_2 units within the ab plane. The unit cell is indicated as dashed lines.*

positions of an interpenetrating cubic sublattice. B–B contacts within the B_6 unit, and linking adjoining B_6 units, are 1.70 Å, Pu–B contacts are 3.03 Å, and the Pu–Pu nonbonding contact is 4.11Å. Plutonium dodecaboride (PuB_{12}) has a cubic NaCl-type fcc lattice (*Fm3m*) in which the plutonium atoms and B_{12} cubeoctahedral clusters occupy the metal and halogen sites, respectively, as shown in Fig. 7.77(b) (Eick, 1965). B–B distances within the B_{12} unit are 1.76 Å, Pu–B distances between plutonium and B_{12} units are 2.79 Å, and the Pu–Pu nonbonding contact is 5.29 Å.

Plutonium hectoboride was originally formulated as 'PuB_{100}' (Eick, 1965), but this phase is most likely of composition PuB_{66}, belonging to a family of metal hectoborides based on the structure of YB_{66} (Potter, 1991; Rogl and Potter, 1997). This structure is exceedingly complicated, and the reader is referred to Richards and Kasper for a detailed description (Richards and Kasper, 1969). A simplified description is that of a well-known 13-icosahedron unit (156 boron atoms) found in β-rhombohedral boron, comprised of 12 B_{12} icosahedra grouped around a 13th central B_{12} unit. The yttrium atoms in YB_{66} are distributed in channels and coordinate to the cage boron atoms.

(c) Properties

Very little is known about the physicochemical properties of plutonium borides. It seems well established that PuB_4 and PuB_{66} are the only congruently melting plutonium borides (Rogl and Potter, 1997). Magnetic susceptibility measurements of PuB_2 and magnetic susceptibility and Mössbauer measurements on solid solutions of $Np_{1-x}Pu_xB_2$ and NpB_2 suggest a tetravalent oxidation state for neptunium, and presumably plutonium in the diborides. PuB_2 was found to be a weak paramagnet, and the data were fit by a modified Curie–Weiss law with and effective paramagnetic moment of $\mu^*_{\mathrm{eff}} = 0.32\mu_B$ and $\theta_p = -30$ K. Renormalization led to $\mu_{\mathrm{eff}} = 0.75\mu_B$ (Chipaux *et al.*, 1990). Smith and Fisk (1982) reported little temperature dependence in magnetic susceptibility of PuB_6.

7.8.3 Plutonium carbides and silicides

(a) The plutonium–carbon system

Four compounds are known in the plutonium–carbon system: Pu_3C_2, PuC_{1-x}, Pu_2C_3, and PuC_2. All these compounds undergo peritectic decomposition at high temperatures. The Pu–C phase diagram according to Green and Leary (1970), and assessed by Kassner and Peterson (1995), is shown in Fig. 7.78. Pu_3C_2 decomposes between 558 (Rosen *et al.*, 1963) and 575°C (Mulford *et al.*, 1960) to ϵ-Pu + PuC_{1-x} and may be unstable at lower temperatures

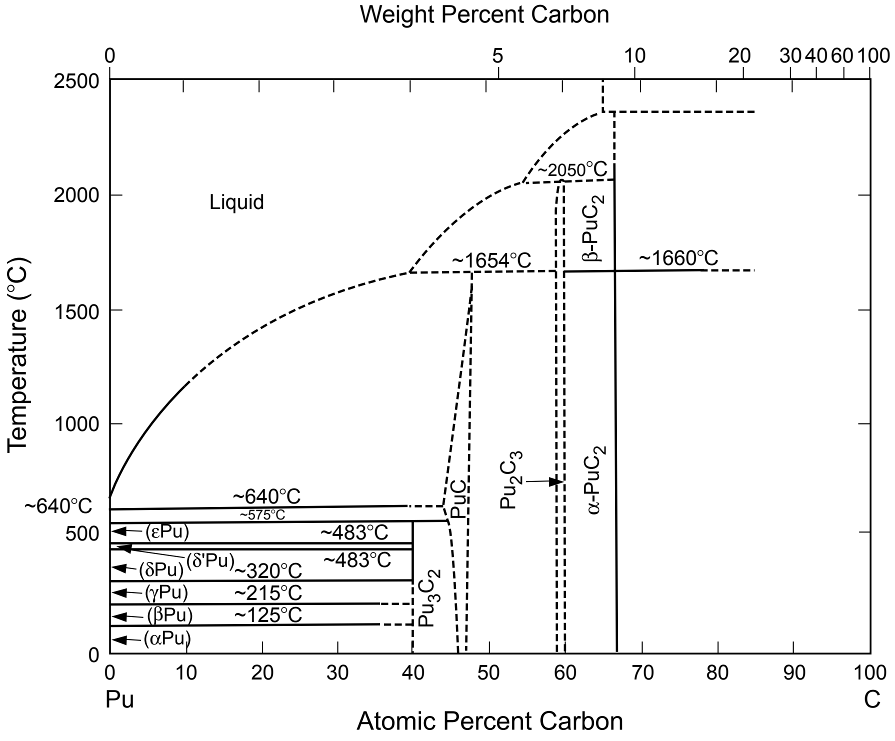

Fig. 7.78 *The plutonium–carbon phase diagram (redrawn from Green and Leary,* 1970*; Kassner and Peterson,* 1995*). See text for discussion of stability of* PuC_2 *below* 1660°C.

(Pascard, 1962). Plutonium monocarbide 'PuC' exists only as substoichiometric PuC_{1-x}, with a stoichiometry ranging from $PuC_{0.6}$ to $PuC_{0.92}$. At 1654°C, PuC_{1-x} decomposes into Pu_2C_3 plus liquid. Plutonium sesquicarbide Pu_2C_3 occurs in a rather narrow phase region around 60 at.% C. It decomposes at 2050°C into the high-temperature cubic phase PuC_2 and liquid (Mulford *et al.*, 1960). Plutonium dicarbide PuC_2 is only stable between 1660 ± 10 and 2230 ± 20°C (Reavis and Leary, 1970). The polymorphic transformation of PuC_2 below 1660°C to give the metastable tetragonal phase was added to the phase diagram in Fig. 7.78 by Kassner and Peterson (1995).

An extensive literature on plutonium carbides exists because actinide carbides have been considered as advanced nuclear fuels. Topical reviews can be found on general behavior (Storms, 1964, 1967; Ogard and Leary, 1970; Potter, 1975), thermodynamics (Holley, 1974; Holley *et al.*, 1984), thermal expansion and density (Andrew and Latimer, 1975), defect and transport properties (Matzke, 1984), and use as nuclear fuel (Russell, 1964; Andrew and Latimer, 1975; Herbst and Matthews, 1982; Handa and Suzuki, 1984).

(*i*) *Preparation*

Quite a few different preparation methods have been used to synthesize plutonium carbides. Carbides of plutonium can be formed by reaction between plutonium metal, plutonium hydrides, or plutonium oxides with elemental carbon at high temperature using furnace or arc-melting techniques (Drummond *et al.*, 1957; Ogard *et al.*, 1962; Pascard, 1962; Kruger, 1963; Chackraburtty and Jayadevan, 1965; Ogard and Leary, 1970). Plutonium oxide reductions using carbon can leave oxygen impurities in the products, and this is particularly true for the cubic monocarbides PuC_{1-x}. The products depend strongly on the temperature of reaction and reaction time. For example, PuC_{1-x} can be prepared by sintering or arc-melting a plutonium carbon mixture at 1000°C for 5 h, by direct reaction of PuO_2 with elemental carbon between 800 and 1350°C, by sintering $PuH_{2.7}$ with carbon in an inert atmosphere between 880 and 1650°C, or by reaction of PuH_2 with Pu_2C_3 at 650–750°C. The sesquicarbide can be obtained by reaction of PuO_2 with carbon under an argon atmosphere between 1250 and 1450°C at 6 h, 1350°C for 2 h or 1300–1400°C under vacuum. Pu_2C_3 can also be obtained by reaction of plutonium hydride with propane at 650–750°C.

(*ii*) *Crystal structures*

The crystal structures of all plutonium carbides, with the exception of Pu_3C_2 have been determined, and crystallographic data are summarized in Table 7.29. The lattice constants depend on the composition and the history of the individual sample. Plutonium monocarbide 'PuC' exists only as substoichiometric PuC_{1-x}, and adopts the cubic NaCl structure with defects in the carbon

Table 7.29 *X-ray crystallographic data for plutonium carbides.*

sublattice (Zachariasen, 1949c; Mulford *et al.*, 1960). As the carbon content increases, all the carbide carbon atoms are replaced by acetylide C_2 units adopting a stoichiometry $Pu_4(C_2)_3$ (equivalent to Pu_2C_3) and PuC_2. Pu_2C_3 is cubic with 12 C_2 groups in the unit cell, with each plutonium atom bonded to nine carbon atoms, three at 2.48 Å, three at 2.51 Å, and three at 2.84 Å (Zachariasen, 1952). This structure is illustrated in Fig. 7.79, where only the shortest set of three Pu–C bonds are indicated. Due to the difficulty in accurately locating carbon atoms in the presence of the larger plutonium atoms by XRD, the carbon atoms were placed in assumed locations with a C–C single bond distance of 1.54 Å. Neutron diffraction studies on the isostructural U_2C_3 revealed a much shorter C–C distance of 1.295 Å (Austin, 1959), which is considerably lengthened relative to C_2 unit in acetylene at 1.20 Å.

Plutonium dicarbide, PuC_2 is a high-temperature compound that is not stable below ~1750°C (Mulford *et al.*, 1960) and decomposes to Pu_2C_3 and carbon. High temperature XRD revealed an fcc structure at 1710°C with a lattice parameter $a_0 = 5.70(1)$ Å (Harper *et al.*, 1968) which is consistent with

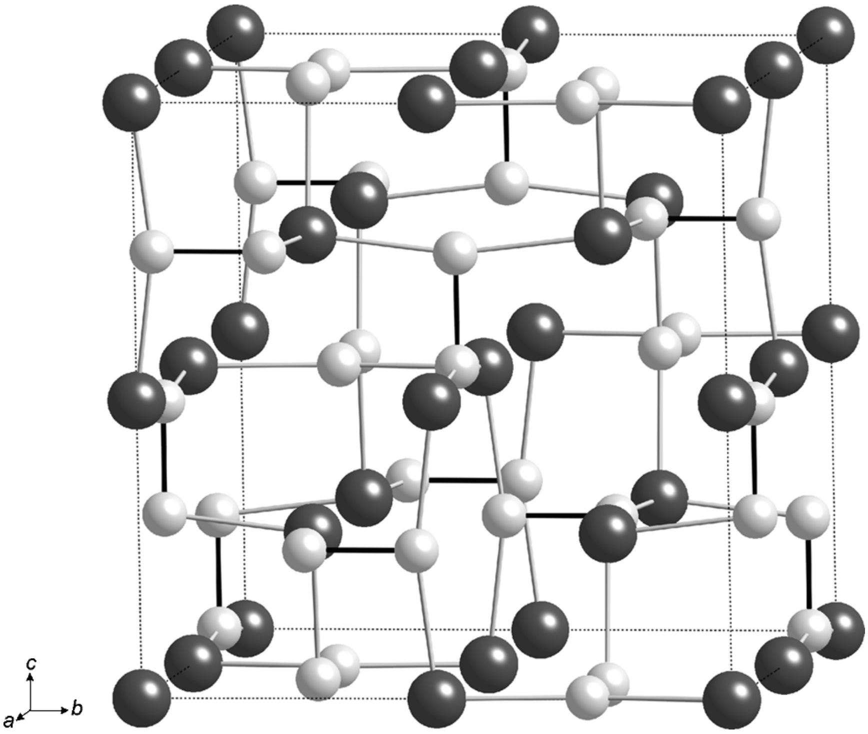

Fig. 7.79 *The solid-state structure of Pu_2C_3 shown looking down the a-axis. Plutonium atoms are black and carbon atoms are gray. The unit cell is indicated as dashed lines. The bold lines between C atoms indicates the* 12 *C_2 groups in the unit cell* (*Zachariasen,* 1952).

the CaC_2 structure that has a NaCl arrangement of Ca atoms and C_2 units (Wells, 1984). A room-temperature structure of what must be considered metastable PuC_2 was found to contain a tetragonal cell, probably due to martensitic transformation on quenching fcc PuC_2 to room temperature (Chackraburtty and Jayadevan, 1965). The tetragonal structure of PuC_2 and its similarity to the NaCl structural unit is shown in Fig. 7.80. For tetragonal PuC_2, the short Pu–C distance is found to be 2.48 Å with Pu–Pu = 3.63 and 3.98 Å (Chackraburtty and Jayadevan, 1965). As in the case of Pu_2C_3, the carbon atom positions are not accurately determined, but a neutron diffraction study on the isostructural tetragonal UC_2 revealed a C–C distance of 1.34 Å (Austin, 1959).

(*iii*) *Chemical properties*

The chemical properties of the plutonium carbides have been studied in some detail (Cleveland, 1979; Wick, 1980). Plutonium monocarbide oxidizes in air at temperatures as low as 200–300°C. It ignites at 400°C in an O_2 atmosphere (Drummond *et al.*, 1957). Compact PuC_{1-x}, kept in air at room temperature, did not show any sign of reaction after 2 months. However, PuC_{1-x} powder was found to be reactive, and sometimes pyrophoric (Ogard *et al.*, 1962). With N_2, PuC_{1-x} reacts more slowly than UC. A PuC_{1-x} sample, kept at 0.5 atm N_2, contains 1 ppm N_2 after 12 h at 200°C and 16 ppm after 12 h at 500°C. If heated

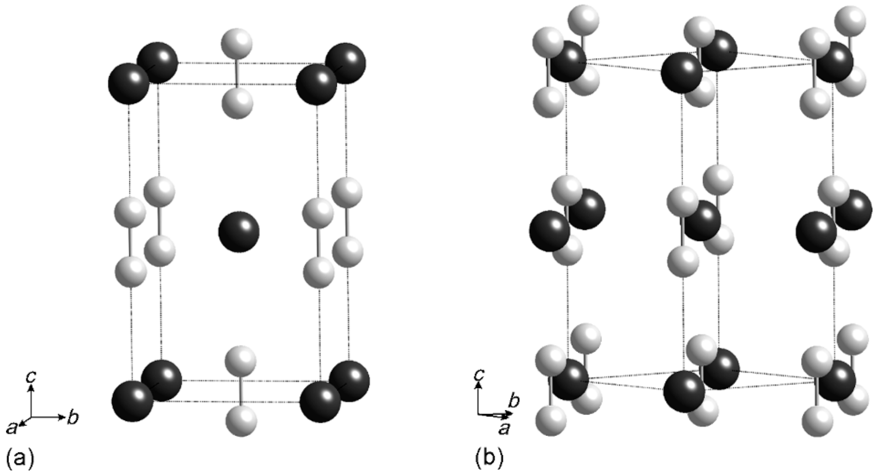

Fig. 7.80 (*a*) *The metastable tetragonal structure of* PuC_2 *shown looking perpendicular to the c-axis, and emphasizing the discrete* C_2 *units within the structure. Plutonium atoms are black and carbon atoms are gray.* (*b*) *The same structure rotated by* 45° *and emphasizing the relationship to the cubic NaCl structure with alternating Pu and* C_2 *units. At high temperature of* 1710°C, $a = b = c = 5.70(1)$ Å.

to 1400°C, the PuC_{1-x} reacts more rapidly to PuN and Pu_2C_3 (Lorenzelli *et al.*, 1966). Plutonium sesquicarbide, Pu_2C_3, shows chemical behavior similar to the monocarbide. It is slightly more stable to oxidation at higher temperatures (Drummond *et al.*, 1957). If heated to 1000°C in H_2, Pu_2C_3 is reduced to $PuC_{0.85}$ (Russell, 1964). PuC_{1-x} reacts with hot water to form $Pu(OH)_3$ and a mixture of H_2 and hydrocarbons. Pu_2C_3 appears to be more stable to hydrolysis in boiling water, but less stable to atmospheric hydrolysis (Drummond *et al.*, 1957).

All the plutonium carbides dissolve in HNO_3–HF mixtures (Storms, 1967). With oxidizing acids, CO_2 is formed. By the dissolution of lower carbides, carbon may be liberated along with hydrocarbons (Storms, 1967) along with organic acids such as mellitic and oxalic acids (Bokelund and Glatz, 1984).

(*iv*) *Thermodynamic properties*

Because of the importance of the plutonium carbides as potential high-temperature reactor fuels, the mechanical, thermal, electrical, magnetic, and thermodynamic properties of these compounds have been determined. For details about these properties and for additional references to the literature, the reader is referred to Holley *et al.* (1984), who reviewed the literature in the 1980s. The 2001 evaluation of plutonium thermodynamic data by the Nuclear Energy Agency (NEA) concludes that little significant thermodynamic information has been published since that time (Lemire *et al.*, 2001) but offers some reassessment of earlier data and provides recommended values for key thermodynamic constants. These are given in Table 7.30.

Monatomic plutonium is the only species that evaporates on heating from Pu–C phases. The equilibria in the solids have been inferred from vapor-pressure measurements (Mulford *et al.*, 1963; Olson and Mulford, 1967; Campbell *et al.*, 1970; Holley *et al.*, 1984). A general survey of the thermal decomposition behavior observed in the plutonium–carbon system has been given by Storms (1967). Specific-heat measurements of plutonium carbides have been reported by numerous authors and reviewed by Holley *et al.* (1984). The NEA review recommends the following temperature dependences (Lemire *et al.*, 2001):

Table 7.30 *Thermodynamic parameters for plutonium carbides.* (*Lemire* et al., 2001).

Compound	$\Delta_f G^\circ_{298}$ (kJ mol^{-1})	$\Delta_f H^\circ_{298}$ (kJ mol^{-1})	S°_{298} (J K^{-1} mol^{-1})	$C^\circ_{p_{298}}$ (J K^{-1} mol^{-1})

$$C_p^o = 120.67 + 4.686 \times 10^{-2}T + 1.9456 \times 10^5 T^{-2} \mathrm{JK^{-1}mol^{-1}} \quad (7.32)$$

(*v*) *Ternary phases*

Several ternary plutonium carbides have been prepared. Of particular importance are the phases formed in the systems Pu–U–C and Pu–Th–C, which may be used in high-temperature reactors and thorium breeders, respectively. The Pu–U–C ternary phase diagram has been reported by Mardon and Potter (1970) and by Rosen *et al.* (1963, 1964). In this system, compounds M_3C_2, MC_{1-x}, M_2C_3, and MC_2 are all observed, where M = (U, Pu), in a wide range of compositions. The Pu–Th–C system has been studied by Reavis and Leary (1970), who reported a partial-phase diagram, and by Dalton *et al.* (1967) and Dalton and Griffin (1964).

A few ternary plutonium carbide phases with transition elements have been prepared by arc melting from the components and have been characterized by their XRD data. These compounds are compiled in Table 7.31. An attempt to estimate ternary phase diagrams for a number of ternary plutonium carbide systems was reported by Holleck (1975). A few mixed carbonitrides, carbide oxides, and carbide hydrides, all of them nonstoichiometric, have been prepared.

(b) The plutonium–silicon system

Five compounds are known in the plutonium–silicon system: Pu_5Si_3, Pu_3Si_2, PuSi, Pu_3Si_5, and $PuSi_2$, melting at 1377, 1441, 1576, 1646, and 1638°C, respectively. The phase diagram determined by Land *et al.* (1965b) and redrawn by Kassner and Peterson (1995) is shown in Fig. 7.81. A recent XRD study by Boulet and coworkers found no new compounds other than the five listed above and confirms the phase diagram (Boulet *et al.*, 2003).

The literature of plutonium silicides is relatively sparse, but there are a few detailed reports on exchange reactions and enthalpies of formation (Krikorian and Hagerty, 1990), physical properties (Taylor, 1966), magnetic properties (Boulet *et al.*, 2003), and the phase diagram (Land *et al.*, 1965b); and an excellent overall review (Potter, 1975).

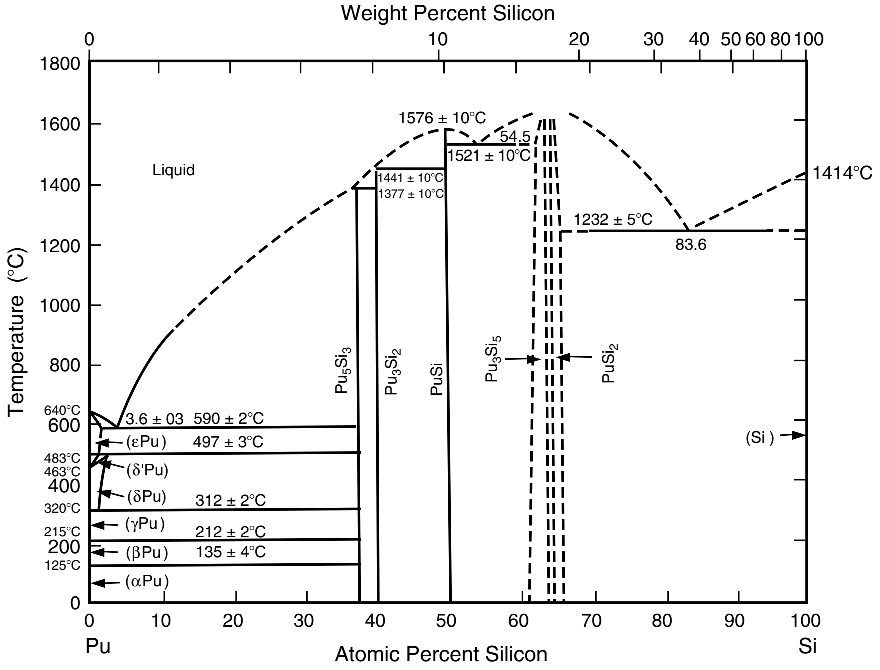

Fig. 7.81 *The plutonium–silicon phase diagram from Land* et al. (1965*b*) *and redrawn from Kassner and Peterson* (1995).

(*i*) *Preparation*

The preparation of plutonium–silicon phases is best carried out by reduction *in vacuo* of plutonium trifluoride with elemental silicon at temperatures above 1200°C in a BeO crucible (Runnalls, 1958):

$$4PuF_3 + (3 + 4x)Si \rightarrow 4PuSi_x + 3SiF_4 \tag{7.33}$$

Volatile SiF_4 is pumped off, and the plutonium silicide remains. The silicides may also be prepared by arc melting of silicon with plutonium metal or plutonium hydride in an argon atmosphere (Pardue *et al.*, 1964b; Land *et al.*, 1965b; Krikorian and Hagerty, 1990), by reduction of PuO_2 with Si or SiC *in vacuo* at 1400°C (Pardue *et al.*, 1964b), and by fluidized-bed reduction of PuO_2 in the presence of SiO_2 with silane (Fletcher *et al.*, 1967).

(*ii*) *Crystal structures*

The crystal structures of all plutonium silicides have been determined. The basic crystallographic data are listed in Table 7.32. Silicon, like boron, is more electropositive than carbon; thus silicides are more closely related structurally to the borides than the carbides. With increasing silicon content, there is an

increasing tendency to catenate into isolated Si_2 units, or into chains, layers or three-dimensional networks of silicon atoms. Plutonium silicides adopt examples of all these structure types.

The plutonium-rich compound Pu_5Si_3 adopts the tetragonal W_5Si_3 structure, and this structural unit is shown in Fig. 7.82 (Cromer *et al.*, 1964). In this structure, there is a silicon chain composed of columns of alternating $SiPu_8$ square antiprisms with Pu–Si = 3.025 Å. The linear silicon chain runs parallel to the *c*-axis with a Si–Si distance of 2.72 Å. Interspersed between the square antiprisms is another chain of edge-shared $PuSi_4$ tetrahedra that also runs parallel to the *c*-axis, with Pu–Pu = 2.72 Å. In the linear plutonium chain, each plutonium atom in the $PuSi_4$ tetrahedra shows a Pu–Si distance of 2.89 Å. The silicon atoms in the $PuSi_4$ tetrahedra bridge to the plutonium atoms in the $SiPu_8$ antiprisms with a Si–Pu distance of 3.01 Å. These bridges are omitted

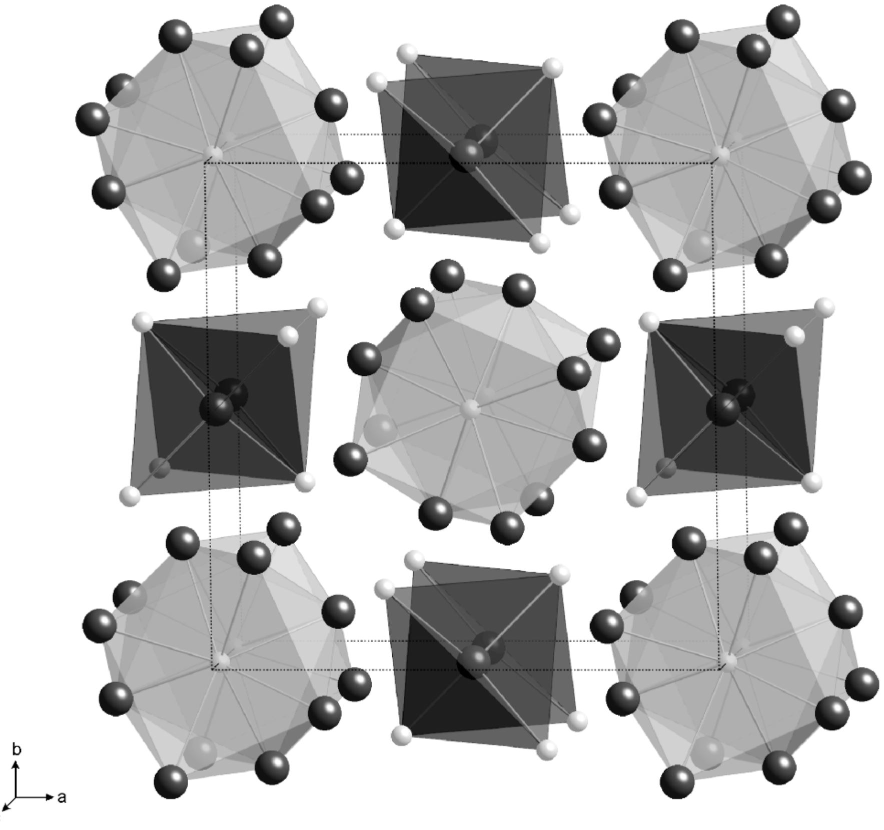

Fig. 7.82 *A polyhedral representation of the solid-state structure of Pu_5Si_3 shown looking down the c-axis, and emphasizing the alternating columns of $SiPu_8$ antiprisms and $PuSi_4$ tetrahedra within the structure. Plutonium atoms are black and silicon atoms are gray.*

from Fig. 7.82 for clarity. Pu_3Si_2 adopts the U_3Si_2 structure, and the basic structural unit is shown in Fig. 7.83. This structure contains a network of Si_2 pairs that are perpendicular to the four-fold axis with Si–Si = 2.35 Å, identical to the Si–Si distance observed in elementary silicon. The plutonium atoms form a puckered cage with Pu–Pu distances of 3.41 Å. The Pu–Si distances range from 2.99 to 3.03 Å.

Plutonium monosilicide is isostructural with ThSi and USi, adopting the FeB structure with infinite one-dimensional zig-zag chains of silicon atoms (Si–Si = 2.35 Å) (Land *et al.*, 1965b). Each silicon atom in the chain is also surrounded by six plutonium atoms at the apices of a trigonal prism with Pu–Si distances spanning the range 2.95–3.03 Å. The PuSi structure is shown in Fig. 7.84. There are four Pu–Pu distances of 3.62 Å, and two Pu–Pu distances of 3.73 Å.

The disilicides form two different structural types that are best considered as defect structures of $PuSi_{2-x}$. There is a hexagonal form of nominal formula Pu_3Si_5 (Runnalls and Boucher, 1955; Ellinger, 1961; Boulet *et al.*, 2003), that adopts the hexagonal AlB_2 structure (discussed for PuB_2, and shown in Fig. 7.75), but the solid is silicon deficient, with vacancies in the silicon sublattice. In this structure there are hexagonal (graphitic) layers of silicon atoms (Si–Si = 2.23 Å) with plutonium atoms interleaved between them (see Fig. 7.75). There is also a tetragonal form that adopts the three-dimensional $ThSi_2$ network structure as shown in Fig. 7.85 (Zachariasen, 1949a,b). In this structure, the silicon atoms form an open, three-coordinated, three-dimensional network. The Si–Si bond lengths are 2.35 and 2.29 Å, which are slightly shorter than that observed in elementary silicon. In the large spaces in this network are the plutonium atoms, each bonded to 12 silicon neighbors with Pu–Si = 3.02 Å. The next nearest neighbors to silicon are six plutonium atoms at this same distance.

(*iii*) *Properties*

The plutonium silicides are hard, brittle, and pyrophoric, with a metallic appearance. They oxidize in air to form PuO_2 (Westrum, 1949b) and are rapidly attacked by water (Pardue and Keller, 1964). Due to their high melting points and high Pu densities, plutonium silicides have been considered as reactor fuels, but the difficulty of preparing them as pure phases has hampered their development for this purpose (Pardue and Keller, 1964; Potter, 1975).

A recent determination of the magnetic properties of PuSi and tetragonal ($ThSi_2$-type) $PuSi_2$ revealed that PuSi orders ferromagnetically around 72 K,

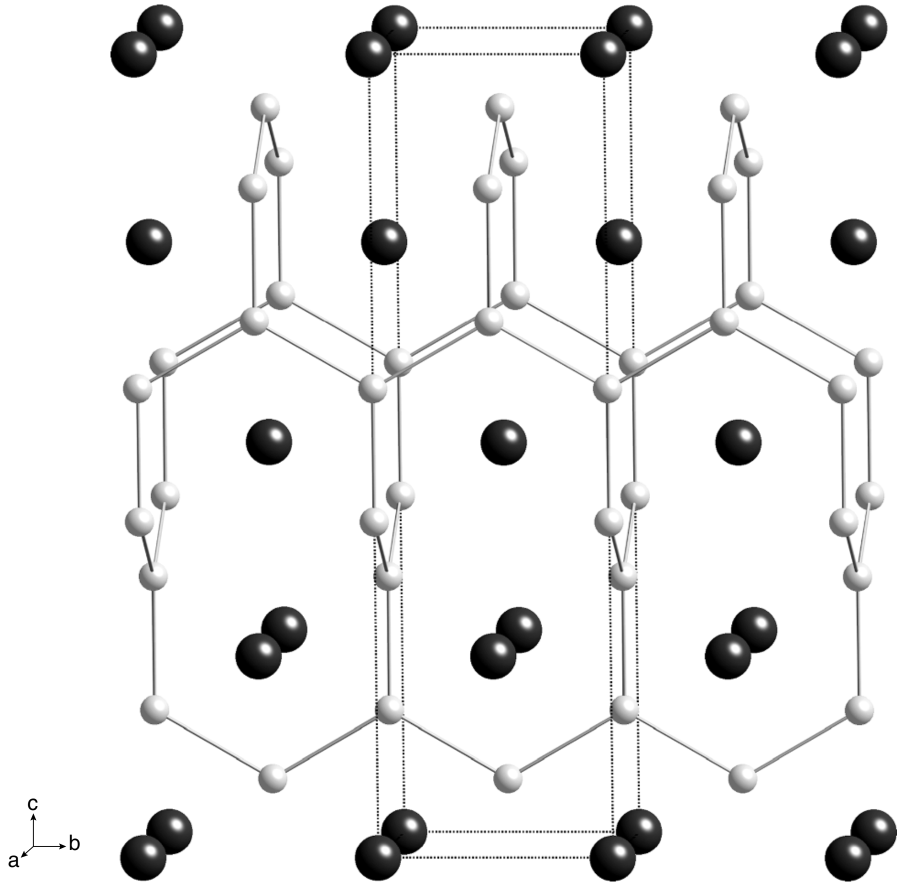

Fig. 7.85 *The solid-state structure of tetragonal $PuSi_2$ shown looking down the a-axis, and emphasizing the three-dimensional network structure of the silicon atoms. Plutonium atoms are black and silicon atoms are gray.*

whereas $PuSi_2$ shows no magnetic ordering (Boulet *et al.*, 2003). The values of the effective moments of PuSi (μ_{eff} ca. $0.72\mu_B$) and $PuSi_2$ (μ_{eff} ca. $0.54\mu_B$) are consistent with a $5f^5$ electronic configuration and a Pu^{3+} oxidation state.

7.8.4 Plutonium pnictides

With pnictogen elements, plutonium forms compounds in three basic families with the highest order composition being PuX_2 that is only found for the heaviest pnictogen elements (X = Sb and Bi). With antimony, thermal dissociation permits the preparation of an intermediate composition Pu_4Sb_3. By far, the most important class of compounds are the monopnictides PuX (N, P, As, Sb, Bi), which form an isostructural series that has played an important role in understanding the degree of localized versus delocalized bonding with 5f electrons.

Plutonium pnictides are generally prepared by reaction of plutonium metal or hydride with the pnictogen in evacuated sealed quartz tubes that are heated to 400–750°C. The monopnictides can be prepared by thermal dissociation of a higher pnictide. Reviews of synthesis (Spirlet, 1991) and structural properties are available (Damien *et al.*, 1986).

(a) The plutonium–nitrogen system

There is only one compound in the plutonium–nitrogen system that is known with certainty: the cubic mononitride PuN. The Pu–N phase diagram has recently been assessed (Wriedt, 1989; Kassner and Peterson, 1995) and is illustrated in Fig. 7.86. The locations of the boundaries on the Pu-rich and N-rich sides of PuN have not been evaluated in detail, but the composition range of PuN is probably quite narrow. PuN decomposes under 1 bar of N_2 pressure at 2570°C into N_2-saturated liquid plutonium and N_2. Liquid plutonium is formed

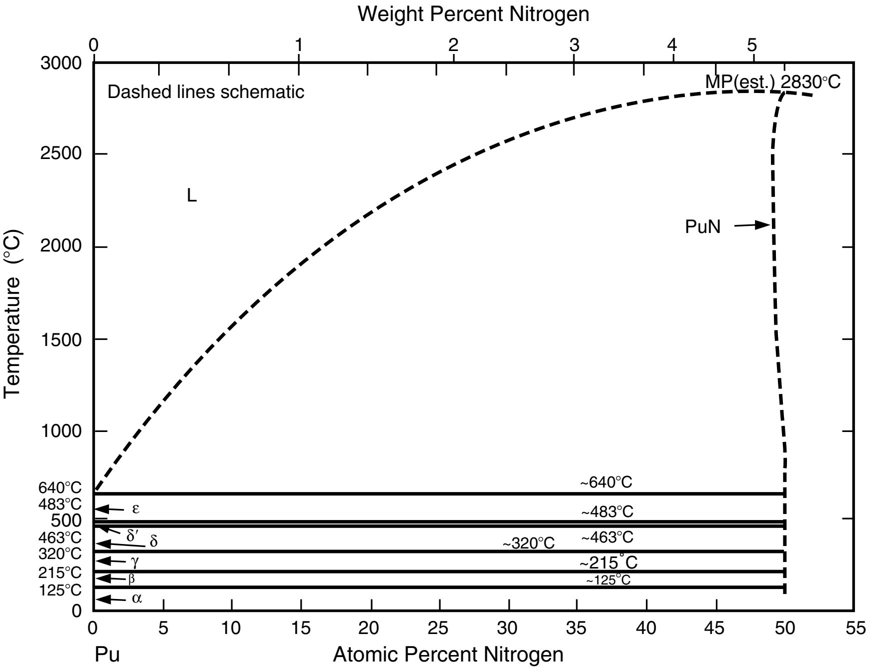

Fig. 7.86 *The plutonium–nitrogen phase diagram* (*Wriedt,* 1989*; Kassner and Peterson,* 1995).

above 1500°C due to incongruent evaporation of PuN. Because of problems associated with sample vaporization, the melting point of PuN has not been observed.

There is a fascinating report by Green and Reedy (1978a) of the observation of matrix isolated PuN_2 containing a molecular N_2 unit and characterized using IR spectroscopy. Theoretical studies discussing the existence, and the nature of chemical bonding in PuN_2 have subsequently appeared (Archibong and Ray, 2000; Tan, 2003).

(*i*) *Preparation*

Cubic PuN can be prepared most conveniently by reaction of metal with H_2 (150–200°C) to produce plutonium hydride, followed by heating the hydride under N_2 at temperatures between 500 and 1000°C (Pardue *et al.*, 1964a, 1967). The preparation can also be accomplished by reaction of plutonium metal with N_2 containing small amounts of H_2 at 250°C (Anselin, 1963a,b; Bridger and Dell, 1967). In view of the facile reactivity of plutonium metal with H_2 (see Section 7.7.1) it is likely that this reaction is catalyzed by surface hydriding of the plutonium metal at 200°C. In the absence of H_2, the direct reaction of pure plutonium metal with N_2, even over a period of 150 h at 1000°C, does not ensure complete conversion to PuN (Brown *et al.*, 1955). The nitride can also be prepared by the carbothermic reduction of PuO_2 under N_2 (Muromura, 1982; Suzuki *et al.*, 1983; Bardelle and Bernard, 1989; Takano *et al.*, 2001), though care must be taken to avoid product contamination with carbon and oxygen impurities. This is a common approach for making nitride fuels as it avoids making large quantities of plutonium hydride in a nuclear facility. The nitride can also be prepared by the reaction of plutonium hydride with ammonia between 600 and 650°C (Abraham *et al.*, 1949c). An interesting low-temperature route to PuN is the reaction of PuI_3 with sodium or potassium metal in liquid ammonia:

$$PuI_3 + NH_{3(l)} + 3M \rightarrow PuN + 3MI + 1.5H_2, \quad M = Na, K \tag{7.34}$$

In this approach, PuI_3 is dissolved in liquid ammonia, followed by reduction with a stoichiometric amount of sodium or potassium metal. The reaction likely proceeds through the *in situ* formation of the active metal amide, MNH_2 (M = Na, K), which undergoes subsequent metathesis with PuI_3. PuN precipitates from liquid ammonia as a black powder, which is washed with liquid ammonia and annealed at 700°C for 24 h (Cleveland *et al.*, 1974, 1975).

Freshly prepared PuN is black, turning brown in moist air due to hydrolysis (Storms, 1964). Formulations of (U, Pu, Zr)N that contain only a few percent of plutonium are golden-yellow. Because of problems with sample vaporization, the melting point of PuN has not been observed, but it has been estimated that congruent melting occurs at 2830 ± 50°C for an N_2 pressure of 50 ± 20 atm (Spear and Leitnaker, 1968).

(*ii*) *Crystal structure*

The crystal structure of PuN was first studied by Zachariasen and shown to exhibit the cubic NaCl structure (Zachariasen, 1949c,d). In cubic PuN, the plutonium and nitrogen atoms alternate in a fcc sphere packing arrangement, with both Pu and N having regular octahedral coordination. Using a lattice parameter of 4.905 Å, the Pu–N and Pu–Pu distances are 2.45 and 3.47 Å, respectively. Many lattice parameter studies of PuN have been reported and recently were summarized (Wriedt, 1989). The rather large variation in lattice parameter is most likely due to the effects of impurities, self-irradiation damage, or nitrogen concentration. A lattice parameter value of 4.918 Å was reported from the results of neutron diffraction on ^{239}PuN at –213°C (Boeuf *et al.*, 1984). Crystallographic properties of PuN and other plutonium pnictides are given in Table 7.33.

(*iii*) *Properties*

Plutonium mononitride is a refractory material with great potential for use as a nuclear reactor fuel (Matzke, 1986; Blank, 1994). It has a high melting point, high density, and high thermal conductivity. Moreover, it is compatible with austenitic steels up to 600°C and with sodium up to its boiling point of 890°C. One drawback is that PuN has a high volatility (due to release of N_2) at the high temperatures possible in a reactor accident. Due to the potential use of PuN in reactor fuels (Sano *et al.*, 1971; Bernard, 1989; Ogawa *et al.*, 1998; Albiol and Arai, 2001), there is an extensive literature on PuN, and topical reviews can be found on the physical and chemical properties (Spear and Leitnaker, 1968; Benedict, 1979), thermodynamic properties (Matsui and Ohse, 1987; Lemire *et al.*, 2001), phase equilibria (Wriedt, 1989), and synthesis (Spirlet, 1991). Selected physical properties of PuN are given in Table 7.34 (Holleck and Kleykamp, 1972; Kleykamp, 1999), and thermodynamic properties of PuN and other plutonium pnictides can be found in Table 7.35.

Powdered PuN reacts with O_2 at 200°C and ignites at 280–300°C to form PuO_2 (Kruger and Moser, 1967a). In moist O_2, the oxidation rate is increased: in the presence of 500 ppm water vapor, the reaction rate at 279°C is three times that without H_2O vapor. In air at room temperature, PuN powder is converted to PuO_2 within 3 days, but compact PuN is oxidized rather slowly (Pardue *et al.*, 1967).

PuN reacts slowly with cold water, but readily with hot water (Bridger *et al.*, 1969). In moist air, PuN decomposes within a few hours at 80–90°C, and within days at room temperature (Storms, 1964). The hydrolysis of PuN was determined in a stream of Ar–H_2O as a function of temperature to give hydrated PuO_2 (Bridger and Dell, 1967). Concentrated mineral acids will decompose PuN with decreasing violence of reaction in the order $HNO_3 > HCl > H_3PO_4 > H_2SO_4 > HF$ (Pardue *et al.*, 1964a).

(b) The plutonium–phosphorus system

Plutonium monophosphide, PuP, is the only well-defined binary plutonium–phosphorus compound known. Cubic PuP can be prepared by reaction of metal with H_2 (150–200°C) to produce plutonium hydride, followed by heating the hydride with PH_3 (Kruger *et al.*, 1966; Kruger and Moser, 1966b). By employing a stepwise reaction consisting of alternate hydride decomposition and reaction of the decomposition product with PH_3, one can obtain very pure PuP product. At least two cycles of alternate hydride decomposition and reaction with phosphine are required. The conversion cycles are followed by 4 h annealing at 1400°C. The preparation can also be accomplished by reaction of powdered plutonium hydride with excess (100–150%) red phosphorus in tantalum-lined pressure vessels at 600–800°C in an argon atmosphere (Moser and Kruger, 1966). After completion of the reaction, excess phosphorus is removed by distillation at 300°C. Alternatively, the phosphide can be prepared by induction melting of plutonium chips with elemental phosphorus *in vacuo* or under pressure of 1 atm of helium. The exothermal reaction goes to completion at 1400°C (Gorum, 1957). Another method involves the reaction of sol–gel prepared PuO_2 with a stream of PH_3 at temperatures of 1000°C or greater (Cogliati *et al.*, 1969).

PuP has a dark-gray color and melts with decomposition at 2600°C under argon. It exhibits the NaCl structure (see Table 7.33) (Gorum, 1957; Kruger *et al.*, 1966), with lattice constants that depend on sample history. Below 125 K, a tetragonal distortion is observed (Mueller *et al.*, 1979). A number of physical properties (microhardness, thermal expansion, thermoelectric power, temperature conductivity, and heat capacity) have been measured (Hall *et al.*, 1985).

PuP is ferromagnetic below a Curie temperature of $T_c = 126 \pm 1$ K. Above this temperature, the magnetic susceptibility has a temperature dependence given by $\chi_m = 190 \times 10^{-6} + N_L\mu^2/[3k(T–126)]$ cm^3 mol^{-1} where $\mu = 1.06\mu_B$ (Lam *et al.*, 1969). The ferromagnetic moment obtained by extrapolation to 0 K was found to be $0.42/\mu_B$ (Lam *et al.*, 1969). The Landé *g*-factor obtained by a correlation between Knight shift and χ_m is $g = 2/7$ (Fradin, 1970). Thermodynamic and magnetic properties have been discussed (Arai and Ohmichi, 1995).

(c) The plutonium–arsenic system

Plutonium arsenide, PuAs, may be prepared by reaction of plutonium metal with excess arsenic under 1 atm of helium or *in vacuo* at 500–1200 K (Gorum, 1957; Pardue *et al.*, 1964b; Mitchell and Lam, 1974) for a period of 3–7 h. It can also be prepared by reaction of PuH_3 with As *in vacuo* (0.02 Torr, 2.6×10^{-5} atm) at temperatures above 400°C, which are slowly increased to 700°C. The product is homogenized *in vacuo* at a still higher temperature (Kruger and Moser, 1967b; Fradin, 1970; Handwerk and Kruger, 1971; Charvillat and Damien, 1973). Finally, it can be prepared by reaction of plutonium partially converted to the hydride with AsH_3 at 250°C and subsequent recycling at 400, 500, 600, and 700°C in a similar manner as just described for PuP in Section 7.8.4(b) (Anselin, 1963b; Lam *et al.*, 1969). Because of the low decomposition temperature of AsH_3 (300°C), the primary reaction is done at 250°C, and only the annealing cycles are carried out at the higher temperatures mentioned above. Plutonium arsenide is a gray, metallic-looking material, black in finely divided form. Its crystallographic properties are listed in Table 7.33.

(d) The plutonium–antimony system

Arc melting of mixtures of plutonium and antimony yields PuSb (Kruger and Moser, 1966a). In addition to the monopnictide, plutonium also forms a dipnictide $PuSb_2$ (Charvillat *et al.*, 1977), and an intermediate composition, Pu_4Sb_3 (Damien *et al.*, 1986). Cubic PuSb melts at 1980 ± 30°C under 3 atm of argon (Mitchell and Lam, 1974).

The diantimonide exhibits an unusual orthorhombic structure formed by ten layers of atoms, and this structure is shown in Fig. 7.87. Each plutonium atom has four nearest antimony atoms ranging 3.15–3.30 Å away forming a distorted Sb_4 square just below, and another just above but rotated by 45 degrees. The local coordination polyhedron about plutonium is that of a distorted square antiprism. The Sb–Sb distances within the square are 3.095 Å, and the Sb–Sb distances linking the two groups of antiprisms are 2.755 Å. The structure is described in more detail for AB_2 rare-earth compounds by Wang and Steinfink (1967).

(e) Valency and electronic structure in PuX compounds

Plutonium monopnictides show moderately delocalized 5f electrons. The degree of localization increases with atomic number of the pnictogen, with delocalization being largely dominated by plutonium–pnictogen interactions. The lattice parameter is affected by this partial delocalization, making it hard to deduce plutonium valence from the crystal structure or lattice parameter value.

Magnetic susceptibility measurements of plutonium monopnictides show high-temperature Curie–Weiss-like behavior that gives effective moments close to the value of $1.24\mu_B$, consistent with an f^5 ion, and trivalent plutonium (Vogt and Mattenberger, 1993, 1995). The ordered magnetic moments are significantly smaller, and the experimental data suggest partial f-electron localization. For example, X-ray photoemission studies of PuSb clearly indicate localized f-electrons (Gouder *et al.*, 2000), while resistivity measurements show a semimetallic Kondo-like behavior (Blaise *et al.*, 1985). Magnetism experiments show a very strong anisotropy in all PuX compounds, with magnetic moments oriented along the [100] direction (Mattenberger *et al.*, 1986). Neutron scattering experiments (Lander *et al.*, 1984, 1985) support Cooper's interpretation of moderate f-electron delocalization being responsible for the reduction in the ordered moment and strong anisotropy in plutonium monopnictides (Cooper *et al.*, 1983). Recent electronic structure calculations of PuX compounds based upon a self-interaction correlated local spin density (SIC-LSD) approach support the interpretation that the plutonium 5f-electron manifold is best described in a mixed picture of localized and delocalized states (Petit *et al.*, 2002).

7.8.5 Plutonium chalcogenides

(a) The plutonium–oxygen system

Binary plutonium oxides, especially PuO_2, are of tremendous technological importance. They find widespread application as nuclear fuels, as long-term storage forms for both spent nuclear fuels and surplus weapons materials, and

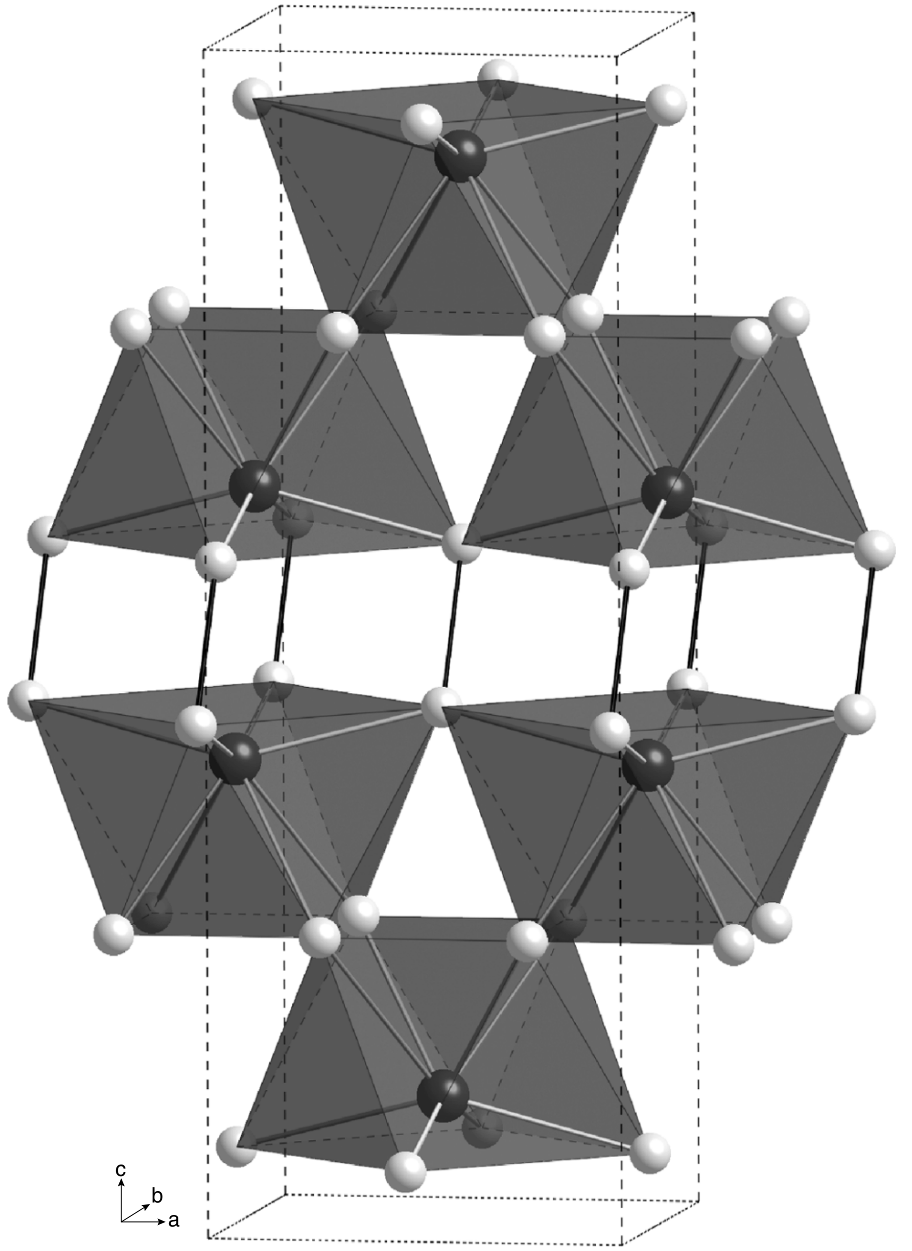

Fig. 7.87 *The solid-state structure of* $PuSb_2$ *shown looking perpendicular to the c-axis, and emphasizing the antiprismatic* $PuSb_8$ *polyhedral layers. Plutonium atoms are black and antimony atoms are gray.*

as heat and power generators (^{238}Pu) for interplanetary exploration. Their properties are also important because oxide particulates contribute to environmental actinide migration, participate in corrosion reactions in nuclear weapons, and exist as chemical intermediates in the purification and preparation of other actinide compounds. This same family of oxides is also of fundamental scientific interest. Even though plutonium oxides were among the first compounds of plutonium to be studied, it is astonishing to consider how much remains unknown about plutonium oxides. A number of reviews on the plutonium–oxygen system have appeared (Chikalla *et al.*, 1962; IAEA, 1967; Wriedt, 1990; Naito *et al.*, 1992).

(*i*) *Phase equilibria*

A good deal of discussion has appeared in the literature regarding the phase diagram for the plutonium–oxygen system, and there are conflicting sets of data for some phases (IAEA, 1967; Wriedt, 1990; Naito *et al.*, 1992; Haschke *et al.*, 2000a). The system is complex, and additional study is still needed to resolve certain issues surrounding the phase diagram. To adequately describe the issues associated with the plutonium–oxygen system, Haschke and Haire (2000) chose to present two diagrams, one based on the most recent assessment with modifications, and another, more pedagogical diagram based upon analogy with the more well-studied and better understood lanthanide oxide systems. There is great utility in this approach, and we have adopted it for our discussion. The proposed phase diagram based on the most recent assessments is shown in Fig. 7.88, and a table of crystallographic data for plutonium oxides is given in Table 7.36.

There are four fundamental equilibrium solid phases in the plutonium–oxygen system. The first of these is the stoichiometric hexagonal sesquioxide of formula Pu_2O_3 with a very small composition range near 60 at.% oxygen and with an ideal stoichiometry of $PuO_{1.5}$. This phase is also commonly known in the literature as hexagonal A-Pu_2O_3, or β-Pu_2O_3, and other designations have also been used (Wriedt, 1990; Haschke and Haire, 2000). We will use the designation A-Pu_2O_3. There is a bcc sesquioxide of composition $PuO_{1.52}$, reported to have only a small composition range near 60.3 at.% oxygen, but this narrow stoichiometry range is not supported by all the available data (Haschke and Haire, 2000). This phase has been commonly referred to as cubic C-Pu_2O_3, α-Pu_2O_3, and α-$Pu_2O_{3+\delta}$, but again, other designations have also appeared in the literature. We will use the designation C-Pu_2O_3.

There is a bcc oxide of intermediate composition $PuO_{1.61}$ with a composition range between 61.7 and 63.0 at.% oxygen that is commonly referred to as C′-Pu_2O_3, α'-Pu_2O_3, $PuO_{1.6+\delta}$, and others. This cubic phase is not stable at room temperature but exists above 335°C. Due to its broad composition range, Haschke and Haire referred to this phase as $PuO_{1.6+\delta}$ to help distinguish this bcc phase from the oxygen-deficient fcc PuO_{2-x}. We will use the designation

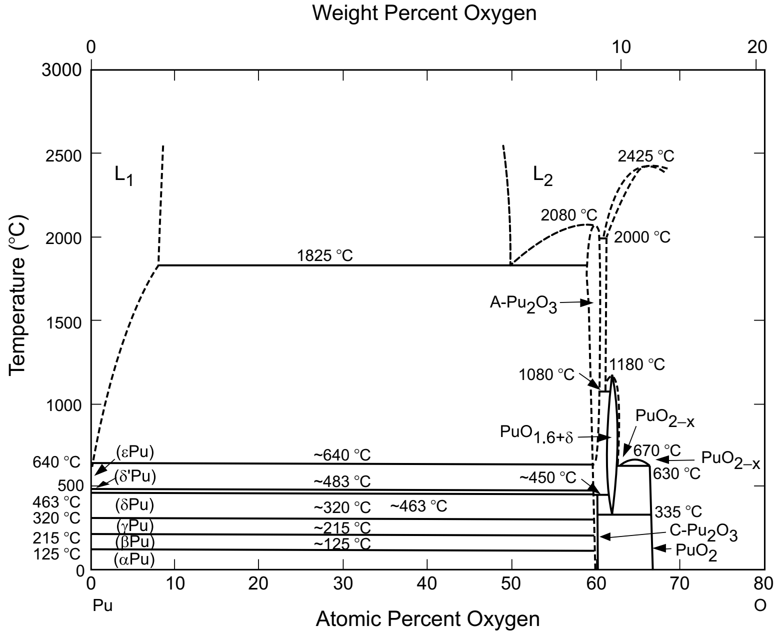

Fig. 7.88 *The plutonium–oxygen phase diagram* (*Wriedt,* 1990; *Naito* et al., 1992; *Haschke* et al., 2000*a*).

$PuO_{1.6+\delta}$. There is a fcc dioxide PuO_2 with a wide composition range that runs from $PuO_{1.6}$ to PuO_2, and sometimes referred to as substoichiometric PuO_2 or PuO_{2-x}. At room temperature, PuO_{2-x} has a fairly narrow composition range between $PuO_{1.98}$ and $PuO_{2.03}$, while at higher temperatures the homogeneity range widens to $PuO_{1.6}$ and PuO_2 as indicated in the phase diagram. Note that the oxygen-deficient fcc $PuO_{1.6}$ (PuO_{2-x}) is not the same as the bcc $PuO_{1.61}$ described above; this is why we prefer the nomenclature $PuO_{1.6+\delta}$ for the bcc phase. On the plutonium-rich side, cubic $PuO_{1.6+\delta}$ coexists with cubic C-Pu_2O_3 until it undergoes a peritectoid decomposition into hexagonal A-Pu_2O_3 and cubic $PuO_{1.6+\delta}$ above 450°C. On the oxygen-rich side of this composition range, C-Pu_2O_3 coexists with PuO_{2-x} below 630°C, and with metal-rich PuO_{2-x} at higher temperatures until it congruently transforms into PuO_{2-x} at 1180°C. Hexagonal A-Pu_2O_3 coexists with oxygen-saturated metal and displays an increasing extent of nonstoichiometry until the congruent melting point of 2080°C is reached. PuO_2 undergoes congruent melting at 2425°C. Only recently has there been enough new data to suggest the addition of a hyperstoichiometric fcc oxide, PuO_{2+x} with composition that runs from stoichiometric PuO_2 to $PuO_{2.27}$ between room temperature and 350°C (Haschke *et al.*, 2000b). This is not shown in Fig. 7.88, but is included in the notional phase diagram shown in Fig. 7.92.

(*ii*) *Preparation*

Plutonium monoxide, PuO

While it has been reported on numerous occasions, the existence of a *stable* condensed oxide of formula PuO is still uncertain and is therefore not indicated in the phase diagram of Fig. 7.88. The material that has been described by many authors is most likely a disordered oxide–carbide $Pu(O_x,C_{1-x})$. Mooney and coworkers (Mooney and Zachariasen, 1949; Zachariasen, 1949d) described powder patterns that could be attributed to cubic PuO, and Holley *et al.* reported a NaCl-type fcc phase with $a_0 = 4.96(1)$ Å as a surface film formed on plutonium metal. Westrum (1949a) describes the material as a semimetallic substance with an almost metallic luster. This surface material has also been observed upon heating oxide-coated plutonium metal *in vacuo* at 250–500°C (Terada *et al.*, 1969). Other reports on the preparation of PuO include the reaction of molten plutonium (microgram quantities) with stoichiometric oxygen generated by thermal decomposition of Ag_2O (Akimoto, 1960), by reduction of PuO_2 with carbon at 1500–1800°C (Skavdahl, 1964), or by reduction of PuOCl or PuO_2 with Ba vapor at 1250°C (Westrum, 1949a). Reshetnikov (2003) has recently claimed to prepare pure PuO by heating PuOCl with calcium at 1200°C, but no characterization data are provided to substantiate the claim. Haschke and Haire (2000) point out that plutonium oxide that results from metal oxidation may be covered with a layer of unbound carbon formed as a result of interaction of the oxide with hydrocarbons or CO_2, and that experiments by Forbes *et al.* (1966) indicate that all products thus obtained contain carbon. The observed lattice parameter is nearly identical to that found for oxide–carbide solid solutions (Mulford *et al.*, 1965; Oetting, 1967). Work on the Pu–O–C phase diagram has shown conclusively that the oxygen-rich limit of the $Pu(O_x,C_{1-x})$ phase lies at a composition of approximately $PuC_{0.3}O_{0.7}$ (Forbes *et al.*, 1966; Taylor *et al.*, 1967; Larson, 1980; Larson and Haschke, 1981). Larson and Haschke (1981) used XPS data to demonstrate that a material believed to be PuO was in fact $PuO_{0.65\pm0.15}C_{0.45\pm0.15}$.

Although the above paragraph argues that most materials that were thought to be PuO were likely contaminated with carbon, and therefore likely to be $Pu(O_xC_{1-x})$ there are several intriguing reports about an unstable, metallic-gray, pyrophoric product that deserve additional study. Reshetnikov (2003) describes an explosion that occurred in 1949 upon grinding a sample thought to be plutonium with a glass rod. Similarly, Haschke described a steel-gray product formed upon the thermal decomposition of PuOH (Haschke *et al.*, 1983; Haschke, 1992). This material underwent a violent exothermic reaction with oxygen, destroying a quartz microbalance container. Such behavior would not be expected for PuO_xC_{1-x}. Thus there may be some instances where a metastable form of solid PuO has indeed been prepared. The full characterization of the material produced by Haschke was not undertaken due its pyrophoric nature (Haschke, 1992), and characterization of the material prepared by Reshetinikov was not provided. We will need to wait for additional characterization data to resolve this issue.

While the existence of solid-phase PuO is unresolved, there is little doubt that gaseous PuO is one of the major species of plutonium oxides in the vaporization process (Green and Reedy, 1978b; Capone *et al.*, 1999; Ronchi *et al.*, 2000). PuO is observed in both the mass spectrum of effusing vapors over PuO_2 (Capone *et al.*, 1999; Ronchi *et al.*, 2000), and in the IR absorption spectra of vapors trapped in argon and krypton matrixes. $Pu^{16}O$ trapped in an argon matrix displays an infrared vibrational frequency of 822.28 cm^{-1} (Green and Reedy, 1978b).

Plutonium sesquioxide phases, Pu_2O_3

There is a good deal of confusion about both the preparative methods and the phase relationships between hexagonal (A-Pu_2O_3) and cubic (C-Pu_2O_3) forms of plutonium sesquioxide. The methods of preparation of hexagonal and cubic forms are very similar, yet these oxides are described as separate and distinct phases at low temperature. As outlined in recent reviews (Wriedt, 1990; Haschke and Haire, 2000), these compounds are thought to be distinct phases because (i) both cubic and hexagonal phases have been observed to coexist; (ii) the transformation between hexagonal and cubic forms has not been observed; and (iii) their regions of composition do not overlap. It has been suggested that kinetic factors may favor the formation of the cubic sesquioxide at low temperature in the presence of plutonium metal (Haschke and Haire, 2000). For example, cubic C-Pu_2O_3 readily forms as a surface layer when PuO_2-coated δ-stabilized plutonium metal is heated to 150–200°C under vacuum (Terada *et al.*, 1969). This observation is highly suggestive that the preexisting fcc lattice of metal atoms in either the underlying metal, the fcc dioxide, or both, imparts some control over the nature of the product in the reaction, and that once the cubic sesquioxide is formed, this phase cannot transform into the hexagonal form unless the temperature exceeds 450°C. The hexagonal form apparently does not transform back into the cubic form at this temperature, suggesting perhaps that more kinetic energy is necessary to rearrange the metal atoms in the lattice. This behavior is not consistent with the known behavior of the isomorphic lanthanide oxides, where hexagonal Nd_2O_3 will transform reversibly to cubic Nd_2O_3 near 600°C (Haire and Eyring, 1994). Thus cubic C-Pu_2O_3 may be only metastable at low temperatures.

Several methods of preparation have been reported for the hexagonal A-Pu_2O_3 sesquioxide. Plutonium dioxide can be reduced with plutonium metal (Holley *et al.*, 1958), dry hydrogen (Flotow and Tetenbaum, 1981), or carbon (Skavdahl, 1964) to form A-Pu_2O_3. Pure hexagonal A-Pu_2O_3 has been prepared by reducing pure PuO_2 with a 20% excess of plutonium turnings or chips in a closed tantalum crucible at 1500°C according to the stoichiometry (Holley *et al.*, 1958):

$$3PuO_2 + Pu \rightarrow 2Pu_2O_3 \qquad (7.35)$$

After a reaction period of 3 h, the excess plutonium metal was removed by sublimation from the open crucible at 1800–1900°C *in vacuo* (Holley *et al.*, 1958; Chikalla *et al.*, 1962, 1964). At higher reaction temperatures, large, flat crystals of hexagonal A-Pu_2O_3 were obtained. In another procedure, Gardner *et al.* (1965) reduced pure PuO_2 powder with a 20% excess of hydride-powdered plutonium metal in a ThO_2 crucible at 1500°C for 3 h in a stream of purified dry hydrogen.

Hydrogen reduction of PuO_2 to produce hexagonal A-Pu_2O_3 can be accomplished at 1550°C in very dry hydrogen purified over titanium turnings (Gardner *et al.*, 1965). Complete reduction of PuO_2 by hydrogen has also been reported to occur in the temperature range 1700–2000°C (Dayton and Tipton, 1961; Flotow and Tetenbaum, 1981). Pure hexagonal A-Pu_2O_3 may be prepared by the stoichiometric reduction of PuO_2 with carbon at (1800 ± 50)°C for 5.5 h in a pure helium atmosphere (Skavdahl, 1964; Forbes *et al.*, 1966) according to the reaction:

$$2PuO_2 + C \rightarrow Pu_2O_3 + CO \tag{7.36}$$

Chikalla and coworkers reported a large-scale preparation (ca. 110 g Pu) of hexagonal A-Pu_2O_3 by sintering pressed compacts of PuO_2 and carbon *in vacuo*, followed by melting under an inert atmosphere (Chikalla *et al.*, 1962, 1964; Skavdahl, 1964). Reaction of PuO_2 with a slight excess of carbon at 1650°C *in vacuo* produced a mixture of hexagonal A-Pu_2O_3 and a small amount of $Pu(O_x,C_{1-x})$. The latter, being more volatile than the Pu_2O_3, could be removed by heating *in vacuo*. Final arc melting resulted in hexagonal A-Pu_2O_3 with an O:Pu ratio of (1.500 ± 0.015), with 175 ppm carbon impurity and 93% theoretical density.

The cubic C-Pu_2O_3 sesquioxide is a silvery, metallic, lustrous solid, which is difficult to prepare by high-temperature methods. Haschke and Haire point out that reports of its preparation by simply heating PuO_2 *in vacuo* to temperatures between 1650 and 1800°C (Westrum, 1949a; Dayton and Tipton, 1961) are suspect because the O:Pu ratio of congruently vaporizing PuO_{2-x} is 1.85–1.90 in this temperature range (Ackermann *et al.*, 1966). The best means of preparation seems to be the heating of PuO_2 coated δ-stabilized plutonium metal to 150–200°C under vacuum (Terada *et al.*, 1969).

Hyperstoichiometric sesquioxide, $PuO_{1.6+\delta}$ (C'-Pu_2O_3, α'-Pu_2O_3, $PuO_{1.61}$)

When PuO_2 is melted, there is an evolution of oxygen resulting in a melt composition of $PuO_{1.62}$, which is the approximate composition of cubic C-Pu_2O_3 (Chikalla *et al.*, 1964). This phase can only be retained with extremely fast quenching. Since it is a high-temperature form of C-Pu_2O_3, it has been given the designation C'-Pu_2O_3 (or α'-Pu_2O_3, $PuO_{1.61}$, $PuO_{1.6+\delta}$). It is likely bcc. Slow cooling of the melt yields a mixture of C-Pu_2O_3 and PuO_{2-x} even in the absence of oxygen. Sari *et al.* (1968) reported that this compound has a composition range from $PuO_{1.62}$ to $PuO_{1.63}$ at 350°C, which extends to a range of $PuO_{1.62}$ to

$PuO_{1.69}$ at 600°C. Because of this broad composition range, we prefer the designation $PuO_{1.6+\delta}$.

Substoichiometric plutonium dioxide, PuO_{2-x}

The oxides between compositions $PuO_{1.61}$ to $PuO_{1.98}$ are mainly single-phase materials at temperatures above about 650°C. They may be prepared by heating PuO_2 at high temperature with carbon, hydrogen, or *in vacuo* (IAEA, 1967). The crystal lattice expands with decreasing oxygen composition (Gardner *et al.*, 1965; IAEA, 1967). Some annealing may be required, but prolonged heating *in vacuo* will cause a change in composition due to incongruent vaporization. This olive-green phase exists in the stoichiometry range $PuO_{1.61}$ to $PuO_{1.98}$ and is closely related to the stoichiometric oxide $PuO_{2.00}$. Its exact composition depends on the temperature and the oxygen partial pressure over the plutonium oxide solid (Drummond and Welch, 1957). Atlas and coworkers performed density measurements at 750°C that are consistent with the formation of oxygen vacancies in the crystal lattice (Atlas *et al.*, 1966). Atlas and Schlehman (1967) conducted a detailed study of the variation in oxygen content, x, with oxygen pressure. The composition–pressure–temperature relationship is shown in Fig. 7.89.

Stoichiometric plutonium dioxide, $PuO_{2.00}$

Plutonium dioxide is formed when metallic plutonium is ignited in air or by calcination of a number of plutonium compounds (except phosphates). Plutonium dioxide often forms when oxygen-containing compounds are heated *in vacuo* or in an inert atmosphere to 1000°C. The most widely used approach to prepare pure, crystalline PuO_2 is by heating Pu(III) or Pu(IV) oxalate to

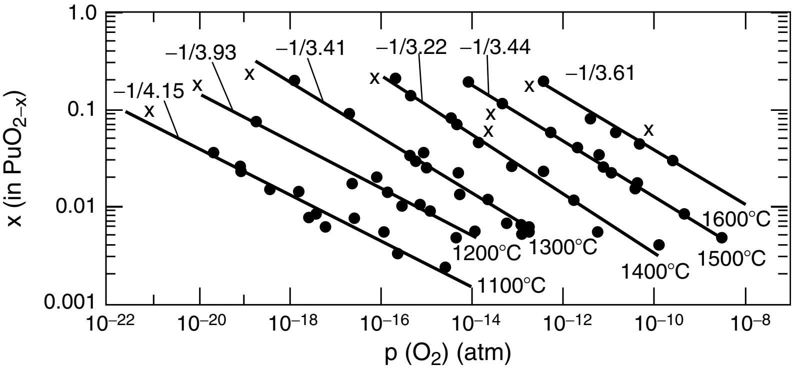

Fig. 7.89 *Variation of x in PuO_{2-x} with temperature and oxygen pressure (Atlas and Schlehman,* 1967*). Slopes (i.e.* –1/4.15, *etc.) of the log–log plots are shown above the lines. Experimental data points marked in x represent values derived from weight change measurements, whereas the circles represent gas-analysis results.*

1000°C in air. The Pu(III) oxalate is often preferred because it forms a powder that is easy to manipulate, while the Pu(IV) oxalate forms a tacky solid (see Section 7.9.1(e)i). The heating rate must be kept slow up to about 700°C to avoid rapid decomposition and gas evolution, followed by heating to 1000°C to remove any residual carbon. Drummond and Welch (1957) studied the stoichiometry of PuO_2 as a function of preparative history, and found that many materials need to be heated to 1250°C to produce reproducible stoichiometric PuO_2.

The method of preparation and process details have a significant influence on the PuO_2 product characteristics, which affect all subsequent uses of the material, such as fabrication and sintering properties of fuel materials containing PuO_2 or its behavior in long-term storage. PuO_2 is normally olive green, but it's observed color is a function of purity, particle size, method of preparation, stoichiometry, and possible reactions with water. The observed colors range from dull yellow, to green, khaki, buff, slate or black. Many of these samples are most likely hyperstoichiometric PuO_{2+x} (see section PuO_{2+x}). All samples turned to a darker, khaki color upon ignition to 1200°C. The qualitative characteristics of various PuO_{2+x} preparations obtained from different starting materials are summarized in Table 7.37 (Drummond and Welch, 1957).

Special preparations of PuO_2

Plutonium dioxide may be pressed and sintered to form pellets or compacts, which may be used in reactor technology or (in the case of $^{238}PuO_2$) in heat- and power-source technology for space exploration. For detailed descriptions, the reader is referred to the *Plutonium Handbook* (Wick, 1980). As an illustrative example of the general pellet-forming process, $^{238}PuO_2$ used to fabricate GPHS and LWRHU fuel pellets (see Section 7.3) for the Cassini mission was subjected to ^{16}O isotope exchange (to reduce neutron emission), ball milling, granulation and seasoning at 1100 and 1600°C to produce $^{238}PuO_2$ granules with <210 μm sized particles. The granules were then blended using those seasoned at

Table 7.37 *Qualitative characteristics of PuO_{2+x} from decomposition of selected materials at* 870°C (*Drummond and Welch,* 1957).

Material	*Color*	*Appearance*
metal	dull yellow	powder
sulfate	yellow-green to green	bulky powder
nitrate	dull yellow	bulky solid
chloride	dull yellow	powder
fluoride	khaki with black traces	granular solid
oxalate	yellow-buff	bulky powder
iodate	buff	very bulky
hydroxide	black with yellow traces	dense, shiny particles

1100°C (60 wt %) with those seasoned at 1600°C (40 wt %) by rolling the granules in a ball-mill jar without balls. After blending, the fuel charges were loaded into a hot press graphite die, placed under vacuum, and heated to 1530°C under a force of 11.8 kN. During hot pressing, the PuO_2 is reduced by the graphite die. After the pellets sat overnight, the PuO_{2-x} stoichiometry was about $PuO_{1.93}$. To oxidize the pellets back to a stoichiometry of PuO_2 and increase their density to meet mission specifications, the pellets were sintered in flowing $Ar–H_2{}^{16}O$ for 6 h at 1000°C, followed by 6 h at 1527°C (Rinehart, 1992, 2001).

Two other forms of PuO_2 also deserve a more detailed description: PuO_2 microspheres and single crystals. Plutonium dioxide microspheres with 10–250 μm diameter may be prepared by the sol-gel process for ^{239}Pu (Wymer and Coobs, 1967; Lloyd and Haire, 1968; Louwrier *et al.*, 1968; Wymer, 1968), ^{238}Pu (Grove *et al.*, 1965; Hass *et al.*, 1966; Hincks and McKinley, 1966), or MOX $(U, Pu)O_2$ (Vaidya *et al.*, 1983; Smolders and Gilissen, 1987; Stratton *et al.*, 1987). In this process, a stable Pu(IV) hydroxide sol is prepared by extraction or evaporation of HNO_3 from $HNO_3–Pu(NO_3)_4$ solution, injection of the resulting sol into a dehydrating organic solvent (for instance, 2-ethylcyclohexanol), and firing the resulting gel to form PuO_2 microspheres (Hass *et al.*, 1966; Lloyd and Haire, 1968; Wymer, 1968).

Very dense microspheres, which have a remarkable freedom from loose α-particle contamination, may be prepared by plasma spheroidization (Jones *et al.*, 1964). In this method, plutonium oxide is first compacted into pellets, which are fired at 1500°C for 1 h in an oxygen-enriched plasma to inhibit loss of oxygen during melting. The resulting compacts are ground to the desired mesh size, and are then fed into an induction-coupled plasma torch, which uses argon, oxygen, or $Ar–O_2$ mixtures as feed gas. In the high temperature of the plasma torch (up to 20,000°C), each plutonium oxide particle immediately melts to a small spherical droplet, which, upon leaving the plasma zone, immediately solidifies into a small sphere with a smooth surface. Depending on the particle size of the feed particles, microspheres from 10 to 250 μm may be obtained (Jones *et al.*, 1964).

Spheres with less than 50 μm diameter are amber-colored and have a clear, vitreous appearance. Those of more than 50 μm diameter do not transmit light and appear opaque black (Jones *et al.*, 1964). If prepared in an O_2 plasma, they have the lattice constants of stoichiometric PuO_2. Each individual sphere usually consists of a single crystal (Jones *et al.*, 1964).

Plutonium dioxide single crystals of considerable size have been prepared by several authors (Phipps and Sullenger, 1964; Schlechter, 1970; Finch and Clark, 1972; Rebizant *et al.*, 2000). Finch and Clark (1972) obtained PuO_2 single crystals from $Li_2O–2MoO_3$ melt in a temperature gradient ranging from 1270 to 1300°C in a tightly closed platinum vessel over a 2 week period. Crystals of 2 × 3 × 3 mm have been obtained in this fashion. Schlechter (1970) grew single crystals of approximately the same size by slow thermal decomposition of

$Pu(SO_4)_2$ either in LiCl–KCl eutectic or in $PbCl_2$–KCl melt at 600–800°C and subsequent cooling at a rate of 2.2°C h^{-1} from 715°C to room temperature. Phipps and Sullenger (1964) obtained PuO_2 single crystals with well-defined faces and edges up to 60 μm long when they prepared plutonium-bearing glass fibers by drawing the molten glass (90% SiO_2–30% Na_2O) from a platinum–rhodium bushing at 1300°C. $(U,Pu)O_2$ single crystals have been grown through a chemical transport reaction (Rebizant *et al.*, 2000).

Higher oxides, PuO_{2+x}, PuO_3, and PuO_4

While plutonium is capable of forming molecular compounds of oxidation state VI and VII, most practitioners have been of the opinion that in the plutonium–oxygen system, the stoichiometric tetravalent oxide $PuO_{2.0}$ represents the highest obtainable binary oxide. The historical basis for this opinion began in 1944, when Moulton (1944) observed that during ignition of plutonyl nitrate, only PuO_2 was formed, but no PuO_3 or any other higher oxide was produced. Moulton took this as evidence for the nonexistence of any oxide of composition higher than PuO_2. In 1953, Brewer (1953) predicted from thermodynamic calculations that any solid anhydrous oxide of plutonium higher than PuO_2 would probably not be stable. This view seemed to be confirmed by the work of Westrum (1949a), who used strongly oxidizing conditions (O_2 at 400°C and 70 atm pressure; ozone at 600–1000°C; atomic oxygen) but failed to oxidize PuO_2. Katz and Gruen (1949) also reported that PuO_2 is not oxidized to a higher oxide with NO_2 or atomic oxygen at 500°C. Moreover, Weigel and coworkers (Marquart *et al.*, 1983) attempted to prepare anhydrous PuO_3 by careful decomposition of PuO_2CO_3, $(NH_4)_2PuO_2(CO_3)_2$, and $PuO_3 \cdot 0.8H_2O$, but did not succeed in preparing any higher oxide. Gouder has attempted to prepare thin films of PuO_3 by reacting PuO_2 with oxygen atoms, and found no evidence for its formation (Gouder, 2005).

A number of recent reports on higher-valent oxides such as $PuO_{2.26}$ in the solid state, and PuO_3 and PuO_4 in the gas phase have challenged these traditional views. While not all of the data are consistent, and there are still disagreements among practitioners, these recent reports strongly suggest that the established views on the oxidation behavior of plutonium are worth reconsideration, and that additional detailed study is appropriate.

PuO_{2+x} As early as 1957, Drummond and Welch (1957) had prepared compositions of PuO_2–$PuO_{2.09}$, and concluded that compounds with O:Pu ratios higher than 2.0 were the result of low temperature ignition of plutonium compounds. Oxygen-rich PuO_2 can also be prepared by heating cubic C-Pu_2O_3 in oxygen at 1000°C, and the material formed in this manner displayed a slightly reduced lattice constant (a_0) of 5.382 Å as compared to 5.396 Å for stoichiometric PuO_2. It was possible that the higher O:Pu ratio in these preparations was attributed to excess oxygen dissolved in the crystal lattice. In other studies, mass changes indicating the formation of $PuO_{2.1}$ during

atmospheric corrosion of plutonium metal had been attributed to adsorption of water (Sackman, 1960).

These views remained widely held until Stakebake and coworkers found evidence for a new fluorite-related phase of composition $PuO_{2.17}$ formed as a surface layer by plutonium metal reaction with water vapor at 200–350°C (Stakebake *et al.*, 1993). XPS data were consistent with the presence of Pu(VI). Confirmatory evidence for the formation of a higher oxide was reported by Haschke *et al.* (2000a,b), who studied the reaction of PuO_2 with water vapor between 25 and 350°C. Mass spectroscopic analysis of the gases produced in this reaction showed that H_2 and H_2O were the only gaseous products and indicated that the reaction proceeds according to the reaction:

$$PuO_2(s) + xH_2O(g) \rightarrow PuO_{2+x}(s) + xH_2(g) \tag{7.37}$$

The final product approached a composition of $PuO_{2.3}$. XRD analyses of the reaction products revealed a single fcc phase with a fluorite-related structure and a slightly expanded lattice. The lattice expansion was accompanied by a linear increase in the O:Pu ratio, consistent with the formation of a solid-solution of PuO_{2+x} in analogy with UO_{2+x} (Allen and Tempest, 1986). Isothermal measurements showed that hydrogen is generated at linear, temperature-dependent rates from which the authors derived an activation energy (E_a) for the reaction of (39 ± 3) kJ mol^{-1}. This was interpreted as being consistent with a chemical reaction, and not with radiolysis, which is expected to be temperature-independent. It should be noted, however, that the rates observed for hydrogen evolution in the reaction of PuO_2 with water vapor at 25°C are in close agreement to the rate of hydrogen evolution observed during exposure of PuO_2 to aqueous salt solutions (Haschke *et al.*, 1983). The report of H_2 being the only gaseous product is not consistent with the observations of Vladimirova and Kulikov (2002), who reported the observation of both H_2 and O_2 in the gas phase during their study of the reaction of PuO_2 with sorbed water using high- and low-burnup plutonium, and therefore different radiolytic dose rates. Their data are consistent with the rates of formation of H_2 and O_2 being in direct proportion to the dose rate. They followed their reactions for 600 days, but did not report on the characterization of the oxide at the end of the experiment.

There is good agreement that water vapor reacts with PuO_2 to generate hydrogen. The generation of hydrogen in storage containers represents a significant safety concern (Haschke and Martz, 1998b), and has led to use of strict standards for stabilization, packaging, and storage of plutonium residue materials that require thermal stabilization using calcinations in air, followed by sealing the materials in nested welded stainless steel containers before storage or transport (Paffett *et al.*, 2003b).

Haschke and coworkers have suggested that the formation of explosive H_2–O_2 mixtures by reaction of water vapor with PuO_2 in air-filled containers is not possible because moisture-enhanced corrosion proceeds via a water-catalyzed cycle (Haschke *et al.*, 2001). In their proposed mechanism, water absorbs strongly on the oxide below 120°C and desorbs as the temperature is increased to 200°C. Dissociative adsorption of water forms surface OH^-, promotes the formation of PuO_{2+x}, and releases H_2. When O_2 is present, they propose a surface catalyzed H_2–O_2 recombination to form surface adsorbed water that then reacts to form PuO_{2+x}, and atomic H on the surface. In the absence of O_2, H atoms associate as H_2 as indicated in equation 7.37 above. Association of H atoms with dissociatively adsorbed oxygen reforms H_2O and prevents the accumulation of H_2 whenever O_2 is present. H_2 appears only after O_2 is depleted.

While this proposed mechanism is plausible, it remains speculative until more data are produced to confirm the proposed mechanisms or to establish an alternative mechanism. What is clear from the above discussion is that our understanding of plutonium oxide chemistry, particularly the associated surface reactions is clearly inadequate.

Gas phase PuO_3 and PuO_4 By analyzing data on transpiration experiments of plutonium oxide, Krikorian and coworkers found that the observed oxygen pressure could only be explained by the presence of a PuO_3 molecule in the gas phase (Krikorian *et al.*, 1997). The presence of gas-phase PuO_3 was confirmed by Ronchi and coworkers a few years later (Ronchi *et al.*, 2000). Knudsen-effusion experiments in combination with mass spectrometry were used to show that PuO_2(s) exposure to oxygen above 1800–1900°C produces gas-phase molecules of PuO_3, along with the expected PuO and PuO_2 gas-phase molecules. These workers concluded that formation of PuO_3(g) was not formed from a gas-phase reaction of PuO_2(g) with oxygen or carbon dioxide gases, but rather the product of a reaction of gaseous oxygen with the surface of the solid PuO_2. In another recent report, Domanov *et al.* (2002) heated PuO_2 in a stream of helium–oxygen and employed a thermogradient tube furnace to separate and condense the volatile components that were subsequently analyzed by α-detection. The data were interpreted as producing volatile or gas-phase PuO_3 and PuO_4. The latter species was expected to have an abnormally high volatility, close to that of OsO_4. As the partial pressure of oxygen was decreased, the yield of the proposed PuO_4 species decreased. These data, while indirect, are quite intriguing. The relationship between the volatile species observed by Domanov *et al.* to those reported by Krikorian *et al.* and Ronchi *et al.* is uncertain. Further study using mass spectrometry as a function of oxygen partial pressure would help to clarify whether gas phase PuO_4 really exists. The clear finding from these studies, however, is that plutonium oxides can exist in oxidation states higher than IV, at least in the gas phase. These findings clearly challenge the traditional view that PuO_2 is the terminal species.

(*iii*) *Solid-state structures*

A summary of crystallographic data for plutonium oxides is given in Table 7.36. The majority of solid-state structures of plutonium oxides are structurally related to the fluorite structure displayed by PuO_2. As a result of these structural similarities, we discuss the fluorite structure first to make the comparison with other oxide structures more understandable.

Cubic PuO_{2-x}

Plutonium dioxide forms a cubic fluorite phase over the composition range of PuO_{2-x}, where $0.4 < x < 0$. The cubic fluorite-type unit cell based upon CaF_2 is illustrated in Fig. 7.72. The lattice consists of an fcc arrangement of plutonium metal cations with O anions occupying most or all the four-fold tetrahedral sites, while the six-fold octahedral sites are vacant. In this structure, when $x = 0$, each plutonium atom is surrounded by eight oxygen atoms at the corners of a cube. Each cubic PuO_8 coordination polyhedron shares an edge with each of 12 neighboring PuO_8 polyhedra as shown in Fig. 7.90a. In this high-symmetry environment, all the Pu–O distances are the same. For a lattice parameter $a_0 = 5.396$ Å, this corresponds to a Pu–O distance of 2.337 Å, and a Pu–Pu distance of 3.816 Å. When $x > 0$, there are disordered oxygen vacancies.

Cubic C-Pu_2O_3

The C-Pu_2O_3 form of the sesquioxide displays the bcc Mn_2O_3 structure that is related to the fluorite structure with a doubled unit cell. The unit cell of the C-type sesquioxide can be considered as consisting of eight fluorite unit cells [a_0(bcc) = $2a_0$(fcc)] from which one-fourth of the oxygen atoms have been removed in an ordered way, and with the metal positions remaining almost unchanged from their fcc positions. The local coordination of the plutonium atom decreases from eight to six, and the PuO_8 cubes become PuO_6 octahedra but now with two types of plutonium atom. For one-fourth of the plutonium atoms, these missing oxygen atoms are at the ends of a body diagonal of the original PuO_8 cube, and for the other three-fourths they are at the ends of a face diagonal. Both PuO_6 coordination groups may be described as distorted octahedral, and each oxygen atom is four-coordinate and approximately tetrahedral. For cubic Pu_2O_3 with $a = 11.02$ Å, one plutonium atom has six equidistant Pu–O distances of 2.367 Å, and another plutonium atom has three pairs of Pu–O distances of 2.342, 2.360, and 2.383 Å. A comparison of the cubic PuO_2 and Pu_2O_3 structures is shown in Fig. 7.90.

Hexagonal A-Pu_2O_3

The A-type hexagonal sesquioxide formed at elevated temperatures displays the A-La_2O_3 crystal structure, typical of light lanthanide sesquioxides (Haire and Eyring, 1994). A striking feature of the hexagonal A-Pu_2O_3 structure is the highly unusual seven-coordination of the plutonium atoms. This gives three different Pu–O distances, three at 2.359, one at 2.353, and three at 2.623 Å. The local PuO_7 geometry is that of a mono-capped octahedron. Actually, there is also an eighth oxygen atom below the opposite face, but a much greater distance of 3.605 Å. This last oxygen atom, together with the seven in the PuO_7

polyhedron forms a distorted cube. These distorted cubes form the basis of the representation given for the A-type lattice given in Fig. 7.91.

Intermediate oxide structures, PuO_{2-x}

Intermediate oxides that display O:Pu stoichiometries between 1.5 and 2.0 (or those with stoichiometry between Pu_2O_3 and PuO_2) are not well characterized for plutonium. In general, intermediate oxides are common to both lanthanides and actinides, although their properties are much better established for the lanthanides. Since both sesquioxides and dioxides are known for plutonium, it is reasonable to assume that plutonium can form a homologous series of intermediate mixed-valent oxide phases Pu_nO_{2n-2} in analogy with the lanthanides. Unfortunately, very few data exist in this stoichiometry region for plutonium, though it is known that heavier actinides, americium, curium, berkelium, and californium form some members of an intermediate An_nO_{2n-2} series

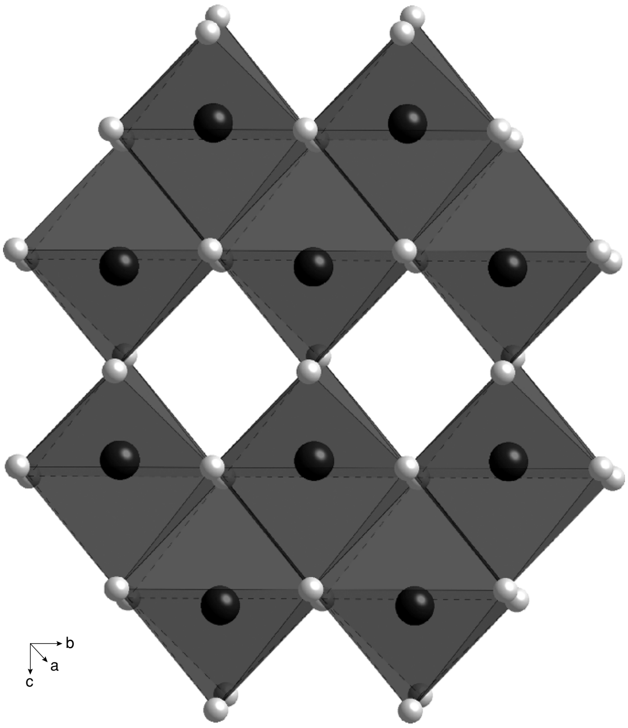

Fig. 7.91 *A polyhedral representation of a layer of the hexagonal A-type* Pu_2O_3 *emphasizing the hexagonal arrangement of Pu atoms. The local coordination environment around Pu has eight near neighbors, giving a highly distorted* PuO_8 *cube. Plutonium atoms are black and oxygen atoms are gray.*

(Haire and Eyring, 1994). Since Pu_2O_3 will take up oxygen to yield a hyperstoichiometric sesquioxide, and PuO_2 will lose oxygen to give a substoichiometric dioxide, the potential for such a series is most intriguing. Upon comparison of the ionic radii and relative free energies of the trivalent and tetravalent oxidation states of plutonium with those of cerium and praseodymium, Haschke concluded that such a mixed-valence series should be stable, and reported data from oxygen titration experiments in which the existence of a series Pu_nO_{2n-2} with $n = 5, 7, 9, 10$, and 12 was inferred (Haschke, 1992). Since the solid phases were not identified, the existence of the Pu_nO_{2n-2} series is not definitive, but clearly this is another area in which more detailed study is warranted.

The possibility of the existence of an intermediate oxide series of formula Pu_nO_{2n-2} is strongly suggested by structural principles established for the more well-studied cerium and praseodymium systems, and forms the basis of the pedagogical phase diagram introduced by Hashke and coworkers (Haschke *et al.*, 2000a), shown in Fig. 7.92. In the structural model upon which this phase diagram is based, there is an fcc array of plutonium atoms in which all (and only) the tetrahedral interstices are occupied with oxygen atoms to form the end-member PuO_2. The intermediate phase compositions and structures are realized by omission of oxygen atoms in a regular way. Except for small shifts away from the vacant oxygen sites, the metal atoms maintain their fcc positions, and this leads to a homologous series Pu_nO_{2n-2} where Pu_2O_3 is the other end-member. Since Pu_2O_3 has a bcc structure, this end-member corresponds to $n = 4$ (Pu_4O_6). With this understanding, it is easy to rationalize the phase diagram of Fig. 7.92. There is a stoichiometric hexagonal sesquioxide (O:Pu = 1.5); a cubic sesquioxide with some vacancies occupied by oxygen (O:Pu = 1.5–1.7), showing variable lattice parameters; an oxide phase corresponding to the Pu_nO_{2n-2} homologous series (rhombohedral, narrow stoichiometry range); a substoichiometric fcc dioxide (O:Pu = 1.8–2.0) with variable and larger lattice parameter than the stoichiometric dioxide; and the stoichiometric and hyperstoichiometric dioxide. Like in the lanthanide systems, the intermediate oxides merge into a continuous PuO_{2-x} solid solution above 700°C. Whether the plutonium oxide system actually contains all of these

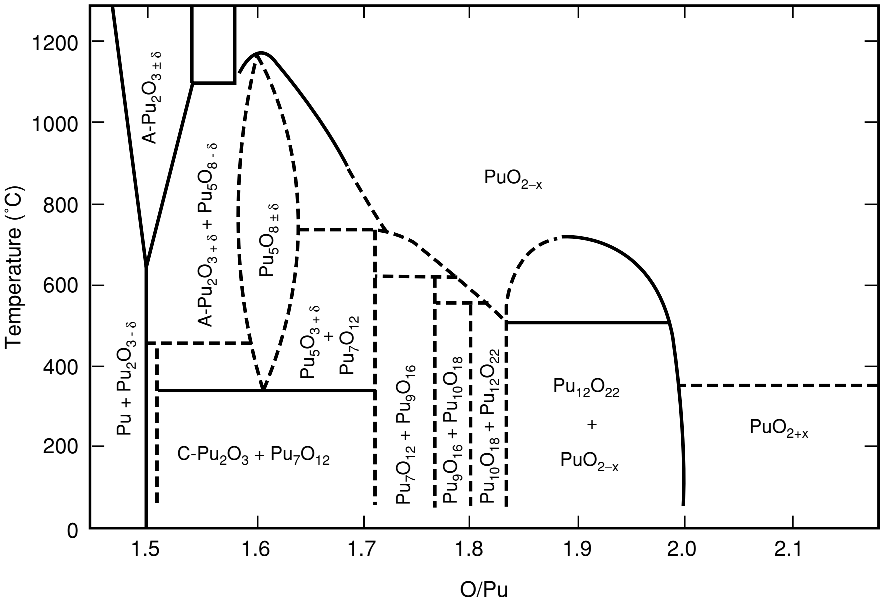

Fig. 7.92 *A pedagogical plutonium–oxygen phase diagram introduced by Hashke and Haire* (2000), *and based upon structural principles established for the more well-studied Ce and Pr oxide systems* (*Haschke* et al., 2000*a*).

features and closely resembles the lanthanide system will require more extensive study.

PuO_{2+x} structural studies

XRD analysis of the products of reaction between PuO_2 and water vapor show a single fcc phase with a fluorite-related structure with an expanded lattice. After reaching a minimum of 5.3975 Å at $PuO_{2.00}$, the lattice parameter increases over a narrow stoichiometry range, consistent with an initial stepwise expansion of the lattice and then a gradual increase with increasing oxygen composition. Results for O:Pu in the 2.016–2.169 range follow Vegard's law, implying that the oxide is a continuous PuO_{2+x} solid solution with a lattice constant given by:

$$a_0 = 5.3643 + 0.01764 \text{ O} : \text{Pu} \tag{7.38}$$

Once the PuO_2 stoichiometry is reached, the lattice parameter is not very sensitive to composition, as shown in Fig. 7.93. Haschke and coworkers proposed that the additional oxygen atoms are accommodated in the vacant octahedral sites in the fluorite lattice, and that charge balance is maintained by replacing Pu(IV) with a higher oxidation state plutonium cation. Initial XPS data were interpreted as being consistent with Pu(VI), but more recent XANES spectroscopy has been interpreted as indicating the presence of Pu(V) (Conradson *et al.*, 2003). Recent EXAFS studies indicate that the original proposal of oxygen atoms in octahedral sites is far too simplistic (Conradson *et al.*, 2004b), and warrants further discussion.

Conradson and coworkers investigated 24 PuO_{2+x} samples prepared by a variety of methods including heterogeneous oxidation of plutonium metal and PuO_2 with gaseous H_2O and/or O_2, and by the hydrolysis and precipitation of the aqueous Pu(IV) ion (Conradson *et al.*, 2003, 2004b). Fourier transforms (FT) of the EXAFS data for selected plutonium oxide compounds are shown in Fig. 7.94. For stoichiometric, ordered $PuO_{2.0}$ the first peak in the Fourier transform is the contribution of the eight nearest neighbor oxygen atoms at 2.33 Å, well separated from the more distant second nearest neighbor peak of 12 plutonium atoms at 3.80 Å (the peaks in Fig. 7.94 are all phase-shifted to lower R). Regular features from the well-ordered extended structure subsequently continue to a very high distance from the central absorbing atom. This spectrum is therefore consistent with the crystal structure of stoichiometric PuO_2 shown in Fig. 7.90a.

However, as x increases from $PuO_{2.00}$ to $PuO_{2.26}$, the amplitudes of all of the peaks in the Fourier transform decrease monotonically, indicative of diminished order via displacements of the plutonium and oxygen atoms from their lattice sites coupled to the incorporation of the nonstoichiometric oxygen atoms into interstitial, essentially defect sites. What contradicts the current models in this process is the splitting of the first oxygen shell in the EXAFS (clearly evident

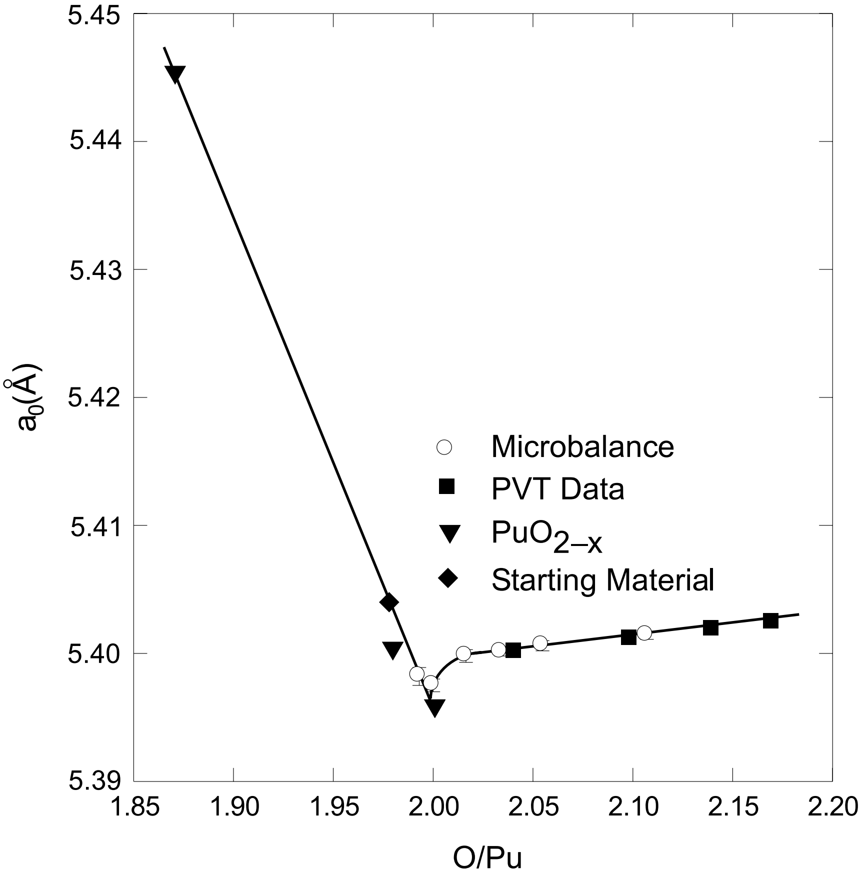

Fig. 7.93 *Variation of the cubic lattice parameter* (a_0) *of* $PuO_{2\pm x}$ *with O:Pu ratio at* 25°C. *Data for* PuO_{2-x} *are shown by gray triangles, microbalance data by open circles, and PVT data by solid squares* (*Haschke* et al., 2000*b*).

in Fig. 7.94) and the appearance of a short Pu–O bond distance of 1.84 Å. Traditional diffraction techniques that probe long-range order have never observed this phenomenon, but the bond distance is similar to the 1.85 Å distance found in axial Pu=O bonds in molecular Pu(v) compounds. Indeed, XANES results were interpreted as being consistent with a mixture of Pu(ɪv) and Pu(v). Combined, these data suggest that as the plutonium center becomes partially oxidized in PuO_{2+x}, there is a strong driving force to form short, strong, covalent Pu=O bonds.

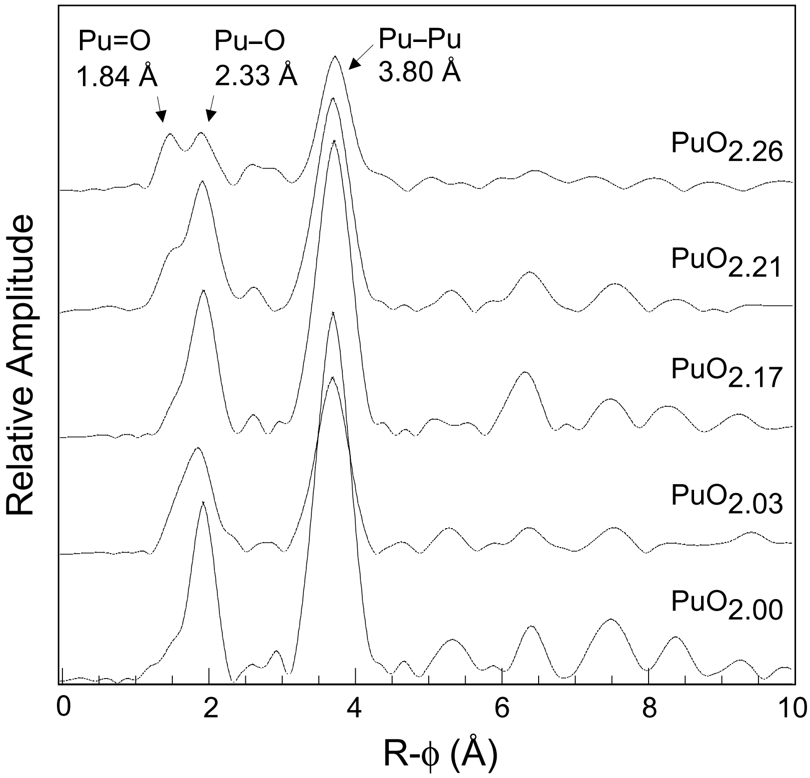

Fig. 7.94 *A comparison of k^3-weighted EXAFS moduli of PuO_{2+x} samples as indicated, and all data are taken from Conradson* et al. (2004*b*). *The peak positions are phase-shifted to lower distance from the actual Pu–O or Pu–Pu distances.*

These data also show that the plutonium atoms retain their essentially fcc positions, and while the plutonium sublattice retains its order through the progression of $PuO_{2.00}$ to $PuO_{2.26}$, the nearest-neighbor oxygen atoms are found in a multisite distribution. In addition to Pu–O distances of 2.33 Å, the additional oxygen atom in PuO_{2+x} generates new bonds both shorter and longer than the 2.33 Å value. These new Pu–O distances were tentatively assigned to bridging O^{2-}/OH^- (2.13, 2.28 Å) and possibly H_2O (2.41 Å) ligands. Based on these observations, Conradson *et al.* suggest that the oxidation produces linear PuO_2^+ moieties that are aperiodically distributed through the lattice, and suggest several structural models that would be consistent with all the observations (Conradson *et al.*, 2004b). Finally, recent XPS results indicate a hydroxylated surface in PuO_{2+x} samples whose thickness depends on exposure conditions (temperature, partial pressure of H_2O) (Paffett *et al.*, 2003a). Much more study in this area is expected in the coming years.

The original report of PuO_{2+x} and its relevance to long-term storage of plutonium through H_2 gas generation has prompted several theoretical studies of this material. To study the electronic structure of PuO_{2+x} with $x = 0.25$, a periodic supercell consisting of four PuO_2 formula units has been used, constituting the conventional fluorite cubic cell of Pu_4O_8 (as shown in Fig. 7.71 for PuH_2). The additional oxygen atom was placed on the octahedral interstitial site, giving rise to a hypothetical Pu_4O_9 compound. Employing a self-interaction correction local spin density method, Petit *et al.* (2003) concluded that stoichiometric PuO_2 displays Pu(IV) with a localized f^4 shell. When oxygen is introduced into the octahedral interstitial site, the nearby plutonium atoms turn into Pu(V) (f^3) by transferring electrons to the oxygen. Oxygen vacancies cause Pu(III) (f^5) to form by taking up electrons released by oxygen (Petit *et al.*, 2003). In another DFT study, Korzhavyi *et al.* (2004) find a similar result, and calculate the thermodynamics for reactions of PuO_2 with either O_2 or H_2O to form PuO_{2+x}. In both cases the reactions are endothermic, i.e. to occur they require a supply of energy. However, the calculations also show that PuO_{2+x} can be formed as an intermediate product by reaction with H_2O radiolysis products such as H_2O_2. While the placement of the interstitial oxygen atom in the octahedral hole of a hypothetical Pu_4O_9 system is not consistent with the experimental findings for PuO_{2+x}, they are consistent with the formation of Pu(V), and offer insights to guide further experimental study.

Penneman and Paffet applied Zachariasen's classic bond strength–bond length relationships (Zachariasen, 1954a,b) to the Pu_4O_9 ($PuO_{2.25}$) entity to suggest that a better description is Pu_4O_8OH containing Pu(V) ions (Penneman and Paffett, 2004, 2005). Bond strength–bond length arguments justify the location of a hydroxide ion, rather than a central oxide ion, in a plutonium dioxide structure, providing an alternative interpretation for the experimental data on plutonium dioxide oxidation by water.

(*iv*) *Properties of plutonium oxides*

Oxygen diffusion

Fluorite-related lanthanide oxides exhibit unusual diffusional properties in that the oxygen substructure (excess interstitial oxygen ions and oxygen vacancies) is mobile below 300°C, which places them in the category of fast-ion conductors (Haire and Eyring, 1994). In actinide oxides of the fluorite structure, interstitial excess oxygen ions and oxygen vacancies are extremely mobile with diffusion rates similar to those of other fluorite-type superionic conductors (Matzke, 1982). Chemical diffusion measurements on PuO_{2-x} reveal relatively high values for diffusion coefficients (Bayoglu and Lorenzelli, 1984), and activation energies in the vicinity of 46 kJ mol^{-1}, which is very close to the migration energy of anion vacancies in UO_{2-x} (49 kJ mol^{-1}) (Chereau and Wadier, 1973; Bayoglu and Lorenzelli, 1979).

For stoichiometric PuO_2, oxygen diffusion has been studied by gas-phase isotope exchange by Bayoglu and coworkers, and by Deaton and Wiedenheft who obtained activation energies of 177 and 187 kJ mol^{-1}, respectively (Deaton and Wiedenheft, 1973; Bayoglu *et al.*, 1983). Murch and Catlow (1987) have suggested that since oxygen interstitials in PuO_2 are almost certainly less mobile than oxygen vacancies, one can assume that the activation energy for oxygen diffusion in stoichiometric PuO_2 can be partitioned into two parts, given by

$$Q = H_F/2 + H_v^m \tag{7.39}$$

where H_v^m is the anion vacancy migration enthalpy and H_F is the enthalpy for anion Frenkel defect formation. With H_v^m given by 46 kJ mol^{-1}, the Frenkel energy is given by 262–282 kJ mol^{-1}.

Melting behavior

The melting behavior of the individual plutonium oxides has been studied by many authors (Holley *et al.*, 1958; Pijanowski and DeLucas, 1960; Chikalla *et al.*, 1962, 1964; Lyon and Baily, 1965, 1967; Chikalla, 1968; Riley, 1970), and has been thoroughly reviewed (IAEA, 1967; Wriedt, 1990; Lemire *et al.*, 2001).

Stoichiometric hexagonal A-Pu_2O_3 ($PuO_{1.50}$) was found to have a melting point of 2085 ± 25°C (Chikalla *et al.*, 1962, 1964), which agrees well with the value of 2075°C reported by Riley (1970). The value of 2080°C was adopted by the IAEA review panel (IAEA, 1967), and by Wriedt (1990) in their reviews.

No melting point can be reported for cubic C-Pu_2O_3 ($PuO_{1.52}$), since this compound undergoes a solid-state peritectoid decomposition to A-Pu_2O_3 ($PuO_{1.5}$) and C′-Pu_2O_3 ($PuO_{1.6+\delta}$) at 450°C (Wriedt, 1990). No melting point for C′-Pu_2O_3 ($PuO_{1.6+\delta}$) can be reported as it transforms congruently to PuO_{2-x} above a temperature of about 1180°C (Wriedt, 1990).

The melting point of PuO_{2-x} depends on the O:Pu ratio. For stoichiometric $PuO_{2.00}$, a number of values have been reported; however, the best values are thought to be those reported by Lyon and Baily (1965, 1967), who found 2390 ± 20°C, or Aitken and Evans (1968) who found a value of 2445°C. These experiments were performed on specimens sealed in tungsten capsules to prevent loss of oxygen. Wriedt (1990) proposed a value of 2445°C, and Adamson *et al.* (1985) recommend the intermediate value of 2428°C.

Vaporization behavior

The plutonium oxide vaporization process is extremely complicated because the solid undergoing vaporization changes its composition during the process. The majority of vapor pressure measurements of plutonium oxides have been carried out by the Knudsen-effusion method (Phipps *et al.*, 1950b; Mulford and Lamar, 1961; Paprocki *et al.*, 1962a; Pardue and Keller, 1964; Ackermann *et al.*, 1966; IAEA, 1967; Capone *et al.*, 1999), with the notable exception of a few mass spectrometry reports (Battles *et al.*, 1968, 1969; Battles and Blackburn, 1969; Kent, 1973). All these data have been reviewed (Wriedt, 1990). The results of these measurements are often conflicting because the condensed oxide phase PuO_{2-x} is at its congruent vaporizing composition, which varies with temperature. When inert containers are used, solid PuO_2 that has a higher O:Pu ratio than the congruent composition will produce vapor with relatively high concentrations of PuO_2(g), O_2(g), and O(g). In contrast, compositions with a lower O:Pu ratio than the congruent composition will produce relatively high concentrations of PuO(g) (Wriedt, 1990). Thus, the early Knudsen measurements yield insufficient information to explain the vaporization behavior of PuO_2 and PuO_{2-x} in detail.

Battles and coworkers (Battles *et al.*, 1968, 1969; Battles and Blackburn, 1969) have determined the species that occur in the vapor of PuO_{2-x} and in the vapor over the binary condensed phase mixture of Pu_2O_3 and $PuO_{1.61}$ over a period of 20 hours. A typical set of data is shown in Fig. 7.95.

In the case of single-phase material, it was found that initially stoichiometric $PuO_{2.00}$ slowly turns into $PuO_{1.831}$ and retains the latter composition. In the vapor, the species PuO_2^+ (g) and PuO^+(g) were observed. At 2219 K the partial pressures of Pu(g) and of O(g) were calculated to be 2.6×10^{-9} and 2.6×10^{-7} atm, respectively. The mass spectrometry results (Battles *et al.*, 1968, 1969; Battles and Blackburn, 1969; Kent, 1973) are in good agreement with those measured by effusion in open containers by Ackermann and coworkers (Ackermann *et al.*, 1966). Partial pressures of O(g), O_2(g), Pu(g), PuO(g) and PuO_2(g) have been tabulated for various PuO_{2-x} compositions and temperatures (Kent and Zocher, 1976; Green *et al.*, 1983).

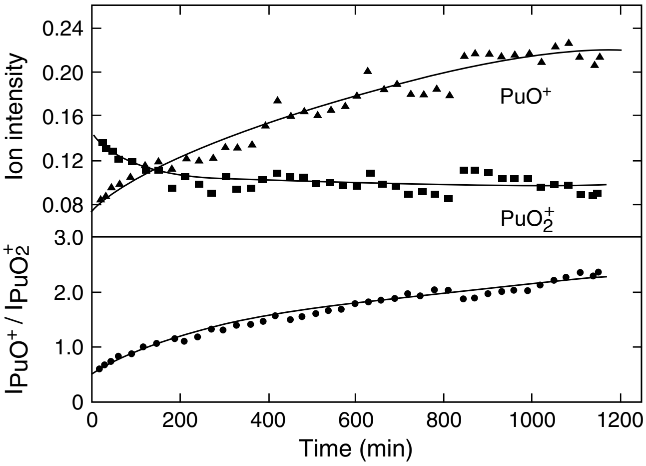

Fig. 7.95 *Mass spectroscopic intensities of gaseous* PuO_2^+ *and* PuO^+, *and the ratio of intensities* $I_{PuO^+}/I_{PuO_2^+}$ *as a function of time at* 2225 K (*Battles* et al., 1968, 1969).

More recently, Krikorian and coworkers suggested that heating PuO_2 in the presence of oxygen produced the PuO_3 molecule in the gas phase (Krikorian *et al.*, 1997), and this was definitively proven by Ronchi and coworkers who used Knudsen-effusion experiments in combination with mass spectrometry to show that PuO_2 exposure to oxygen above 1800–1900°C produces a gas phase molecule PuO_3, along with the expected PuO and PuO_2 gas phase molecules (Ronchi *et al.*, 2000).

Thermodynamic properties of plutonium oxides

The thermodynamic properties of the plutonium oxides have been studied and assessed by numerous authors, and the reader is directed to extensive compilations by Rand (1966), IAEA (1967), Wriedt (1990), and the recent OECD-NEA review of plutonium and neptunium thermodynamics (Lemire et al., 2001). A summary of the most recent OECD-NEA selected thermodynamic data for plutonium oxides is given in Table 7.38.

Stoichiometric Pu_2O_3 ($PuO_{1.5}$) Flotow and Tetenbaum (1981) measured the low-temperature heat capacity from –265 to 77°C on a sample of $^{242}Pu_2O_3$. The heat capacity (C°_p) and entropy (S°) at standard conditions derived from their data were selected by the OECD-NEA reviewers, and are given in Table 7.38 (Lemire *et al.*, 2001). Estimates of the heat capacity of Pu_2O_3 at higher temperatures have been given by IAEA (1967), Glushko (1982), and Besmann and Lindemer (1983). The NEA reviewers recommended the following expressions for heat capacity of Pu_2O_3 over two separate temperature ranges.

(298.15 – 350K)

$$C^\circ_p = 169.466 - 79.98 \times 10^{-3} T - 25.459 \times 10^5 T^{-2} \text{J K}^{-1}\text{mol}^{-1} \quad (7.40)$$

(350 – 2358K)

$$C^\circ_p = 122.953 + 28.548 \times 10^{-3} T - 15.012 \times 10^5 T^{-2} \text{J K}^{-1}\text{mol}^{-1} \quad (7.41)$$

There are no direct measurements of the enthalpy of formation of Pu_2O_3. The value has been derived indirectly from the partial molar Gibbs energies and enthalpies of oxygen in the single-phase oxides Pu_2O_3 and PuO_2, and the two-phase fields between these phases. A thorough discussion of the data and measurement techniques is available in the most recent reviews (IAEA, 1967;

Table 7.38 *Thermodynamic parameters for plutonium oxides* (*Lemire* et al., 2001).

Compound	$\Delta_f G^\circ_{298}$ (kJ mol^{-1})	$\Delta_f H^\circ_{298}$ (kJ mol^{-1})	S°_{298} (J K^{-1} mol^{-1})	C°_{p298} (J K^{-1} mol^{-1})
Pu_2O_3	−1580.4 ± 10.1	−1656.0 ± 10.0	163.0 ± 0.6	117.0 ± 0.5
$PuO_{1.61}$	−834.8 ± 10.1	−875.5 ± 10.0	83.0 ± 5.0	61.2 ± 5.0
PuO_2	−998.1 ± 1.0	−1055.8 ± 1.0	66.13 ± 0.26	66.25 ± 0.26

Wriedt, 1990; Lemire *et al.*, 2001). The recommended values for the enthalpy and Gibbs energy of formation are listed in Table 7.38.

Hyperstoichiometric $PuO_{1.52}$ (*C*-Pu_2O_3) The only thermodynamic data for this phase are the enthalpies of combustion reported by Chereau *et al.* (1977). Their values correspond to an enthalpy of formation of –845 kJ mol^{-1} (Lemire *et al.*, 2001).

Hyperstoichiometric $PuO_{1.6+\delta}$ No experimental data are available. Thermodynamic functions were estimated by NEA reviewers (Lemire *et al.*, 2001).

Stoichiometric $PuO_{2.00}$ The thermodynamic properties of stoichiometric $PuO_{2.00}$ have been the subject of a large number of studies (Sandenaw, 1963; Pardue and Keller, 1964; Ackermann *et al.*, 1966; Rand, 1966; Kruger and Savage, 1968; Engel, 1969; Ogard, 1970; Flotow *et al.*, 1976), and have been extensively reviewed (IAEA, 1967; Cordfunke *et al.*, 1990; Wriedt, 1990; Carbajo *et al.*, 2001; Lemire *et al.*, 2001).

To overcome difficulties performing low-temperature heat capacity measurements on $^{239}PuO_2$, Flotow *et al.* (1976) performed studies with the less radio active isotopes $^{242}PuO_2$ and $^{244}PuO_2$ to avoid problems associated with radiation damage of the solid for low temperatures up to 350 K. These measurements are thought to provide the most reliable values for standard heat capacity (C_p°) and entropy (S°). Their values were selected by the NEA review, and are listed in Table 7.38. High-temperature measurements of enthalpy were measured by Kruger and Savage (1968), Engel (1969), Ogard (1970), and Oetting (1982). Fink (1982) used these data to derive a complex expression for heat capacity, and these were refit to polynomials by Cordfunke *et al.* (1990). The Fink expressions were recently modified by the NEA review to give the following polynomial expression over the temperature range 298.15–2500 K (Lemire *et al.*, 2001):

$$\begin{aligned} C_p^\circ = {} & 84.495 + 10.639 \times 10^{-3} T - 6.1136 \times 10^5 T^2 \\ & - 19.00564 \times 10^5 T^{-2} \text{J K}^{-1}\text{mol}^{-1} \end{aligned} \tag{7.42}$$

The original polynomial functions derived by Fink are far more complex than the NEA modification, and for more information the reader is referred to the original Fink citation (Fink, 1982) or a recent review by Carbajo *et al.* (2001).

There is good agreement between authors on the values for the enthalpy and Gibbs free energy (Holley *et al.*, 1958; Glushko, 1982). The values accepted by the NEA review are given in Table 7.38 (Lemire *et al.*, 2001).

Chemical properties of plutonium oxides

Dissolution of PuO_2 PuO_2 that has been ignited at high temperatures is difficult to dissolve. Christensen and Maraman (1969), Gilman (1965, 1968), Ryan and Bray (1980), and Nikitina *et al.* (1997a,b), have reviewed the methods reported. In general, the rate of dissolution for each reagent often depends on the ignition temperature used to prepare the oxide and on the previous history of the sample. The reagent most frequently used is a boiling mixture of 16 M HNO_3 with 1 M HF as a fluoride complexant. Instead of HF, H_2SiF_6, or Na_2SiF_6 may also be used. High-temperature fired PuO_2 is dissolved only slowly. Irradiated PuO_2 dissolves better, the rate of dissolution being higher, the higher the burnup.

The difficulty in dissolving PuO_2 has led to the search for aggressive approaches to achieve dissolution, such as the use of fused salts (Harvey *et al.*, 1947; Feldman, 1960; Crocker, 1961), dioxygen difluoride, O_2F_2 (Malm *et al.*, 1984), or krypton difluoride, KrF_2 (Asprey *et al.*, 1986). Dioxygen difluoride, and krypton difluoride react readily with PuO_2 to form PuF_6 and/or PuO_2F_2, but this approach has not been pursued on a large scale because of the extreme difficulty in handling KrF_2 and O_2F_2. Two major improvements to the dissolution of PuO_2 have recently appeared. They are based on the electrochemical oxidative dissolution in HNO_3 with Ag(II) as a catalyst (Bourges *et al.*, 1986; Sakurai *et al.*, 1989, 1993; Madic *et al.*, 1992), and oxidative dissolution catalyzed by Ce(IV) in the presence of anions of oxygen-containing acids of group IV–VII elements (Horner *et al.*, 1977; Scheitlin and Bond, 1980). The kinetics and mechanism of these processes and their use for dissolving plutonium from recycled products and wastes have been reviewed (Nikitina *et al.*, 1997a).

Compatibility with Container Materials Because of its importance as a nuclear reactor and heat source fuel, the compatibility of PuO_2 with refractory materials (both metals and ceramics) has been extensively studied. Paprocki *et al.* (1962b) studied the chemical reactions of plutonium dioxide with reactor materials.

An extensive study of the compatibility of $^{238}PuO_2$ with container materials has been reported by Selle *et al.* (1970a,b). They studied the reactions of $^{238}PuO_2$ with container materials such as tantalum, molybdenum, tungsten, rhenium, platinum, rhodium, and their alloys in the temperature range 1000–2500°C and for time periods up to 532 days. For the results, the reader is referred to the comprehensive original reports. Such studies have led to the use of iridium–0.3% tungsten alloys for encapsulation of $^{238}PuO_2$ general-purpose heat sources, and Pt–30%Rh alloys for encapsulation of $^{238}PuO_2$ light weight radioisotope heater units (see Section 7.3).

(b) The plutonium–sulfur, -selenium, and -tellurium systems

With heavier chalcogen elements (X = S, Se, and Te), plutonium forms binary compounds in four basic families (Table 7.39) with the highest-order composition being PuX_3 that is only found for tellurium. All the heavy chalcogen

elements form the series of substoichiometric complexes PuX_{2-x}. For the sesquichalcogenides of formula Pu_2X_3, sulfur forms an α-phase, all the chalcogenides form a γ-phase, while selenium and tellurium form an η-phase. All the heavier chalcogenides form the simple binary PuX.

(*i*) *Preparation*

All of the heavier chalcogenide compounds of plutonium can be prepared by gas–solid reaction between the appropriate stoichiometry of plutonium hydride (PuH_x) and chalcogen element in quartz tubes sealed under secondary vacuum (Damien, 1973, 1976; Damien and De Novion, 1981; Damien *et al.*, 1986). After a typical reaction time of 1 week at 350–750°C, the dichalcogenide, PuX_{2-x} is formed. Compounds with lower X/Pu ratio can be prepared by thermal decomposition of PuX_{2-x} in a sealed tube where one end is kept outside the furnace to allow for the deposition of the chalcogen element. The monochalcogenide, PuX requires much-higher temperature for formation. Typically the quartz tube is heated to 800°C, and the products are pressed into pellets and sintered at 1200–1600°C. This approach works for all the chalcogenide elements except tellurium. Reaction of plutonium hydride with excess tellurium under high vacuum at 350°C for 1 week produces $PuTe_3$ (Damien, 1973). The plutonium tritelluride undergoes decomposition in a stepwise fashion to produce $PuTe_{2-x}$ at 400°C, η-Pu_2Te_3 at 700°C, and γ-Pu_2Te_3 at 900°C (Allbutt *et al.*, 1970; Damien, 1973).

In addition to preparation using plutonium hydride, all the plutonium chalcogenides (sulfur, selenium, tellurium) may be prepared by direct synthesis from the elements (Gorum, 1957; Marcon and Pascard, 1966a,b; Kruger and Moser, 1967a; Marcon, 1969; Wastin *et al.*, 1995). For volatile compounds, the reactions may be carried out in two- or three-zone vacuum-sealed quartz tubes that are placed in a temperature gradient resistance furnace (Spirlet, 1982; Spirlet and Vogt, 1982). The product stoichiometry and phase is controlled by the reaction temperature and stoichiometry of reactants. For compounds that are not highly volatile, excellent results have been obtained when using levitation melting in an induction coil or in a Hukin magnetic levitation cold crucible, by semilevitation melting on a pedestal, or by arc melting (Wastin *et al.*, 1995).

There are other methods for preparation of a few specific plutonium chalcogenide. In the early work of Abraham *et al.* (1949b), PuS was accidentally obtained when PuF_3 was reduced with Ca vapor in a BaS crucible at 1250°C. High-purity PuS may also be obtained when compact plutonium metal is first reacted to give the hydride, the hydride is ground to powder in an inert-gas atmosphere, and, after decomposition to the metal, is reacted with H_2S. A similar reaction of the plutonium hydride with H_2S may also be used to prepare α-Pu_2S_3. Finally, PuSe can be obtained by reacting a higher selenide with plutonium metal (Marcon, 1969).

(*ii*) *Solid-state structures*

Crystallographic properties of binary plutonium chalcogenides are summarized in Table 7.39.

Plutonium tritelluride crystallizes in the orthorhombic $NdTe_3$ structure type (Norling and Steinfink, 1966; Damien, 1973). In this structure, the unit cell contains 12 planar layers each consisting of a single type of atom. Since the separation between the plutonium and tellurium layers is about 0.9 Å, the two layers can be considered as a single puckered layer. In this way, the structure can be described as consisting of four puckered Pu–Te layers and four densely packed tellurium layers. Each plutonium atom is surrounded by nine near-neighbor tellurium atoms, and the $PuTe_9$ coordination polyhedron approximates a capped square antiprism with a distortion of the plutonium atom out of the center of the tellurium prism, as depicted in Fig. 7.96.

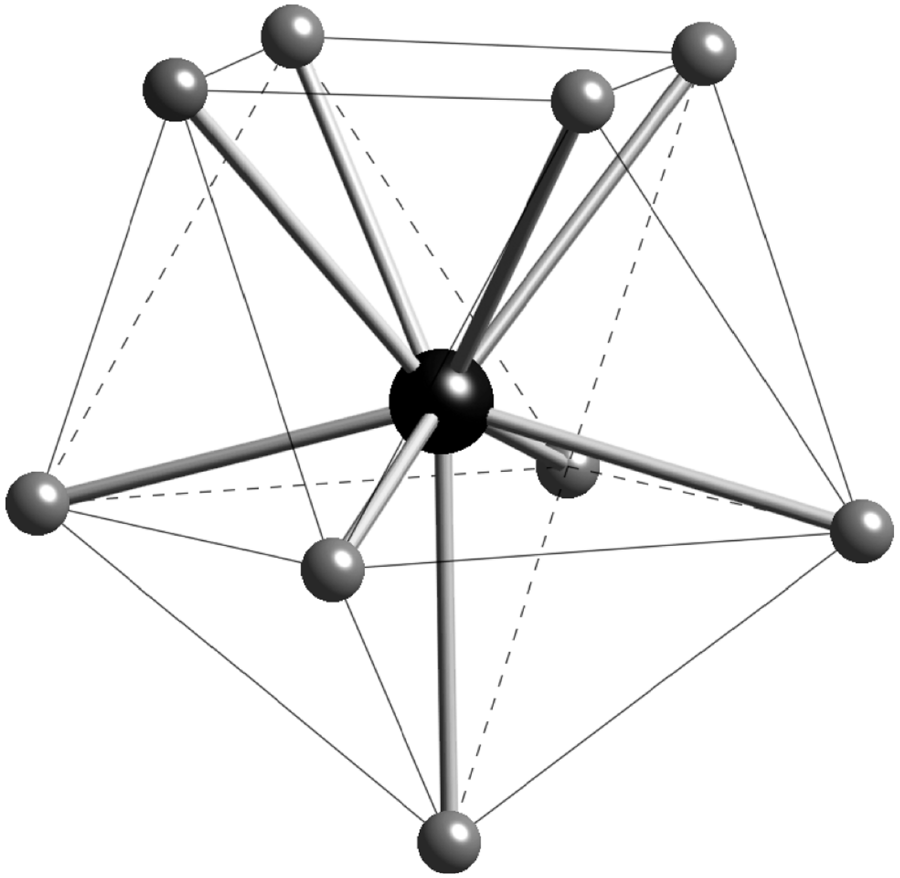

Fig. 7.96 *Local coordination sphere around plutonium in* $PuTe_3$ *and* PuX_2*. The plutonium atom is black and tellurium atoms are gray.*

The ideal structure of plutonium dichalcogenides, PuX_2 is the anti-Fe_2As in space group *P*4/*nmm* ($Z = 2$) (Damien *et al.*, 1986). In this structure, layers of five chalcogen atoms in the basal face-centered square plane are separated by two slabs of alternating Pu^{3+} (nine-fold coordination) and X^{2-} ions. The local PuX_9 coordination polyhedron is identical to that seen in $PuTe_3$, depicted in Fig. 7.96. All the PuX_{2-x} compounds are distorted from this idealized structure due to the formation of X–X bonding pairs within the basal planes. A typical structure is shown in Fig. 7.97. This distortion gives rise to a number of pseudo-cubic, tetragonal, orthorhombic, and monoclinic ($\beta = 90°$) anti-Fe_2As superstructures (Flahaut, 1979; Rolland *et al.*, 1994). From Table 7.39, it can be seen that all PuX_{2-x} ($X =$ S, Se, and Te) compounds display the pseudo-tetragonal cell of the anti-Fe_2As structure, with the exception of PuS_2, which displays the monoclinic ($\beta = 90°$) $CeSe_2$ variant of the structure (Marcon and Pascard, 1968).

The sesquichalcogenides of plutonium are isostructural with the rare-earth analogs (Damien *et al.*, 1986). The low-temperature stoichiometric phase,

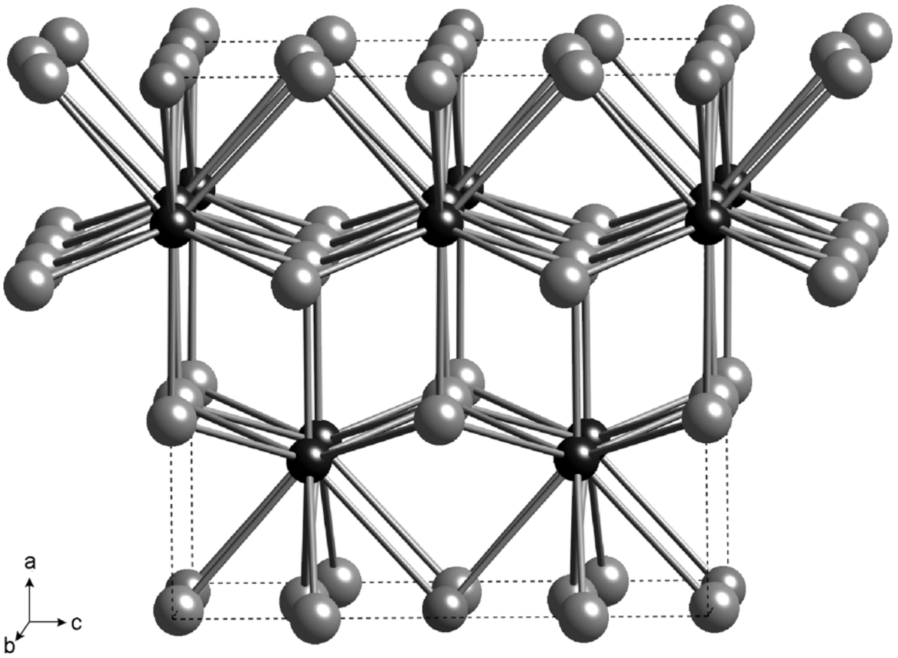

Fig. 7.97 *Solid-state crystal structure of plutonium dichalcogenides,* PuX_2*, emphasizing the local* PuX_9 *coordination. The X–X bonding pairs are not indicated for clarity. The distortions in the chalcogen layers due to X–X bonding are clearly evident in this model, based on monoclinic* $LaTe_2$ (*Stöwe,* 2000). *Plutonium atoms are black and chalcogen atoms are gray.*

referred to as α-Pu_2X_3 only exists for the sulfide, and has the orthorhombic La_2S_3-type structure, with two plutonium sites displaying local PuS_7 and PuS_8 coordination. The high-temperature γ-Pu_2X_3 phase is not a stoichiometric phase, and exists over a range of compositions varying from Pu_2X_3 to Pu_3X_4. This phase displays the cubic Th_3P_4 structure, where the coordination number of the plutonium atom is eight. For selenium and tellurium, there is a η-Pu_2X_3 phase that displays the orthorhombic U_2S_3 structure. The η-Pu_2Se_3 is thermally unstable and transform near 800°C into the cubic γ-Pu_2Se_3 of the Th_3P_4 structure. Early reports of a β-phase for Pu_2S_3 have been shown to be incorrect, as the material is now known to be a ternary oxychalcogenide (Carre *et al.*, 1970). All monochalcogenides of plutonium (PuX) have the cubic NaCl crystal structure.

(*iii*) *Properties*

The monochalcogenides have a metallic luster that can be described as gold, copper, and black for the sulfide, selenide, and telluride, respectively. The monochalcogenides have been the subject of extensive study directed towards understanding valency and the itinerant or localized nature of their 5f electrons. Several excellent overviews are available (Rossat-Mignod *et al.*, 1984; Buyers and Holden, 1985; Dunlap and Kalvius, 1985; Fournier and Troc, 1985; Santini *et al.*, 1999; Wachter, 2003).

Single crystal samples of PuX have been examined by neutron scattering, magnetic susceptibility, and electrical resistivity. All of the PuX compounds ($X = S, Se, Te$) are nonmagnetic with magnetic susceptibilities that are almost temperature independent for temperatures above 50 K (Lander *et al.*, 1987). Electrical resistivity increases continuously from room temperature with two changes of thermal behavior around 200 and 30 K, confirming the hypothesis that the PuX compounds are semiconductors with small energy gaps. Fournier *et al.* (1990) suggest that the ground state of the monochalcogenides is a weak magnetic nonconducting $6d^1$–$5f^5$ Kondo state with a high Kondo temperature of ca. 400 K.

Wachter and coworkers proposed that these properties of PuX compounds can be consistently explained by the assumption that the plutonium chalcogenides are related to the high-pressure intermediate-valent form of the isoelectronic samarium chalcogenides. Pressure in the divalent SmX serves to enhance f–d hybridization to achieve an intermediate valence state, whereas in PuX, f–d hybridization is achieved without pressure because of the larger radial extension of the 5f wave functions relative to the 4f wave functions. Using PuTe as an example, they conclude that SmTe achieves the same state under a pressure of 58 kbars, and achieves an intermediate valence of 2.75 (Wachter *et al.*, 1991). The intermediate valence model is supported by experimental measurement of elastic constants and observation of a negative value for c_{12} (–39 GPa) (Mendik *et al.*, 1993; Wachter *et al.*, 2001). Photoemission measurements on PuSe films

(Gouder *et al.*, 2000) were interpreted as a 5f localization and not an intermediate valent configuration where 5f and 6d states hybridize. Wachter suggested that the existence of a strong Pauli paramagnetism gives a high DOS near the Fermi level, complicating the interpretation. Recent photoemission studies on PuTe single crystals confirm the presence of a strong three-peak structure near the Fermi level in agreement with of an intermediate valence state in PuTe (Durakiewicz *et al.*, 2004).

(c) Ternary and polynary plutonium chalcogenides

A large number of ternary and polynary plutonium/metal chalcogenides have been described in the literature. The majority of these compounds are ternary and quaternary oxide phases, some of which have gained technological importance. The term 'ternary oxide phases' in this context includes two general classes of material. The first are oxoplutonate compounds with PuO_x^{n-} polyhedral anions and mono-, di-, or trivalent metal cations. A typical example would be Ba_3PuO_6. The second general class are oxometallate compounds with MO_x^{n-} polyhedral anions of main group or transition metal elements in which the plutonium serves as the tri- or tetravalent counter cation. A typical example of this class of compound would be $PuCrO_3$.

Ternary and polynary sulfides, selenides, and tellurides are few, generally not well characterized and will not be discussed.

(*i*) *Preparation of alkali metal oxoplutonates*

When plutonium dioxide and alkali metal oxides, hydroxides, peroxides, or carbonates are intimately mixed and heated in a stream of oxygen, inert gas, or vacuum, they react to form ternary oxide phases in which the plutonium is the central atom of an oxoplutonate anion $\left(PuO_x^{n-}\right)$ and may assume any of the oxidation states from IV to VII. Alkali metal oxoplutonates have been prepared with all the alkali metals with the exception of francium.

Pu(IV). The only alkali oxoplutonate(IV) known at the time of writing is greenish brown Li_8PuO_6, which is obtained by heating a Li_2O–PuO_2 mixture (4.2:1) in a sealed evacuated tube at 600°C (Keller *et al.*, 1965b).

Pu(V). For pentavalent plutonium, Li_7PuO_6, Li_3PuO_4, and Na_3PuO_4 have been reported. These compounds may be obtained by reaction of Li_2O or Na_2O with PuO_2 in an oxidizing atmosphere for 8 h at 700–900°C, respectively. Li_3PuO_4 may be prepared by heating a 3:1 mixture of $LiOH \cdot H_2O$ and PuO_2 in an oxygen stream at 900°C for 24 h (Yamashita *et al.*, 1992). M_3PuO_4 compounds are also reportedly obtained by thermal decomposition of hexavalent M_6PuO_6 for 4 h in an argon atmosphere to give the M_3PuO_4 product and PuO_2 (1100°C, M = Li; 1000°C, M = Na) (Keller, 1964). Brownish-green Li_7PuO_6 was prepared by reacting Li_3PuO_4 with two equivalents of Li_2O at 600°C for 6 h in an evacuated quartz tube (Koch, 1964).

Pu(VI). For hexavalent plutonium, M_6PuO_6, M_4PuO_5, (M = Li, Na), and M_2PuO_4 (M = K, Rb, Cs) compounds have been prepared. These compounds may be either dark green (M_6PuO_6) or brown (M_4PuO_5 and M_2PuO_4). The compounds M_4PuO_5 and M_6PuO_6 dissolve in dilute acids to form yellow-brown or yellow-green aqueous solutions (respectively) and show characteristic Pu(VI) absorption spectra (Koch, 1964).

Li_6PuO_6 is obtained by heating a 3:1 mixture of Li_2O and PuO_2 at 400–500°C in an oxygen atmosphere. If a 2:1 mixture is used, Li_4PuO_5 is formed. When Li_4PuO_5 is heated at 900–1000°C, Li_3PuO_4 is formed. Li_4PuO_5 may also be prepared by heating a 4:1 mixture of $LiOH \cdot H_2O$ and PuO_2 under an oxygen stream at 600°C for 24 h (Yamashita *et al.*, 1992).

Heating a 2:1 mixture of Na_2O and PuO_2 in an oxygen atmosphere at 400°C results in the formation of cubic α-Na_4PuO_5, which may be converted to tetragonal β-Na_4PuO_5 by raising the temperature to 500°C. At 900°C, β-Na_4PuO_5 decomposes to Na_3PuO_4. When a 3:1 mixture of Na_2O and PuO_2 is used, α-Na_4PuO_5 is produced at 400°C; and Na_6PuO_6 is produced at 500°C. Upon heating Na_6PuO_6 to 750°C, it is converted to β-Na_4PuO_5 (Koch, 1964; Keller *et al.*, 1965a).

The M_2PuO_4 class of compounds (M = K, Rb, Cs) may be conveniently prepared by reaction of a 2:1 mixture of MOH with PuO_2 in gold crucibles under an oxygen atmosphere, and heated to at least 450°C (Hoekstra and Gebert, 1977). These compounds decompose in air above 650°C. The rubidium and cesium analogs may also be prepared by heating the corresponding oxoplutonates (VII), M_3PuO_5 to temperatures above 320°C (Pagès *et al.*, 1971a,b).

Pu(VII). For heptavalent plutonium, M_5PuO_6 (M = Li, Na) and M_3PuO_5 (M = Rb, Cs) have been reported. Greenish-black Li_5PuO_6 is formed when a 3:1 mixture of Li_2O and PuO_2 is heated in a stream of oxygen at 430°C (Keller and Seiffert, 1969). The corresponding sodium compound, Na_5PuO_6, has not yet been isolated in the pure state. However, the reaction product of Na_2O_2 and PuO_2 in O_2 atmosphere at 400°C, yields a green aqueous solution upon dissolution in dilute aqueous hydroxide, which shows the characteristic absorption spectrum of Pu(VII) (Keller and Seiffert, 1969).

The black compounds M_3PuO_5 (M = Rb, Cs) have been obtained by heating 3:1 mixtures of the corresponding superoxide MO_2 with PuO_2 at 250°C for more than 6 h. These compounds are reportedly less sensitive to air than the corresponding Np compounds, but have a lower thermal stability. At 320°C, they reportedly decompose to M_2PuO_4 and M_2O_2 (Pagès *et al.*, 1971a,b).

(*ii*) *Preparation of ternary and quaternary alkaline-earth oxoplutonates*

The oxoplutonates of the alkaline-earth elements can be prepared in a manner similar to the alkali-metal oxoplutonates. The alkaline-earth oxides, peroxides or carbonates react with PuO_2 to form alkaline-earth oxoplutonates, in which the plutonium may occur in oxidation states III, IV, V, VI, and VII.

Pu(III). The only alkaline-earth oxoplutonate(III) that has been reported is $BaPu_2O_4$, which is formed by reacting a 1:3:2 mixture of BaO, elemental Pu and PuO_2 (Keller, 1962). An intimate mixture of Pu, PuO_2, and BaO is first heated in a stream of hydrogen to convert plutonium metal to hydride (PuH_x). The resulting mixture of PuH_x, PuO_2, and BaO is powdered in an inert-gas atmosphere and then heated in a stream of argon at 600°C for 2 h and at 1200°C for 8 h. At 600°C, the plutonium hydride decomposes, and the resulting finely divided metal reacts with PuO_2 to give Pu_2O_3. The Pu_2O_3 in turn reacts with BaO to form $BaPu_2O_4$, which may be isostructural with the lanthanide compounds $BaPr_2O_4$ and $BaNd_2O_4$ (Keller, 1962). No lattice constants of $BaPu_2O_4$ have been reported.

Pu(IV). Discrete alkaline-earth oxoplutonates(IV) can be prepared with the heavy alkaline-earth elements strontium and barium but not for the lighter alkaline-earth elements beryllium and magnesium. Beryllium and magnesium oxides react with PuO_2 to form solid solutions rather than stoichiometric compounds. The mutual solubilities of $MO–PuO_2$ systems (M = Be, Mg) have been determined by Hough and Marples (1965) and by Carroll (1964). With the heavier alkaline-earth elements, heating stoichiometric mixtures of MO (M = Sr, Ba) with PuO_2 gives $MPuO_3$ (Chackraburtty *et al.*, 1963; Chackraburtty and Jayadevan, 1964). Chackraburtty and coworkers have recommended the use of excess alkaline-earth oxide (3:1 mixtures) to ensure complete conversion of PuO_2 to oxoplutonate. The excess alkaline-earth oxide may be subsequently removed by extraction with methanol (Russell *et al.*, 1960; Keller, 1962, 1964; Chackraburtty and Jayadevan, 1964). $BaPuO_3$ has also been prepared by ball-milling a stoichiometric mixture of $BaCO_3$ and PuO_2, followed by heating under argon at 1197°C for 24 h (Christoph *et al.*, 1988). $SrPuO_3$ and $BaPuO_3$ can also be prepared by reduction of Sr_3PuO_6 or Ba_3PuO_6 in a stream of hydrogen at 1600–1800°C.

Pu(V). Deep black $Ba_3PuO_{5.5}$ is obtained by reacting a mixture of Ba_3PuO_6, PuO_2, and BaO in a stream of argon at 1100–1200°C. It is uncertain whether this compound contains Pu(V) or a mixture of Pu(IV) and Pu(VI) (Keller, 1962, 1964). There are a few quaternary compounds of general formula Ba_2MPuO_6, where M is a trivalent metal ion (M = La, Nd, In). These compounds are prepared by heating a 4:1:1:1 mixture of PuO_2, $PuO_2(NO_3)_2{\cdot}nH_2O$, M_2O_3, and BaO_2 in a platinum crucible at 750–950°C for 8–10 h (Awasthi *et al.*, 1968).

Pu(VI). For hexavalent plutonium, there are ternary alkaline-earth oxoplutonates (VI) of formula $MPuO_4$ and M_3PuO_6 (M = Ca, Sr, Ba) and quaternary compounds of general formula Ba_2MPuO_6, where M is a divalent metal ion (M = Sr, Mn, Pb, Mg, Ca). It is uncertain whether the manganese compound, Ba_2MnPuO_6, contains Mn(II)/Pu(VI) or Mn(III)/Pu(V).

M_3PuO_6 compounds have been prepared by heating 3:1 to 5:1 mixtures of MO (M = Ca, Sr, Ba) with PuO_2 in a stream of oxygen at 950–1050°C

(M = Ca) (Chackraburtty *et al.*, 1963; Awasthi *et al.*, 1968), 900–1200°C (M = Sr), or 800–1300°C (M = Ba) (Keller, 1962, 1964). Sr_3PuO_6 and Ba_3PuO_6 form solid solutions, which range in composition from Ba_3PuO_6 to $Ba_{0.75}Sr_{2.25}PuO_6$.

The reaction of a 1:1 mixture of SrO and PuO_2 in an oxidizing atmosphere at 900–1000°C yields $SrPuO_4$ (Keller, 1962, 1964). $BaPuO_4$ appears to be produced by shaking Ba_3PuO_6 with excess, CO_2-free water for 15–30 min. BaO dissolves and leaves $BaPuO_4$ as the residue (Keller, 1962, 1964).

Pu(VII). Alkaline-earth oxoplutonates(VII) have not yet been prepared by solid-state reactions at elevated temperatures, as has been done with alkali oxoplutonates (VII). However, the compound $Ba_3(PuO_5)_2 \cdot xH_2O$ was obtained by precipitation with $Ba(OH)_2$ from aqueous solutions of Pu(VII) (Komkov *et al.*, 1968).

(*iii*) *Solid-state structures*

Characterization of most alkali and alkaline-earth oxoplutonates are limited to X-ray powder diffraction data. These data have been summarized in Table 7.40. All of the oxoplutonate compounds contain PuO_6^{n-} polyhedra that are octahedral with six equidistant Pu–O bonds, or tetragonally distorted with two short (plutonyl-like) and four long, or four short and two long Pu–O bonds. Representative examples of these structure types will be discussed.

Perovskites – $MPuO_3$

Plutonium (and other light actinides) form an extensive class of complex oxides that are related to the perovskite ($CaTiO_3$) structure in which Pu(IV), Pu(VI), or Pu(VII) ions exist in octahedral PuO_6^{n-} coordination. General structural classifications of perovskites have been discussed (Galasso, 1968; Wells, 1984; Zhou and Goodenough, 2005). The idealized ABO_3 perovskite structure consists of a simple cubic lattice with apex-shared, BO_6 octahedra with large A cations at the center of the unit cell, bonded to 12 oxygen atoms situated at the centers of the cell edges. In this ideal ABO_3 structure, all atomic positions are fixed by symmetry and the packing is very dense. In most perovskites, the actual unit cell symmetry is lower than cubic, which can be accomplished by rotation of the BO_6 octahedra allowing a lengthening of the B–O bonds and lowering the effective A-site coordination number (typically to eight).

Through rotation of a BO_6 unit, the perovskite structure can accommodate a large range of A:B:O radius ratios. Barium plutonate ($BaPuO_3$) is an excellent example of how a 5f element is accommodated into this important structure type. The structure of $BaPuO_3$ had been somewhat controversial, the cell symmetry being reported variously as cubic or orthorhombic (Russell *et al.*, 1960; Keller, 1962; Chackraburtty *et al.*, 1963; Christoph *et al.*, 1988). Christoph and coworkers utilized Zachariasen's bond-length–bond-strength relationships to predict that in the structure of $BaPuO_3$ the PuO_6 octahedra

[c] Original space group B centered, recalculated by Roof (1989) in standard setting A*mm*2.

[d] Keller *et al.* (1965a) reported that Li_5PuO_6 and Na_5PuO_6 are hexagonal and isotypic with rhenium analogs Li_5ReO_6 and Na_5ReO_6. Betz and Hoppe (1984) described the structures of Li_5ReO_6 and Na_5ReO_6 as being monoclinic. Roof (1989) recalculated both Pu structures using the data from Betz and Hoppe, and these are the cell constants reported here with $\beta = 110.24°$ for Li_5PuO_6 and $\beta = 111.01(1)°$ for Na_5PuO_6.

should rotate by about 11 degrees to give the theoretical Pu–O distance predicted by Zachariasen's relationship. This prediction was tested by performing a low-temperature neutron diffraction study on $Ba^{242}PuO_3$ which confirmed the expectations of a distortion away from the cubic perovskite structure (Christoph *et al.*, 1988). The idealized cubic and experimentally confirmed orthorhombic solid-state structures are illustrated in Fig. 7.98. In the low-temperature neutron structure, the PuO_6 octahedra are rotated by about 15 degrees from the idealized position in the cubic perovskite, and this is indicated in Fig. 7.98(b). The PuO_6 rotation gives Pu–O–Pu angles of 157.07 (8) and 160.53(5) degrees. The plutonium atom coordination is only slightly distorted from octahedral with Pu–O distances of 2.2306(5), 2.2295(12), and 2.2230(12) Å. The mean Pu–O distance is 2.228 Å.

Double perovskites M_3PuO_6 and Ba_2MPuO_6

Another important class of plutonium perovskite oxide is the so-called 'double perovskite' typified by M_3PuO_6 (M = Ba, Sr) and Ba_2MPuO_6 (M = Mg, Ca, Sr, Mn, Zn). The double perovskite can be considered as an ideal perovskite with M^{2+} and Pu^{6+} ions occupying alternating octahedral sites in a cubic unit cell with doubled cell edges. The ordered fcc structure (*Fm*3*m*) has the elpasolite (K_2NaAlF_6) structure, and the basic structural unit is shown in Fig. 7.99. This figure maintains the same orientation as Fig. 7.98, and emphasizes the alternating PuO_6 and MO_6 octahedra in the double perovskite structure. As in the ideal

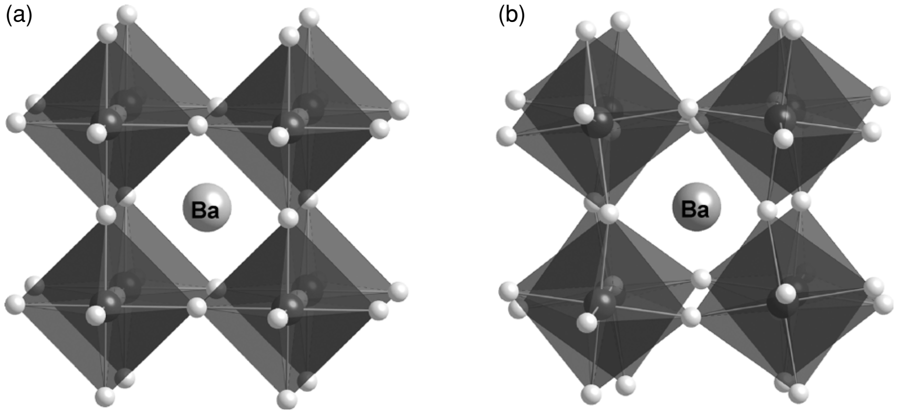

Fig. 7.98 *Idealized cubic (a) and experimental orthorhombic (b) crystal structures of $BaPuO_3$, emphasizing the rotation of the local PuO_6 octahedra between cubic and orthorhombic symmetries. The cubic structure is based on the original report by (Russell* et al., 1960), *and the orthorhombic structure is based on the low-temperature neutron diffraction study (Christoph* et al., 1988). *In this polyhedral representation, the plutonium atoms are dark gray (center of octahedra), oxygen atoms are white, and the central barium atom is light gray.*

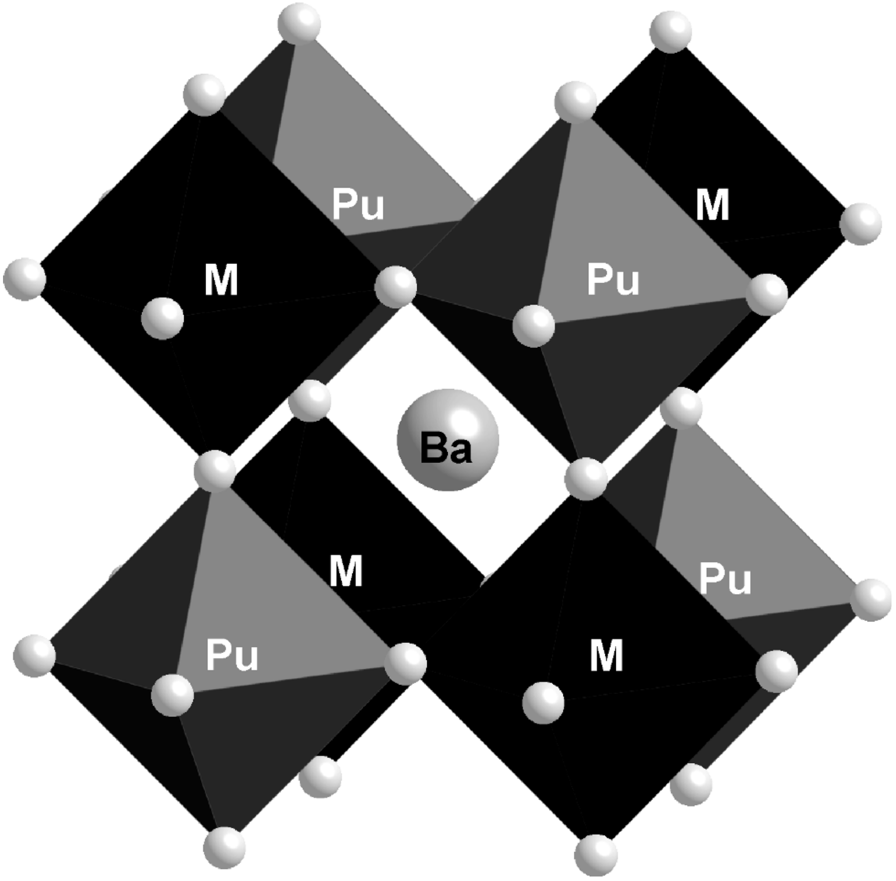

Fig. 7.99 *Polyhedral representation of the idealized double perovskite structure of* Ba_2MPuO_6 *compounds. This polyhedral representation emphasizes the alternating octahedral* PuO_6 *(gray) and* MO_6 *(black) sites in the structure. The central barium ion is light gray.*

perovskite structure, many of these compounds are distorted away from ideal cubic symmetry, and this is often observed as the presence of extra, weak diffraction lines (Gens *et al.*, 1985).

M_4PuO_5

These hexavalent compounds are isostructural with M_4UO_5 (M = Li, Na) and crystallize in tetragonal space group I4/*m*. The solid-state structure of Li_4PuO_5 displays an extended pseudo-octahedral chain of $PuO_4(\mu\text{-}O)_2$ units with a square-planar arrangement of four short equatorial Pu–O bonds of 1.98 Å,

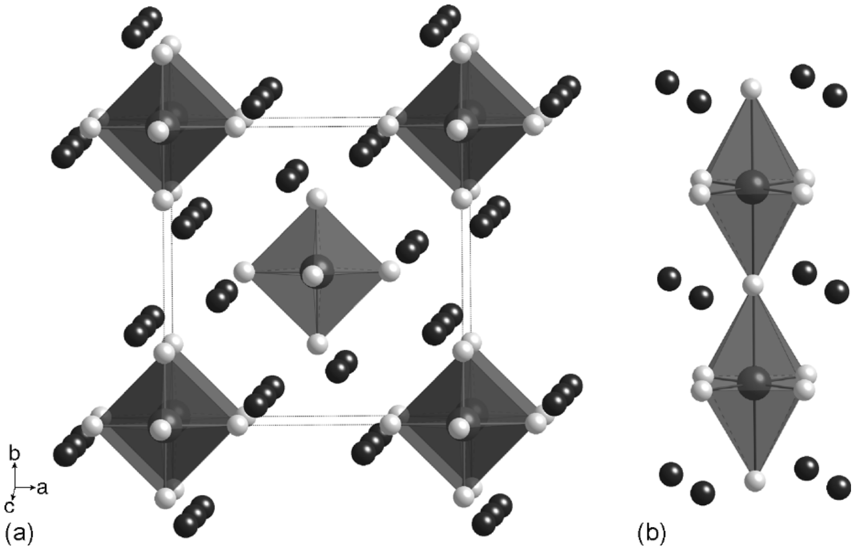

Fig. 7.100 *Polyhedral representation of the solid-state structure of M_4PuO_5 compounds. (a) A view looking down the crystallographic c-axis, and (b) a view perpendicular to the c-axis. The view in (b) emphasizes the distorted PuO_6 polyhedra (gray) surrounded by Li or Na ions (black).*

and two longer axial Pu–O bridging bonds of 2.21 Å that link the planar PuO_4 units together (Keller *et al.*, 1965a). The basic structural unit is shown in Fig. 7.100. This compound is isostructural with β-Na_4PuO_5 that has four short Pu–O bonds of 2.09 Å and two longer Pu–O bonds of 2.29 Å (Keller *et al.*, 1965a). This class of compound is significant in that it demonstrates that hexavalent complex actinide oxides do not necessarily retain actinyl (AnO_2^{2+}) ions with two short metal–oxygen bonds in the solid state.

M_5PuO_6

For heptavalent actinides, Keller reported that M_5PuO_6 (M = Li, Na) compounds were hexagonal and isotypic with rhenium analogs M_5ReO_6 (M = Li, Na) (Keller *et al.*, 1965a). Since Keller's original report, Betz and Hoppe (1984) determined that the structures of M_5ReO_6 were monoclinic and characterized by tetragonally distorted MO_6^{5-} units. In 1994, Morss and coworkers reexamined the structures of both Li_5NpO_6 and Li_5ReO_6 by neutron diffraction and confirmed the monoclinic structure for Li_5ReO_6, but in contrast to the original report, the structure of Li_5NpO_6 was not identifiable (Morss *et al.*, 1994). Thus the actual solid-state structure of M_5PuO_6 compounds remains unresolved.

(*iv*) *Ternary and quaternary oxides of plutonium with main group and transition elements*

A number of ternary oxides of plutonium with the oxides of metallic and semimetallic elements have been prepared. In these compounds plutonium occurs as Pu(III) or Pu(IV), and the tendency for plutonium to assume the role of the cation increases as one proceeds from group III toward group VII elements. A wide variety of compositions are observed, with stoichiometric compounds and nonstoichiometric phases being formed. The crystallographic properties of those compounds having a stoichiometric composition are summarized in Table 7.41. Compounds of the type $PuXO_4$, containing Pu(III) and X = P or As, as well as the phosphates and arsenates of Pu(IV) and Pu(VI) will be discussed in Section 7.8.5.c(i).

Trivalent compounds

Ternary and quaternary oxides containing trivalent plutonium range from simple compounds of the types $PuMO_3$ and $PuMO_4$, to more complex formulae such as $Pu(ReO_4)_3$, or to complicated silicate structures such as $Ba_2Pu_8(SiO_4)_6O_2$ related to apatite.

$PuMO_3$. This class of compound displays the perovskite structure (Fig. 7.98), but with Pu(III) now serving the role of the cation. These compounds have been prepared by Russell *et al.* (1960) for M = Al(III), V(III), Cr(III), and Mn(III), and by Keller *et al.* (1972) for M = Sc(III) by heating mixtures of PuO_2 with the appropriate metal oxide (Al_2O_3, V_2O_5, CrO_3) or carbonate ($MnCO_3$) under argon or hydrogen atmospheres between 1500 and 1600°C for several hours (Russell *et al.*, 1960). Attempts to prepare analogous compounds with M = Fe (III) and Ga(III) were unsuccessful (Chackraburtty and Jayadevan, 1964).

Ba_2PuPaO_6. This is the only known compound in this class, and it shows a double perovskite structure (Fig. 7.99). This compound is prepared as a white powder by heating a 4:1:1 mixture of $BaCO_3$, Pa_2O_5, and Pu_2O_3 at 1350–1400°C *in vacuo* (Keller, 1965b). It is unknown whether this compound contains Pu(III)/Pa(V) or Pu(IV)/Pa(IV).

$PuMO_4$. A few such compounds have been prepared with M = Nb(V) or Ta(V), and contain trivalent plutonium. They are obtained by heating intimate mixtures of Pu_2O_3 and M_2O_3 and M_2O_5 *in vacuo* at 1200°C (Keller and Walter, 1965).

$Pu(ReO_4)_3$. Reaction of plutonium(III) oxalate with Re_2O_7 yields green plutonium(III) perrhenate, $Pu(ReO_4)_3$. This salt-like compound is also obtained by solid-state reaction of PuO_2 with Re_2O_7. $Pu(ReO_4)_3$, is deliquescent in air, and forms hydrates with 1, 2, or $3H_2O$. $Pu(ReO_4)_3$ decomposes at 700°C to PuO_2 and Re_2O_7 (Silvestre *et al.*, 1977). The X-ray powder pattern of anhydrous $Pu(ReO_4)_3$ has not yet been interpreted.

Pu(III) silicates. No simple plutonium(III) silicates are known. However, De Alleluia and coworkers (De Alleluia *et al.*, 1983) have prepared a number of

[k] $\beta = 107.78(10)°$.

[l] $\beta = 116.3(1)°$.

complex silicates of the types $Pu_8(SiO_4)_6$; $Pu_{9.33}(SiO_4)_6O_2$; $M_2Pu_9(SiO_4)_6O_2$ (M = Li, Na), $M_2Pu_8(SiO_4)_6O_2$ (M = Mg, Ca, Sr, Ba), and $Sr_3Pu_6(SiO_4)_6$. All these compounds have hexagonal apatite-type structures, some with lattice defects. All these compounds, which show the blue color of Pu(III), are prepared by reducing mixtures of PuO_2, SiO_2, and the respective alkali or alkaline-earth oxides in ultrapure H_2 at temperatures between 1100 and 1400°C in alumina or iridium vessels for periods up to 3 days. In these systems, the reduction to Pu(III) is accomplished much more readily than the reduction to Pu(III) in other mixed oxide systems.

Tetravalent compounds

$PuMO_4$. Compounds of this type containing M = Si or Ge can be obtained by hydrothermal synthesis from 1:1 mixtures of PuO_2 and MO_2 at 250°C. They may also be prepared by solid-state reactions at 1200°C from the same components (Keller, 1963). $PuSiO_4$ is green; $PuGeO_4$ is pale brown or olive brown.

$Pu(MO_3)_4$. These compounds contain Pu(IV) and M(V) (M = Nb, Ta) and may be obtained by solid-state reaction of a 2:1 mixture of M_2O_5 and PuO_2 (Keller, 1965a).

$Pu(MO_3)_2$. The only representative of this type of compound is white plutonium(IV) tellurite, $Pu(TeO_3)_2$, which is prepared by heating a 1:2 mixture of PuO_2 and TeO_2 for 24 h at 700°C (Wroblewska *et al.*, 1979).

$Pu(MO_4)_2$. The only compound of this type known now is brown-red plutonium(IV) molybdate, $Pu(MoO_4)_2$. This compound may be prepared by heating a stoichiometric mixture of PuO_2 and MoO_3 for 2 h at 500°C, followed by 4 h at 800°C (Tabuteau *et al.*, 1972).

A number of quaternary plutonium(IV) molybdates have been obtained by reaction of $Pu(MoO_4)_2$ with M_2MoO_4 (M = Li, Na, K, Rb, Cs) compounds at high temperature (Tabuteau *et al.*, 1972). Reaction of Li_2MoO_4 with $Pu(MoO_4)_2$ at 500°C gives $Li_4Pu(MoO_4)_4$. $Li_4Pu(MoO_4)_4$ melts congruently at 630°C and has a reversible solid-state transformation at 510°C. Solid-state reaction of Na_2MoO_4 with $Pu(MoO_4)_2$ at 600°C gives $Na_2Pu(MoO_4)_3$ and $Na_4Pu(MoO_4)_4$. Both compounds show peritectic decomposition, $Na_2Pu(MoO_4)_3$ at 714°C and $Na_4Pu(MoO_4)_4$ at 708°C. Similarly, $M_2Pu(MoO_4)_3$ and $M_8Pu(MoO_4)_6$ have been prepared by solid-state reactions between M_2MoO_4 and $Pu(MoO_4)_2$ (M = K, Rb). With Cs_2MoO_4, only $Cs_2Pu(MoO_4)_3$ has been prepared by solid-state reaction with $Pu(MoO_4)_2$ (Tabuteau *et al.*, 1972).

Pu(IV) perrhenates. Plutonium(IV) perrhenate tetrahydrate, $Pu(ReO_4)_4 \cdot 4H_2O$, is obtained as a red powder by dissolving the oxalate $Pu(C_2O_4)_2 \cdot 6H_2O$ in 0.5 M perrhenic acid solution, evaporating the resulting solution to dryness, and heating the residue to a temperature below 100°C. So far, the anhydrous compound has not been prepared. At 250°C, $Pu(ReO_4)_4{\cdot}4H_2O$ decomposes partially to $Pu(ReO_4)_3$ (Silvestre *et al.*, 1977).

Pu(IV) vanadates. No simple plutonium(IV) vanadate has been prepared. However, Pagès and Freundlich (1976) prepared a number of quaternary plutonium(IV) vanadates of the types $MPu_2(VO_4)_3$ (M = Li, Na, Ag) and $M'Pu(VO_4)_2$, (M′ = Ca, Sr, Cd). Heating a 4:3:1 mixture of PuO_2, V_2O_5, and Ag_2O at 500°C produces $AgPu_2(VO_4)_3$. The corresponding alkali compounds (M = Li, Na) are prepared by heating 1:1:3 mixtures of M_2CO_3, PuO_2, and V_2O_5 at 700–750°C. The alkaline-earth compounds are obtained in the same manner from a mixture of $M'CO_3$, PuO_2, and V_2O_5. The compounds $MPu_2(VO_4)_3$ and $M'Pu(VO_4)_2$ have the zircon structure, while $AgPu_2(VO_4)_2$ has the scheelite structure.

(d) Ternary oxides of plutonium with lanthanide oxides

No stoichiometric compounds of plutonium oxides with lanthanide oxides have been observed. The following systems have been studied in some detail: PuO_2–CeO_2 (Farkas, 1966), PuO_{2+x}–$YO_{1.5}$ (Jackson and Rand, 1963), PuO_2–$EuO_{1.5}$ (Haug, 1963; Haug and Weigel, 1963), PuO_2–$HoO_{1.5}$ (Engerer, 1967), PuO_2–$TmO_{1.5}$ (Leitner, 1967), and PuO_2–$LuO_{1.5}$ (Sriyotha, 1968). Preliminary data are available for the systems PuO_{2+x}–$YO_{1.5}$ (Jackson and Rand, 1963) and PuO_{2+x}–$EuO_{1.5}$ (Haug, 1963; Haug and Weigel, 1963), while pseudo-binary phase diagrams have been established for the systems PuO_{2+x}–$HoO_{1.5}$ (Engerer, 1967), PuO_{2+x}–$TmO_{1.5}$ (Leitner, 1967), and PuO_{2+x}–$LuO_{1.5}$ (Sriyotha, 1968) up to temperatures of 1700°C in oxygen-free atmosphere (argon) and in 1 atm O_2. A detailed discussion of all these systems is beyond the scope of this work.

From these phase diagrams, it may be concluded that $PuO_{2\pm x}$ may dissolve considerable amounts of $LnO_{1.5}$ to form a solid solution. For instance, in the system $PuO_{2\pm x}$–$HoO_{1.5}$, 46.0 mol% $HoO_{1.5}$ at 1250°C, and 72.0 mol% at 1700°C. The anion defects formed by inclusion of $LnO_{1.5}$ into the PuO_2 lattice may be partially compensated by oxidation of Pu(IV) to Pu(>IV). For instance, the average oxidation number $\overline{W}$ of plutonium in the system PuO_{2+x}–$HoO_{1.5}$ at $p(O_2) = 1$ atm for a composition of 50 mol% $HoO_{1.5}$ and 1400°C was found to be $\overline{W} = 4.36$ at an O:(Pu + Ho) ratio of 1.84 (Engerer, 1967). At a composition of 70 mol% $HoO_{1.5}$ and 1100°C, it was found to be $\overline{W} = 4.51$ at an O:(Pu + Ho) ratio of 1.68. In general, the average oxidation number of the plutonium in the fluorite phases containing lanthanide elements is lower than the corresponding oxidation number in the uranium or neptunium systems at approximately the same composition in the fluorite phases.

The solubility of $PuO_{2\pm x}$ in $LnO_{1.5}$ (Ln = Ho, Tm, Lu) is considerably larger than the solubility of uranium or neptunium oxides. In the system PuO_{2+x}–$HoO_{1.5}$ and at $p(O_2) = 1$ atm, it is 18.5 mol% PuO_2 at 1100°C, and 25 mol% at 1550°C (Engerer, 1967).

A different situation exists in the system $PuO_{2(+x)}$–CeO_2. At 1000°C, the compositions PuO_2–CeO_2 form a series of solid solutions throughout the whole range of concentrations. Microspheres of PuO_2–CeO_2 have been prepared by the sol-gel process (Farkas, 1966). A detailed X-ray study of the lattice constants of various compositions demonstrates that the solid solutions obey Vegard's law (Mulford and Ellinger, 1958).

(e) Ternary oxides of plutonium with actinides

Ternary oxides of plutonium with actinides have been prepared with thorium, protactinium, uranium, and curium.

(*i*) *The plutonium–thorium system*

At 1000°C the PuO_2–ThO_2 system, forms a series of solid solutions throughout the whole composition range (Mulford and Ellinger, 1958) and these follow Vegard's law. Above 1650°C, under an argon atmosphere, a partial phase separation with formation of C-Pu_2O_3 takes place. The melting points of $(Th,Pu)O_2$ solid solutions are practically constant up to 25 wt % Th and show a linear increase at higher Th contents. $(Pu,Th)O_2$ microspheres have been prepared by the sol–gel process and in the induction-coupled plasma torch.

(*ii*) *The plutonium–uranium–oxygen system*

The plutonium–uranium–oxygen system is one of the best-understood plutonium–actinide oxide systems due to its widespread application in nuclear reactor fuel. For this reason, the mixed plutonium–uranium oxide system has been extensively studied. In spite of this great technological importance, only relatively limited data have been reported in the open literature. There is much more information in the proprietary literature of fuel manufacturing organizations. Plutonium–uranium oxides of general formula $(U,Pu)O_2$ are often referred to as 'mixed oxide' or MOX, and can refer to fuels containing 2–30% PuO_2. These fuels behave very differently depending on the percentage of PuO_2. Fuels for light water reactors (LWR) only contain a small percentage of plutonium (2–6%), and will therefore behave like UO_2 with a small amount of impurity, while fuels for fast breeder reactors (FBR) have a higher percentage of plutonium (15–35%), and behave very differently (Schneider and Roepenack, 1986). Four plants currently produce commercial quantities of MOX fuel. Two are in France, one in Belgium, and one in the United Kingdom. In 2000, about 190 metric tons per year of MOX was produced, incorporating 10–12 metric tons of plutonium. MOX production capacity is presently around 300 metric tons per year, using 18–22 metric tons of plutonium. Since 1963 about 400 metric tons of plutonium have been used in MOX. We only cover the fundamental aspects of the plutonium–uranium–oxygen system; for further details, the reader is referred to part C of the *Gmelin Handbook* (Koch, 1972), to the *Plutonium Handbook* (Wick, 1980), and to a number of original papers (Russell *et al.*, 1962; Markin and Street, 1967; Thuemmler *et al.*, 1967; Benedict and Sari, 1969; Dean *et al.*, 1970; Sari *et al.*, 1970), and reviews (IAEA, 1967; Matzke, 1982; Schneider and Roepenack, 1986; Matthews, 1987; Baily *et al.*, 1989; Bernard, 1989; Bairiot and Deramaix, 1992; Carbajo *et al.*, 2001; Bairiot *et al.*, 2003).

The plutonium–uranium–oxygen phase diagram

The details of the Pu–U–O phase diagram up to 1000°C have been obtained primarily through lattice constant measurements at high temperature and on quenched samples. It is well established that mixed uranium–plutonium oxides with stoichiometric compositions form a continuous solid solution from UO_2 to PuO_2, and the lattice parameters follow Vegard's law (see Fig. 7.101) so long as the stoichiometry is carefully controlled (Markin and Street, 1967; Thuemmler *et al.*, 1967).

The room-temperature phase diagram of the ternary U–Pu–O system is shown in Fig. 7.102 (IAEA, 1967; Markin and Street, 1967; Benedict and Sari, 1969; Koch, 1972). The system is characterized by four single-phase regions: orthorhombic U_3O_8; a cubic fluorite phase, $MO_{2\pm x}$, which occupies the largest area of the single-phase region; a cubic superstructure, M_4O_9; and a fcc C-M_2O_3 phase.

The orthorhombic U_3O_8 phase includes plutonium in its lattice to form $(U, Pu)_3O_{8-x}$ (Benedict, 1970). The maximum amount of plutonium accommodated at 1000°C corresponds to a Pu:(U + Pu) ratio of 0.06, which decreases to 0.02 at 1400°C. It is assumed that the plutonium ions introduced into the lattice occupy the U_{II} positions in U_3O_8.

The fluorite phase $(U,Pu)O_{2\pm x}$ may be hyperstoichiometric, stoichiometric, or substoichiometric with regard to the O:(U + Pu) ratio. The stoichiometric region corresponds to the pseudo-binary system UO_2–PuO_2, in which the lattice constants obey Vegard's law (see Fig. 7.101). Since PuO_2 loses oxygen at high temperature, deviations from Vegard's law can be observed. At room temperature, the range of the single-phase substoichiometric fluorite structure goes up to the ratio $Pu:(U + Pu) = 0.17$. A large region with two cubic phases extends from Pu:(U + Pu) ~0.20 up to the binary Pu–O system. One of these two cubic phases is an fcc phase with $O:(U + Pu) = 1.985$. In the range $0.2 \leq Pu:(U + Pu) \leq 0.5$, this phase is in equilibrium with a second fcc phase; and for higher plutonium contents, in equilibrium with a bcc phase of the C-Pu_2O_3 type. In the region $Pu:(U + Pu) > 0.5$ with low O:(U + Pu) ratios, there exists a bcc single-phase region, which extends up to $Pu:(U + Pu) = 0.95$ and contracts for $Pu:(U + Pu) = 0.97$ to a single line at O:(U + Pu) ~1.51. In the region $Pu:(U + Pu) \geq 0.97$, a hexagonal phase of A-Pu_2O_3 type exists.

Oxidation of $(U,Pu)O_2$ mixtures yields one- or two-phase products, depending on conditions (Brett and Fox, 1966). In the hyperstoichiometric fluorite phase $(U,Pu)O_{2+x}$, only U is oxidized to U (>IV). At room temperature, for a ratio $Pu:(U + Pu) \leq 0.30$ and for $O:(U + Pu) \leq 2.20$, a two-phase region $M_4O_9 + MO_{2+x}$ is observed. The M_4O_9 phase exists in the range $2.20 \leq O:(U + Pu) \leq 2.27$. For $O:(U + Pu) > 2.27$ and $Pu:(U + Pu) < 0.5$, a Pu-rich

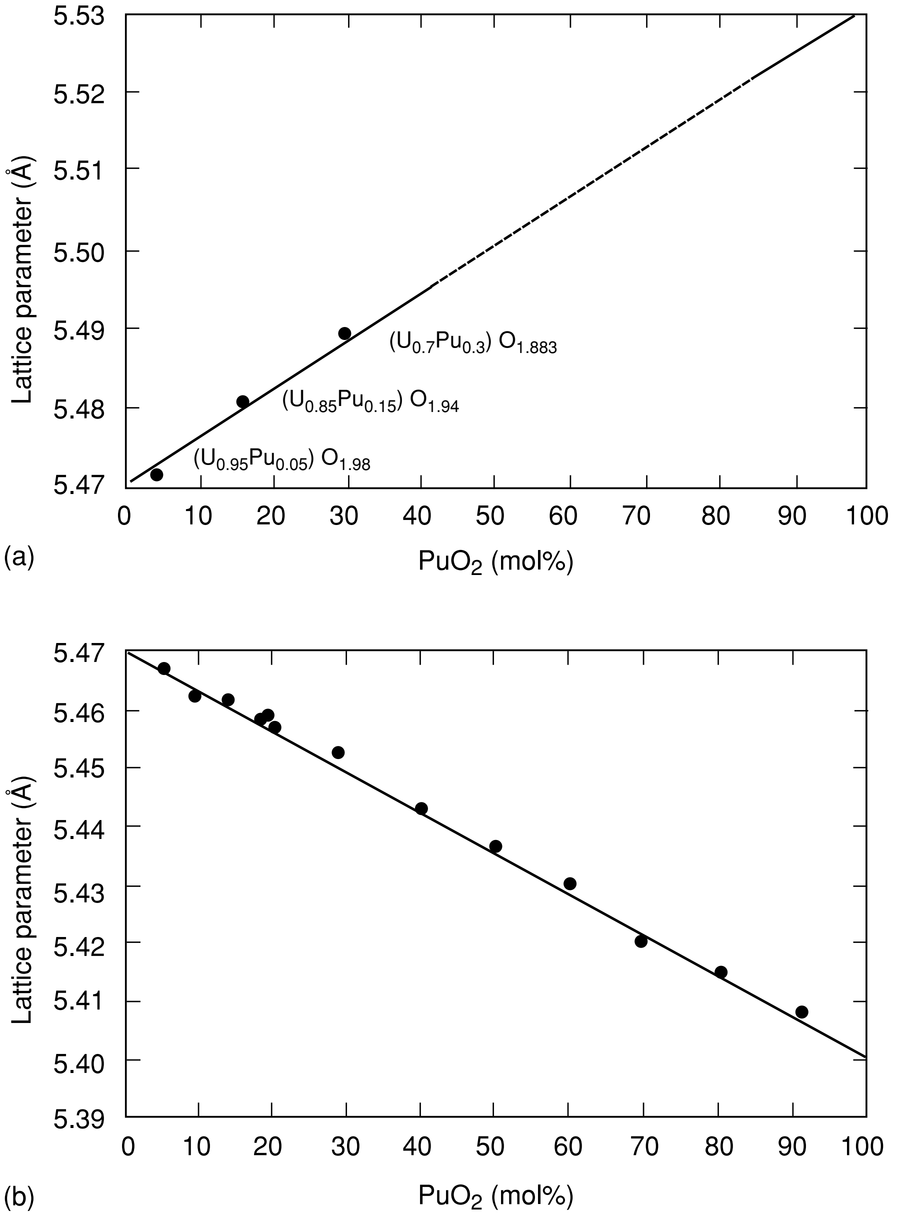

Fig. 7.101 *Lattice parameters of UO_2–PuO_2 mixed oxides that show* (*a*) *the dependence on O*:*M ratio, and* (*b*) *the dependence on PuO_2 concentration* (*Thuemmler* et al., 1967).

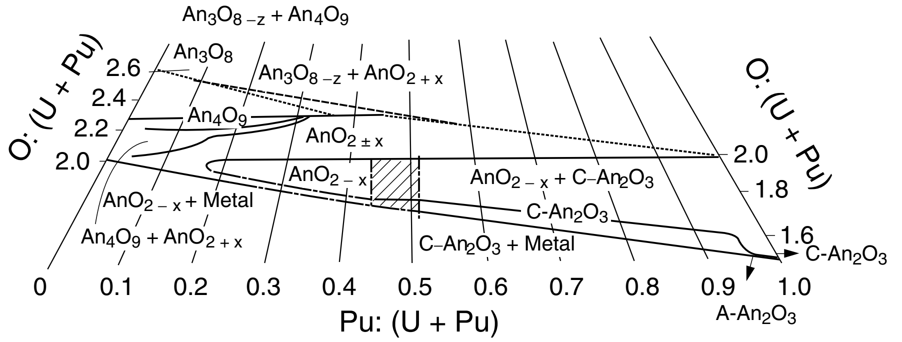

Fig. 7.102 *The phase diagram for the ternary U–Pu–O system in the composition range* (*U,Pu*)O_2–(*U,Pu*)$O_{2.67}$ *at room temperature* (*Benedict and Sari,* 1969).

fluorite phase is in equilibrium with uranium-rich M_3O_8. The oxidation of (U,Pu)O_2 at 600°C yields a metastable U_3O_7 type phase for Pu:(U+Pu) <0.25 and O:(U+Pu) $= 2.28$. Dean and Boivineau (1970) postulate a rhombohedral phase at composition M_7O_{12} for up to 60 at.% plutonium. According to Nakayama (1971), the phase relationships in the U–O system apply to $0.8 > y > 0.7$ in the MOX system $(U_yPu_{1-y})O_{2+x}$. For $y > 0.7$ there exists the tetragonal phase $(U_yPu_{1-y})O_{2+0.36y}$, which is stable up to 600°C.

Preparation

The preparation of well-defined uranium–plutonium mixed oxides is of particular importance because it is applied to the industrial production of nuclear fuel element materials. The majority of all work reported deals with oxides that contain up to 30% PuO_2, the type commonly encountered in fuel element fabrication. Oxides with more than 30% PuO_2 are much less-frequently studied. A large body of literature has been accumulated on the production of (U,Pu)O_2 ceramics for use in nuclear reactors, and a detailed account of all of this work is beyond our scope. The reader is referred to the reviews given in the *Plutonium Handbook* (Wick, 1980), the *Gmelin Handbook* (Koch, 1973c), and the peer-review literature (Schneider and Roepenack, 1986; Baily *et al.*, 1989; Bernard, 1989).

The major technical challenge in preparing (U,Pu)O_2 for fuel applications is to produce a product with the maximum degree of homogeneity. There are two main routes to deliver the required properties: comilling of UO_2 and PuO_2 and coprecipitation of UO_2 and PuO_2. Once the (U,Pu)O_2 material is formed, both processes entail mixing, pressing, sintering, and grinding operations (Schneider and Roepenack, 1986; Baily *et al.*, 1989; Bernard, 1989; Güldner and Schmidt, 1991). Hundreds of tons of mixed oxide (MOX) fuel have been produced using these processes.

Coprecipitation Processes The main process is the ammonium/uranyl/plutonyl/carbonate process (AUPuC) that produces a powder that is soluble in nitric acid. In this approach, gaseous NH_3 and CO_2 are dissolved into a mixed uranyl/plutonyl nitrate aqueous solution (<40% Pu) to generate an AUPuC of formula $[NH_4]_4[(U,Pu)O_2(CO_3)_3]$. The AUPuC precipitates as a coarse green crystalline product. These crystals are calcined into a $(U,Pu)O_2$ powder by firing at 800°C under a reducing atmosphere of N_2/H_2. The resulting $(U,Pu)O_2$ shows good flowability and sinterability (Schneider and Roepenack, 1986).

Comilling Processes Comilling generally involves mechanical grinding of UO_2 and PuO_2 powders followed by a granulation step before pressing into pellets. This process has been employed extensively at the CEA (Commissariat à l'Energie Atomique) plant in Cadarache, France. An alternate comilling approach designed by Belgonucleaire, and practiced at the French MELOX plant is referred to as the micronized master blend (MIMAS) process. In this process, plutonium and uranium oxides are mixed into a master blend that is 30% PuO_2. The master blend is homogenized and micronized in a dry ball mill, and then blended with free-flowing UO_2 powder to achieve the desired plutonium enrichment, and then pellitized (Schneider and Roepenack, 1986; Baily *et al.*, 1989; Bernard, 1989).

Properties

Due to their technological importance, the thermophysical properties of mixed uranium–plutonium oxide phases have been studied in detail. Unfortunately, most of these data are not available in the open literature. The data that are available have been critically reviewed by Fink (1982) and by Carbajo *et al.* (2001). Much of the discussion that follows has been summarized from those critical reviews.

Vaporization Behavior Vapor pressure measurements on the $(U,Pu)O_2$ system were carried out by Dean *et al.* (1970) with a Knudsen-effusion cell using ^{239}Pu and ^{233}U. Mass spectroscopy studies of vaporization of the $(U,Pu)O_2$ system were carried out by Ohse and Olson (1970), Battles *et al.* (1970), and Raj *et al.* (1999) to evaluate the effect of O:M ratio on the nature of gaseous species. These workers found that the total vapor pressure varies with O:M ratio and goes through a minimum value, suggesting there is no congruently vaporizing composition.

Solidus and Liquidus Temperatures There is an extensive literature on melting behavior. UO_2 melts at a higher temperature (2730–2876°C) than PuO_2 (2238–2445°C), and the $(U,Pu)O_2$ solid solution melts at a temperature between that of pure UO_2 and pure PuO_2. The liquidus and solidus curves of the PuO_2–UO_2 system are shown in Fig. 7.103 for the stoichiometric

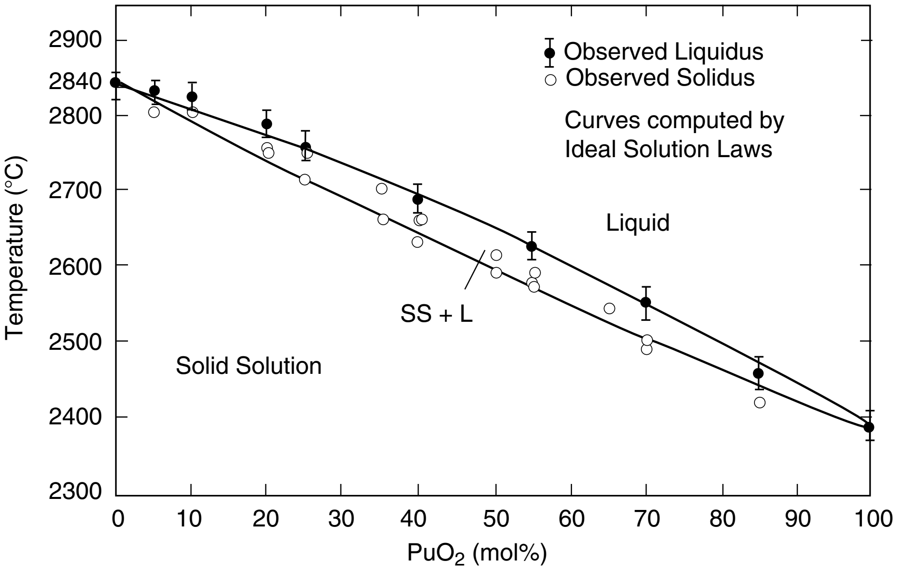

Fig. 7.103 *The solid–liquid phase diagram for the UO_2–PuO_2 system at stoichiometric composition AnO_2 (Lyon and Baily,* 1967*).*

compositions (Lyon and Baily, 1967). In MOX fuel, the actual melting temperature decreases with increasing PuO_2 content of the fuel as shown in Fig. 7.103 and with burnup (Carbajo *et al.*, 2001). Adamson has developed the following equations that predict the liquidus [$T_L(y)$] and solidus [$T_S(y)$] temperatures (in K), where y is the mole fraction of PuO_2 in $(U,Pu)O_2$ (Adamson *et al.*, 1985).

$$T_L(y) = 3120 - 388.1y - 30.4y^2 \tag{7.43}$$

$$T_S(y) = 3120 - 655.3y + 336.4y^2 - 99.9y^3 \tag{7.44}$$

Thermal Expansion and Density MOX fuel density is a function of the fuel composition, temperature, porosity, burnup, and O:M ratio (Carbajo *et al.*, 2001). The $(U,Pu)O_2$ is slightly heavier than UO_2. The density decreases with temperature due to thermal expansion. Fuel burnup changes the porosity and hence the density. At low burnup, the density increases by densification, and at higher burnup the density decreases due to swelling (Carbajo *et al.*, 2001). Martin (1988) developed equations to describe the thermal expansion and density of stoichiometric $(U,Pu)O_2$ compositions. The densities of UO_2 and PuO_2 at 273 K are 10.97 and 11.46 g cm^{-3}, respectively. The density of the solid solution $(U_{1-y}Pu_y)O_2$ changes according to the linear scaling law below, with y being the mole fraction of PuO_2 (Carbajo *et al.*, 2001).

$$\rho_s(273) = 10970 + 490y(\text{kg m}^{-3}) \tag{7.45}$$

Enthalpy and Heat Capacity Enthalpy and heat capacity are functions of the temperature, fuel composition (fractions of UO_2 and PuO_2), gadolinium content (added as a burnable neutron "poison"), O:M ratio, and burnup. The heat capacity is an important thermodynamic property that is necessary for understanding the various chemical interactions likely to occur during the irradiation of the fuel as well for modeling fuel behavior. Temperature and composition are the main influences on both enthalpy and heat capacity. Both enthalpy and heat capacity increase with temperature. The heat capacity reaches a maximum at the melting point, and then decreases. The heat capacity of UO_2 is lower than that of PuO_2. Carbajo *et al.* (2001) recommended the calculation of enthalpy and heat capacity of solid MOX fuel $U_{1-y}Pu_yO_2$ by using the Neumann–Kopp molar additivity rule, since the $(U,Pu)O_2$ system is an almost ideal solid solution. For example, to calculate the specific heat, one would use:

$$\text{Cp}(\text{T}, \text{MOX}) = (1 - y)\text{Cp}(\text{T}, \text{UO}_2) + y\text{Cp}(\text{T}, \text{PuO}_2) \tag{7.46}$$

where the heat capacity values for UO_2 and PuO_2 are calculated using polynomial expressions developed by Fink (2000) for UO_2, and Cordfunke *et al.* (1990) for PuO_2. Enthalpy polynomials were derived by integrating the Cp equations. For a detailed discussion, listings of the polynomial expressions, and tables of the necessary constants used in these equations, the reader is referred to the original publications (Cordfunke *et al.*, 1990; Fink, 2000; Carbajo *et al.*, 2001). A recent study by Kandan and coworkers experimentally verified that the enthalpies of $(U,Pu)O_2$ solid solutions does obey the Neumann–Kopp molar additivity rule (Kandan *et al.*, 2004).

Enthalpy of Fusion There is only one experimental value for the enthalpy of fusion of a MOX fuel of composition $U_{0.8}Pu_{0.2}O_2$, where Leibowitz *et al.* (1974) obtained a value of 67(3) kJ mol^{-1}.

Thermal Conductivity The thermal conductivity of MOX fuels is a function of the temperature, fuel composition, porosity, burnup, and deviation from stoichiometric composition. Thermal conductivity is a property that does not follow the law of mixtures. The existing data have been reviewed by Carbajo *et al.* (2001). The thermal conductivity decreases with temperature up to approximately 2000 K and then increases with temperature. Addition of PuO_2 to the fuel or increasing porosities reduces the thermal conductivity. Burnup, and/or deviations from stoichiometry significantly decrease the thermal conductivity. For fully dense MOX fuel, Carbajo *et al.* recommended an equation that is a combination of that proposed by Dureiz *et al.* (2000) and that of Ronchi *et al.* (1999). For full details and discussion, the reader is referred to the review by Carbajo *et al.* (2001).

7.8.6 Plutonium halides and oxyhalides

The decreasing stability of the higher actinide oxidation states in progressing from uranium through neptunium to plutonium is perhaps most clearly revealed in the halogen compounds of plutonium. With the significant and most important exception of fluorine (and, to a minor degree, chlorine), all the halogens form solid binary trihalides of general formula PuX_3 (X = F, Cl, Br, I). For tetrahalides, the only stable solid is the tetrafluoride, PuF_4, while the binary tetrachloride is only marginally stable in the high temperature gas phase as $PuCl_4(g)$. Gas phase data have been interpreted in terms of PuF_5, but there are no known pentahalides, PuX_5, in the solid state (Jouniaux, 1979; Jouniaux *et al.*, 1979; Kleinschmidt, 1988). Fluorine forms the only binary PuX_6, the technologically important hexafluoride, PuF_6. All the halogens form trivalent oxyhalides PuOX (X = F, Cl, Br, I), while fluorine forms a number of oxyfluorides that include pentavalent $PuOF_3$, and hexavalent $PuOF_4$ and PuO_2F_2.

Complex tetrahalide salts of formula M_2PuX_6 are known for X = F, Cl, Br, where M is a monovalent cation. The fluoride ion forms a range of complex salts of general formula $MPuF_5$, $MPuF_6$, M_2PuF_6, M_3PuF_7, M_4PuF_8, and $M_7Pu_6F_{31}$ for the appropriate choice of monovalent cation, M.

Plutonium hexafluoride is by far the most volatile compound of plutonium and is of extraordinary interest in that it makes possible the study of a gaseous binary compound with a rare-earth-like f^2 electron configuration.

A number of reviews have been published in which the properties of the halides have been discussed in detail (Katz and Sheft, 1960; Hodge, 1961; Bagnall, 1967a,b; Brown, 1968; Peterson, 1995).

(a) Plutonium fluorides

(*i*) *Preparation*

Because of their importance in the preparation of plutonium metal (see Sections 7.7.1 and 7.7.2), the binary plutonium fluorides have received a fair amount of attention. Their preparation has been discussed in detail by Johns and Moulton (1944), Reavis *et al.* (1960), Dawson *et al.* (1951), and Dawson and Truswell (1951). The most common procedures involve hydrofluorination of plutonium dioxide or oxalates to generate PuF_3 and PuF_4, while stronger oxidizing conditions such as F_2 will generate PuF_6.

$$2PuO_2 + H_2 + 6HF \xrightarrow{600^\circ C} 2PuF_3 + 4H_2O \qquad (7.47)$$

$$Pu_2(C_2O_4)_3 + 6HF \xrightarrow{600^\circ C} 2PuF_3 + 3CO + 3CO_2 + 3H_2O \qquad (7.48)$$

$$2Pu(C_2O_4)_2 + 6HF \xrightarrow{600°C} 2PuF_3 + 3CO + 5CO_2 + 3H_2O \tag{7.49}$$

$$PuO_2 + 4HF \xrightarrow[O_2]{550°C} PuF_4 + 2H_2O \tag{7.50}$$

$$PuO_2 + 3F_2 \overset{300°C}{\rightleftharpoons} PuF_6 + O_2 \tag{7.51}$$

$$PuF_4 + F_2 \overset{300°C}{\rightleftharpoons} PuF_6 \tag{7.52}$$

Hydrogen fluoride stored in iron cylinders contains hydrogen, which forms on reaction with the container. Occasionally sulfur dioxide is present. Under reducing conditions like these, PuF_3 results. To secure positive results, either hydrogen may be added, or the absence of reducing agents can be ensured by the addition of oxygen. Between room temperature and 150°C, hydroxyfluorides of the type $Pu(OH)_2F_2$ or $Pu(OH)F_3$ are produced by reaction of PuO_2 with HF. These intermediate compounds are readily converted either to PuF_3 by HF and H_2, or to PuF_4 by HF and O_2 by raising the temperature above 200°C. Instead of plutonium dioxide or one of the oxalates, various other plutonium(III) or plutonium(IV) compounds may also be used as starting materials for fluoride preparations, such as plutonium(IV) nitrate or plutonium peroxide.

Plutonium trifluoride

Plutonium trifluoride is insoluble in water and may therefore be prepared as a hydrate by precipitation from aqueous solution by addition of hydrofluoric acid to an aqueous Pu(III) solution. The preparation of PuF_3 from solution is best accomplished by first reducing Pu(IV) with hydroxylamine (Dawson *et al.*, 1954b) or with SO_2 (Jones, 1953; Weigel, 1965). The purple crystals of the hydrated trifluoride, $PuF_3 \cdot nH_2O$, appear to contain less than one water molecule of hydration. According to Jones (1953), the exact composition of the hydrated compound is $PuF_3 \cdot (0.40 \pm 0.05)H_2O$.

Anhydrous PuF_3 may be obtained by heating $PuF_3 \cdot nH_2O$ in a stream of hydrogen fluoride gas at 200–300°C, or by first heating plutonium(III) oxalate in a stream of hydrogen at 150 to 600°C, followed by hydrogen fluoride at 200 to 300°C (Dawson and Truswell, 1951). The latter method has been used on the 100–350 g scale. PuF_4 may be reduced directly to anhydrous PuF_3 by heating in a stream of hydrogen at 600°C (Garner, 1950).

Plutonium tetrafluoride

Addition of hydrofluoric acid to aqueous plutonium(IV) solutions precipitates pale pink plutonium tetrafluoride hydrate, $PuF_4 \cdot 2.5H_2O$. Attempts to dehydrate this substance by heating *in vacuo* did not yield anhydrous plutonium tetrafluoride, but rather the trifluoride. According to Dawson *et al.* (1954b), this rather surprising result may be accounted for by the following reaction scheme:

$$\mathrm{PuF_4 + H_2O \rightleftharpoons PuO_2 + 4HF} \tag{7.53}$$

$$\mathrm{3PuF_4 + PuO_2 \rightleftharpoons 4PuF_3 + O_2} \tag{7.54}$$

with a net reaction of:

$$\mathrm{4PuF_4 + 2H_2O \rightleftharpoons 4PuF_3 + 4HF + O_2} \tag{7.55}$$

Increasing temperature and high vacuum displaces the equilibrium toward the right and aids in the production of the trivalent fluoride. Both plutonium trifluoride and tetrafluoride hydrates are insoluble in water and will dissolve in acid only sparingly. By contrast, they may be dissolved with comparative ease in aqueous solutions of ions that form stable complexes with fluoride ions, such as Zr(iv), Fe(iii), and Al(iii), or with BO_3^{3-} which forms BF_4^-. Solutions of 0.1 M HNO_3 saturated with boric acid or aluminum nitrate are therefore especially well suited for the dissolution of PuF_3 or PuF_4. Detailed procedures for the dissolution of PuF_4 with nitric acid have been summarized by Navratil (1969a–c).

Plutonium tetrafluoride hydrate, $PuF_4 \cdot 2.5H_2O$, may be dehydrated in a stream of HF gas to anhydrous PuF_4. According to Khanaev *et al.* (1967), the dehydration of $PuF_4 \cdot 2.5H_2O$ proceeds through the successive formation of $PuF_4 \cdot 2.5H_2O$, and ultimately anhydrous PuF_4.

Both plutonium trifluoride and plutonium tetrafluoride react with oxygen at elevated temperatures. Fried and Davidson (1949) concluded that the reaction of plutonium trifluoride with oxygen proceeds according to the equation:

$$\mathrm{4PuF_3 + O_2 \xrightarrow{600^\circ C} 3PuF_4 + PuO_2} \tag{7.56}$$

This conclusion was confirmed by Dawson and Truswell (1951), who measured the oxygen partial pressure for the reverse reaction of PuF_4 with PuO_2. In the presence of water vapor and oxygen, the reaction product is PuO_2 (Dawson and Elliott, 1953). Plutonium tetrafluoride is stable in oxygen at 600°C and *in vacuo* at 900°C. On heating PuF_4 *in vacuo*, some material sublimes and the residue is found to be PuF_3. Fried and Davidson (1949) interpreted this as a disproportionation of PuF_4 into PuF_3 and PuF_5. Dawson *et al.* (1951) confirmed these conclusions but were able to show that the sublimate is probably not PuF_5. It is possible that the compound formed in this process is an oxyfluoride, as observed by Jouniaux *et al.* (1979) for the reaction of PuO_2 with F_2.

Intermediate fluoride and plutonium pentafluoride

During the preparation of plutonium hexafluoride (see below), a brick-red solid residue has been observed. This solid was identified by X-ray powder diffraction and fluorine analysis by pyrohydrolysis to be the mixed-valent compound

Pu_4F_{17} (Mandleberg *et al.*, 1956). Hawkins (1956) and Gendre (1962) have also reported evidence for the existence of this compound, but it has not been isolated in the pure state. Jouniaux and coworkers proposed the formation of gas-phase PuF_5 in their thermochromatographic study (Jouniaux *et al.*, 1979), and Kleinschmidt (1988) also interpreted his mass spectroscopy results on PuF_6 in the presence of alumina in terms of formation of this gas-phase species.

Plutonium hexafluoride

It is well known that fluorine oxidizes transition metals to their highest oxidation states. This general characteristic also holds true for plutonium. The high volatility of PuF_6 has made this compound of great technological importance, and therefore a considerable amount of information about PuF_6 is available.

Plutonium hexafluoride was first prepared at Los Alamos by Florin and coworkers (Florin, 1950a,b, 1953; Florin and Tannenbaum, 1952; Florin *et al.*, 1956). The preparation and determination of some fundamental properties was carried out at Harwell by Mandleberg and colleagues (Hurst *et al.*, 1953; Mandleberg *et al.*, 1953, 1956), while Malm and coworkers (Malm and Weinstock, 1954; Weinstock and Malm, 1956a,b) performed extensive research on the basic properties of PuF_6 at Argonne National Laboratory. Scientists at Argonne (Chemical Engineering Division) performed extensive research on PuF_6 in connection with the development of the fluoride volatility process (Adams *et al.*, 1957; Steindler *et al.*, 1958, 1959; Steindler, 1963). The review by Steindler (1963) gives an excellent summary on the preparation and properties of plutonium hexafluoride.

Plutonium hexafluoride is most easily prepared by using elemental fluorine as an oxidizing–fluorinating agent with PuF_4 or PuO_2, typically at 600°C according to the following reactions:

$$PuO_2 + 3F_2 \rightleftharpoons PuF_6 + O_2 \tag{7.57}$$

$$PuF_4 + F_2 \rightleftharpoons PuF_6 \tag{7.58}$$

The fluorination of plutonium dioxide produces oxygen, which accumulates in any apparatus in which the gases are recirculated over the unreacted solid, and periodic removal of oxygen is required to avoid dilution of fluorine. Since plutonium tetrafluoride is always formed in the fluorination of plutonium dioxide, the preferred method of preparing PuF_6 is the fluorination of PuF_4.

The preparation of PuF_6 from PuF_4 and F_2 proceeds at a reasonable rate only at fairly high temperatures, typically at 300°C. Passage of fluorine over PuF_4, in a conventional tube furnace is possible, but is not very efficient. In order to prevent thermal decomposition of the PuF_6 product, special reaction vessels are employed to permit rapid condensation of the volatile products close to the point of their preparation. Fluorination reactor vessels of this type were first used by Florin and coworkers (Florin, 1950a,b, 1953; Florin and Tannenbaum, 1952; Florin *et al.*, 1956), and by Weinstock and coworkers (Malm and

Weinstock, 1954; Weinstock and Malm, 1956b). Two of these reactor designs are shown in Fig. 7.104. The starting charge of PuF_4 is placed in a nickel dish, which is heated in a fluorine atmosphere by an induction coil. The induction coil consists of copper tubing, through which liquid nitrogen is circulated, such that the coil serves as both the heating element and the product condenser. Once formed, the PuF_6 product collects on the surface of the coil in crystalline form. This type of reactor works very well for gram-quantity preparations. For larger quantities, fluidized-bed fluorination is the preferred method. Quantities up to 500 g of Pu have been volatilized in the fluidized-bed fluorination of PuF_4. For details of the technique, see Levitz *et al.* (1968).

The use of elemental fluorine at elevated temperature is the only known method of economically producing PuF_6. Los Alamos researchers evaluated

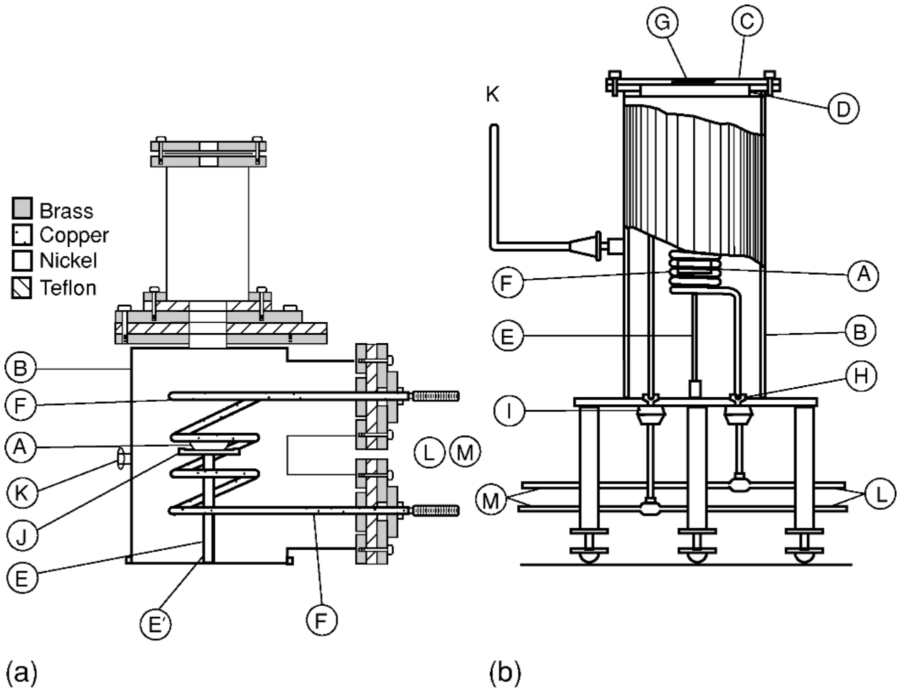

Fig. 7.104 *Two fluorination reactors for the preparation of plutonium hexafluoride. (a) The reactor used by Florin, Tannenbaum and Lemons, and (b) the reactor used by Weinstock and Malm. The legend for both reactors is as follows: A, nickel dish filled with* PuF_4*; B, brass reactor can; C, removable cover for loading the reactor; D, tongue and groove Teflon gasket for closure; E, nickel supporting rod for nickel dish; E′, nickel supporting tube; F, copper tubing induction coil that also serves as cooling coil; G, Fluorothene window; H, Teflon seal and insulator; I, Micalox insulator; J, support for nickel dish; K, connecting line to fluorine source, storage vessels and pumping systems; L, RF connection; M, liquid nitrogen circulation.*

the use of alternative oxidation fluorinating agents that proved capable of producing PuF_6 at or below room temperature (Eller *et al.*, 1992). Plutonium tetrafluoride, oxide, and oxyfluorides are all readily converted to PuF_6 by reaction with gaseous dioxygen difluoride O_2F_2 or O_2F_2/HF solutions at or below room temperature (Malm *et al.*, 1984; Erilov *et al.*, 2002). In a similar fashion, gaseous krypton difluoride, KrF_2 will also produce PuF_6 at ambient or low temperatures (Asprey *et al.*, 1986). The ability of both O_2F_2 and KrF_2 to volatilize plutonium at ambient temperature at moderate rates could have practical applications for recovery of plutonium as volatile PuF_6 from solid wastes.

Plutonium hexafluoride, when rigorously freed from traces of hydrogen fluoride, can be handled in glass equipment. Samples of PuF_6 can be purified by trap-to-trap distillation at cryogenic temperatures to remove HF, F_2, and other impurities. The handling and manipulation of PuF_6 is a very hazardous operation. A broken container means the spreading of hazardous plutonium through the air by the volatile and hydrolytically reactive hexafluoride. An actual multigram release of plutonium from a ruptured container has occurred and has been described by Trevorrow *et al.* (1965). Kessie and Ramaswami (1965) have described methods to prevent the spread of PuF_6 vapor through the ventilation system by operating the vacuum line containing the compound in a moist atmosphere. This hydrolyzes any escaped PuF_6 and converts it to PuO_2F_2, which is a filterable solid.

The rate of formation of plutonium hexafluoride by fluorination of the dioxide and the tetrafluoride was studied by Steindler (1963), who derived activation energies between 43.5 and 52.3 kJ mol^{-1}. These activation energies were found to be greater, the smaller the specific surface area. In the case of a PuF_4 sample having a bulk density of 1.3 g cm^{-3}, the rate of reaction with fluorine was found to follow the relationship

$$\log_{10}(\text{rate/mg PuF}_4\ \text{cm}^{-2}\text{h}^{-1}) = 5.917 - 2719/T \qquad (7.59)$$

The dependence of the reaction rate on the F_2 partial pressure is shown in Fig. 7.105 (Steindler, 1963).

(*ii*) *Solid-state structures*

Crystallographic data for plutonium halide and oxyhalide compounds are given in Table 7.42.

PuF_3. Plutonium trifluoride crystallizes in hexagonal (trigonal) symmetry and adopts the LaF_3 (tysonite) structure. Zachariasen (1949d) indexed the powder pattern based on hexagonal symmetry in space group $P6_3/mmc$. Subsequent work has shown that the tysonite structure has the larger trigonal cell ($P\bar{3}c1$), where $a_0 = a'_0/\sqrt{3}$ (Cheetham *et al.*, 1976). The polymeric structure is complicated, but the simple description is that each plutonium atom is surrounded by nine fluorine atoms, and the plutonium atoms lie on a two-fold axis of symmetry.

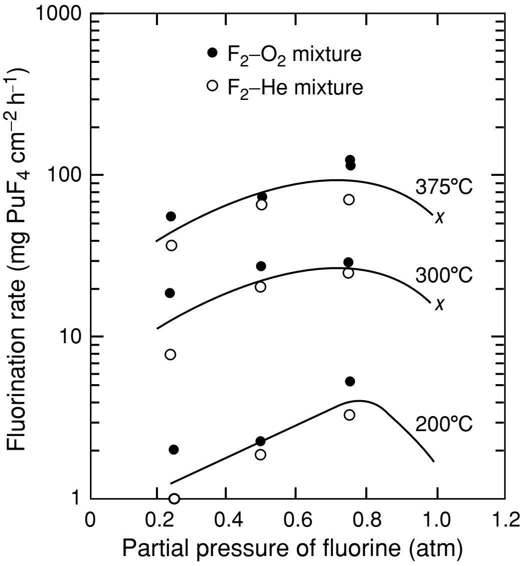

Fig. 7.105 *Fluorination of PuF_4 by fluorine diluted with He/O_2 mixtures to produce PuF_6* (*Steindler,* 1963).

PuF_4. Plutonium tetrafluoride has the ZrF_4 structure and is isostructural with all the lanthanide and actinide tetrafluorides (Wells, 1984). It possesses monoclinic symmetry, space group C2/*c*, with 12 molecules per unit cell (Zachariasen, 1949d). The basic repeating unit contains five plutonium atoms arranged in a distorted pyramid with four plutonium atoms forming a distorted base, and the fifth occupying the apex of the pyramid. Both types of nonequivalent plutonium atom are surrounded by eight fluorine atoms forming a slightly distorted square antiprism that shares vertices with eight other antiprisms. The local PuF_8 pseudo-antiprismatic coordination geometry in PuF_4 is illustrated in Fig. 7.106.

PuF_6. The solid-state structure of PuF_6 was determined by XRD by Florin and coworkers (Florin *et al.*, 1956). Crystalline PuF_6 possesses orthorhombic symmetry with four molecules per unit cell, with Pu–F distances spanning a range from 2.01 to 2.13 Å. The individual PuF_6 molecules in the crystal do not exhibit perfect octahedral symmetry, but spectroscopic studies clearly show that the compound retains octahedral symmetry in the gas phase (see below).

(*iii*) *Properties*

The plutonium trihalides have a small but finite volatility at elevated temperatures. Phipps *et al.* (1949, 1950a) were the first to measure the vapor pressures of the trihalides PuX_3, where X = F, Cl, and Br. In the case of PuF_3, the results are

Table 7.42 *Some physical constants and X-ray crystal structure data for plutonium halides and oxyhalides.*

[a] Originally reported by Zachariasen in hexagonal space group P6_3/*mmc*. The hexagonal LaF_3 (tysonite) has trigonal space group P$\bar{3}$*c1*, which is the likely space group for PuF_3. To transform from P6_3/*mmc* to P$\bar{3}$*c1*, one would use $a_0 = a'\sqrt{3}$ to derive $a_0 = 7.092$ (Å), which is the value reported above.

[b] $\beta = 126.0(2)$.

[c] Lattice constants refined from original data by Roof (1989).

[d] Original space group C*cmm*, changed to standard setting C*mcm* by Roof (1989).

[e] $\beta = 92.97(3)$.

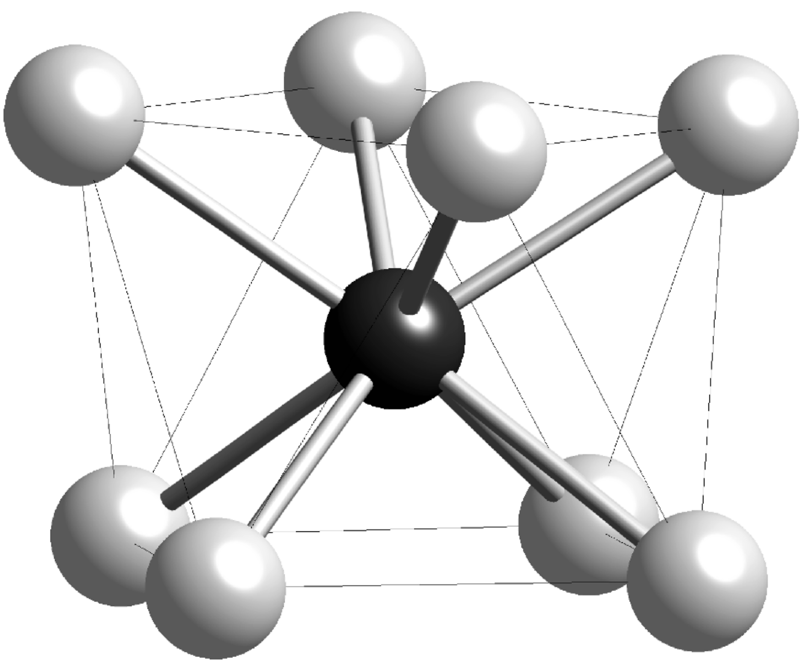

Fig. 7.106 *A view of the local coordination geometry of PuF_4 that emphasizes the local PuF_8 pseudo-antiprismatic coordination environment. The plutonium atoms are black and fluorine atoms gray.*

somewhat conflicting. In the work of Phipps *et al.* (1949, 1950a), an apparent inflection in the vapor–pressure curve implied an improbably low value for the melting point of 1447 K. A direct measurement by Westrum and Wallmann (1951) yielded values of (1698 ± 2) K for the melting point and (1699 ± 2) K for the solidification point, leading these authors to a different interpretation of the data and thus to a vapor–pressure equation that was different from the equation(s) given by Phipps *et al.* (1949, 1950a). Carniglia and coworkers (Carniglia, 1953; Carniglia and Cunningham, 1955) also measured the PuF_3 vapor pressure. Their data, agreed in general with the results of Phipps *et al.* (1949, 1950a), but the calculated enthalpies and entropies are both somewhat smaller. Kent (1968) reinvestigated the PuF_3 vapor pressure in the range 1243–1475 K by evaporating a mixture of PuF_3 and plutonium metal from a tantalum Knudsen cell attached to a mass spectrometer. He observed the species PuF_2^+, PuF^+, and Pu^+, but very little PuF_3^+. Kent used these data to obtain several important thermodynamic quantities, and have been reviewed by Lemire *et al.* (see Table 7.43).

The vapor pressure of PuF_4 has been measured by Mandleberg and Davies (1954, 1961), Chudinov and Choporov (1970), and Berger and Gäumann

(1961). Rand (1966) and Lemire *et al.* (2001) critically assessed these data. They prefer the results of Chudinov and Choporov to the data reported by the two other groups of authors. Chudinov and Choporov used a modified Knudsen method employing a nickel effusion cell, which is not attacked by fluorides. Rand discounts the measurements reported by Mandleberg and Davies because the tantalum effusion cell used by these authors would have reduced PuF_4 to PuF_3. On the basis of the known instability of PuF_5, there is also reason to believe that the disproportionation of PuF_4 into PuF_3 and PuF_5 postulated by Mandleberg and Davies is unlikely to occur, because the calculated pressure of PuF_6 in equilibrium with PuF_4 at 1200 K is 10^{-11} Torr, and because PuF_5 is less stable than PuF_6. The data of Berger and Gäumann (1961) yield too small an entropy change for a sublimation process, suggesting some reduction in their platinum effusion vessel. Another serious objection to these results is the implication that PuF_4 appears to be less volatile than UF_4, something that is not consistent with general trends in vapor pressures of other actinide halides.

In the case of $PuCl_3$ and $PuBr_3$, the only measurements reported are those by Phipps *et al.* (1949, 1950a) and, for $PuCl_3$, those by Weinstock (1944). No other recent measurements are reported. The vapor–pressure equations for PuI_3 were reported by Katz and Sheft (1960).

A detailed assessment and review of the important thermodynamic quantities such as the enthalpy of formation, standard entropy, heat capacity, and fusion data have been given by Lemire *et al.* (2001). Selected thermodynamic constants are given in Table 7.43.

Plutonium hexafluoride is a low-melting, highly volatile solid, whose vapor has the brown color of nitrogen dioxide, and which melts to a deep brown, transparent liquid. The following melting points have been reported: 325 K (52°C), 327 K (54°C), 323.7 K (50.5°C), and 324.74 K (51.59°C), the most-accurate value being the last, measured at $p = 533$ Torr. The boiling point was reported as 335.3 K (62.15°C).

The vapor pressure of PuF_6 has been measured by several authors (Hurst *et al.*, 1953; Mandleberg *et al.*, 1953, 1956; Florin *et al.*, 1956 Adams *et al.*, 1957). The most careful determination and description is that of Weinstock *et al.* (1959), who fit their data to a three-term function of temperature to derive a number of important thermochemical properties. A refit of their data by Lemire *et al.* (2001) gives $\Delta_{\mathrm{subl}}H^{\circ} = (48.65 \pm 1.00)$ kJ mol^{-1} and $\Delta_{\mathrm{f}}H^{\circ} = -(1861.35 \pm 20.17)$ kJ mol^{-1}.

Additional thermodynamic data for PuF_6 have been assessed and compiled by Rand (1966), Fuger *et al.* (1983), and Lemire *et al.* (2001). Thermodynamic data calculated from spectroscopic measurements were reported by Sundaram (1962), Nagarajan (1962), and Hawkins *et al.* (1954).

The PuF_6 molecule has 15 fundamental modes of vibration. These vibrations fall into two groups according to their predominant Pu–F stretching (ν_1, ν_2, ν_3) or bending (ν_4, ν_5, ν_6) modes. The symmetries of these modes indicate that ν_3, ν_4, ν_5, and ν_6 are all triply degenerate, ν_2 doubly degenerate, and ν_1 nondegenerate.

[a] Temperature coefficients of this function are tabulated by Lemire *et al.* (2001) in their Table 4.3.

Only ν_3 (stretching) and ν_4 (bending) are infrared active. The first comprehensive gas-phase absorption spectrum covering 4,000–20,000 cm^{-1} was reported by Steindler and Gunther in 1964 (Steindler and Gunther, 1964a,b). The observed spectrum is shown in Fig. 7.107. These measurements were refined in the wavelength region between 3000 and 9000 cm^{-1} by Walters and Briesmeister (1984) using a very long pathlength cell. In both of these early studies, the spectrometers gave spectral resolutions of several wavenumbers so that vibrational components of the spectra were not resolved. Kugel *et al.* (1976) studied PuF_6 at much higher resolution using an intracavity laser quenching technique. Analysis of the room-temperature absorption spectrum is rendered difficult by the clustering of electronic transitions as well as number of hot bands that result from the low-energy bending vibrations (ν_4, ν_5, ν_6). In a low-temperature matrix, the elimination of rotations and hot bands greatly simplifies the spectral analysis. Dewey *et al.* (1986) studied the absorption and emission of matrix-isolated PuF_6 at 8 K and were able to assign transitions below 17,000 cm^{-1}. From these data, all the vibrational frequencies have been determined from the fundamental or combination bands, and they are compiled in Table 7.44 (Dewey *et al.*, 1986).

Kim and coworkers studied the fine structure in the vibronic band near 800 nm, resolving Coriolis fine structure at the Doppler-limited resolution (Kim *et al.*, 1987). Finally, David and Kim (1988) reported the entire absorption spectrum of PuF_6 in the near IR and visible regions at high sensitivity and high resolution. They measured isotope shifts between $^{239}PuF_6$ and $^{242}PuF_6$ to identify the specific vibrational modes. The Raman spectrum of PuF_6 has not yet been observed, because of the rapid photochemical decomposition at 5641 Å (Hawkins *et al.*, 1954).

The magnetic susceptibility of plutonium hexafluoride was measured at several temperatures by Gruen *et al.* (1956). Molar susceptibilities of 131×10^{-6} cgs units at 81 K and of 173×10^{-6} cgs units at 131 K were observed. Gruen *et al.* indicated that, based on the small susceptibilities observed compared with the susceptibility of isoelectronic compounds of U(IV), Np(V), and PuO_2^{2+}, which show larger, strongly temperature-dependent values, the ground electronic state of plutonium hexafluoride is nondegenerate (see Section 7.9.3). Furthermore, the first excited state of plutonium hexafluoride must be at least 1000 cm^{-1} (0.12 eV) above the ground state, which means that there is a much greater splitting than required for the isoelectronic U(IV) compounds.

Florin *et al.* (1956) studied the equilibrium system

$$PuF_6(g) \rightleftharpoons PuF_4(s) + F_2(g) \tag{7.60}$$

and obtained the equilibrium constant in the range 160–600°C. Their data showed a significant break at 308°C, suggesting a phase change. Weinstock and coworkers (Malm and Weinstock, 1954; Weinstock and Malm, 1956a) reported a measurement of the equilibrium constant at 220°C. Trevorrow and coworkers (Trevorrow and Shinn, 1960; Trevorrow *et al.*, 1961) reexamined this system and made a careful determination of the equilibrium constant in the

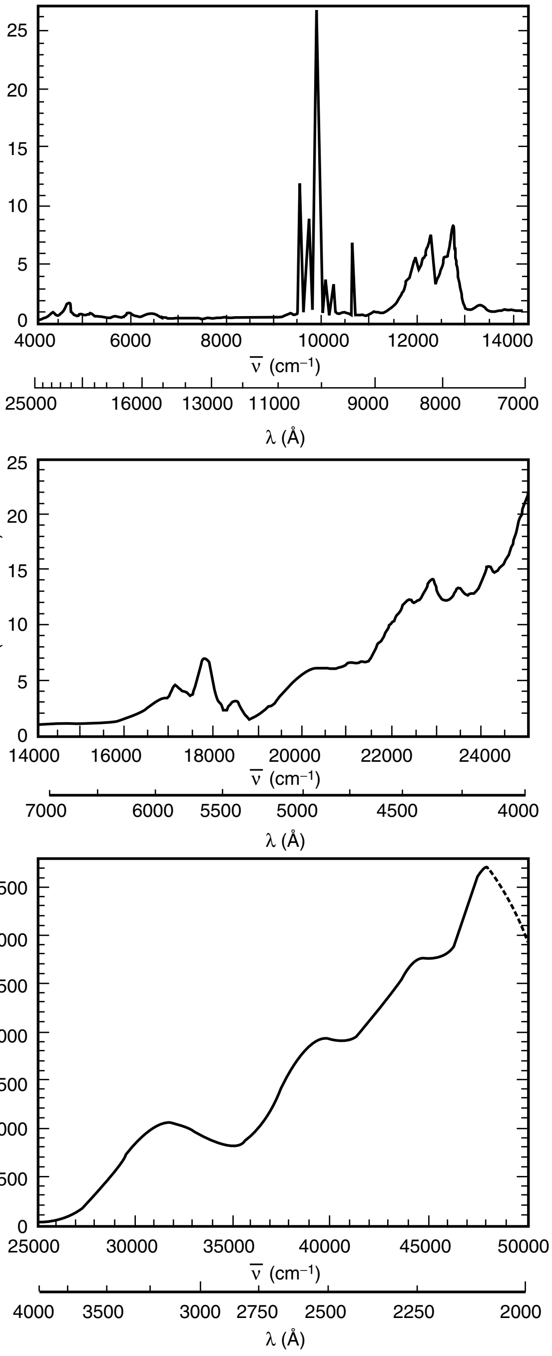

Fig. 7.107 *The absorption spectrum of gaseous PuF_6 from Steindler and Gunther* (1964*a*).

temperature range 150–400°C. Fig. 7.108 shows a plot of the log of the equilibrium constant K_p versus inverse temperature using the data of various authors (Florin *et al.*, 1956; Trevorrow and Shinn, 1960; Trevorrow *et al.*, 1961). Trevorrow and Shinn (1960) measured the equilibrium constant of the reverse reaction in the temperature range 170–395 K. This equilibrium has been measured at high pressures of fluorine (up to 825 bar) (Steindler *et al.*, 1958) and found to be pressure-independent. The free energy of the reaction

$$PuF_4(s) + F_2(g) \rightarrow PuF_6(g) \tag{7.61}$$

can be calculated from the equation

$$\Delta G^\circ = -RT \ln K = 2.55 \times 10^4 + 5.27T(\mathrm{K})\mathrm{J\ mol^{-1}} \tag{7.62}$$

The calculated value of ΔG° at 275°C is (28.36 ± 0.38) kJ mol^{-1}. The mean value of ΔH° for the reaction is (25.48 ± 0.59) kJ mol^{-1} and the mean value of ΔS° for the reaction is –(5.44 ± 0.84) J K^{-1} mol^{-1}.

Radiation decomposition

The α radioactivity of ^{239}Pu (Table 7.1) causes a continuous decomposition of PuF_6 (Steindler *et al.*, 1963; Wagner *et al.*, 1965). As the emitted α particle travels through the crystal lattice, bonds are ruptured and decomposition of PuF_6 to F_2 and lower plutonium fluorides occurs. The observed rate of decomposition (Gruen *et al.*, 1956) of gaseous PuF_6 is not a linear function of time but decreases with time from 1.78 to 0.064% of the initial PuF_6 (100 Torr) per day in the range from 0.5 to 571 days at 26°C. The initial high decomposition rate of 1.78% per day may be partly attributed to the reaction of the PuF_6 with the

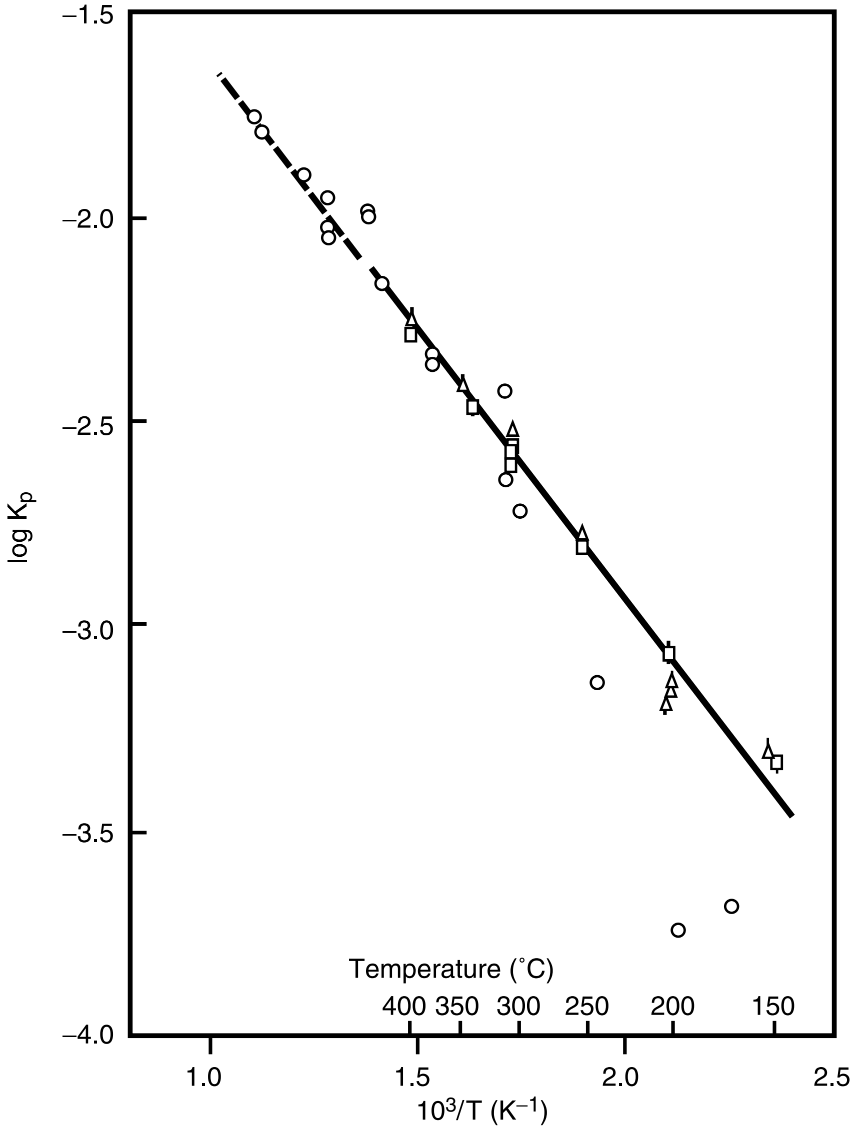

Fig. 7.108 *The relationship between the equilibrium constant and temperature for reaction* 7.60 (*Trevorrow and Shinn,* 1960). *Open circles are data from Florin* et al. (1956), *triangles are from Trevorrow* et al. *with heating to equilibrium, and squares are from Trevorrow* et al. *with cooling to equilibrium* (*Trevorrow* et al., 1961).

container material. If the pressure of the PuF_6 is lowered from 100 to 50 Torr, a lower decomposition rate is observed. Malm measured surprisingly low gas pressure in decades-old, sealed PuF_6 cylinders at ANL, and it was believed to be the result of recombination, probably involving F atoms (Morss, 2005).

Increase of the temperature introduces some thermal decomposition besides radiation decomposition. Observed rates after 77 days were (0.64 ± 0.66)% per day at 82°C, but only (0.18 ± 0.03)% per day at 26°C. Other factors influencing the decomposition of PuF_6 include the initial pressure and presence or absence of PuF_4, and presence or absence and partial pressure of He, Kr, O_2, N_2, or F_2. The exact mechanism of PuF_6 decomposition is still not completely known.

Steindler *et al.* (1963) studied the decomposition of PuF_6 under the influence of γ radiation. This is important because of the possible use of PuF_6 in the fluoride volatility process (see Section 7.5.7(c)). It was observed that PuF_6, if exposed to fission-product radiation, decomposes to form PuF_4 and F_2 with a *G*-value of (7.5 ± 1.7). Addition of 1 atm of He does not significantly change the *G*-value (number of molecules decomposed per 100 eV of radiation absorbed). Krypton, on the other hand, causes a marked enhancement of PuF_6 decomposition by γ radiation. The *G*-value observed in the presence of F_2 or O_2 is less than that observed with pure PuF_6. On the other hand, irradiation of mixtures of $PuF_4 + F_2$ produced larger quantities of PuF_6 than those calculated from the thermodynamic equilibrium constant at the temperature of the irradiation.

Because of the decomposition of PuF_6 by its own α radiation, the compound is best stored in the gaseous state under reduced pressure.

Chemical properties

Because plutonium hexafluoride tends to decompose into PuF_4 and F_2, it is a highly reactive fluorinating agent. The majority of its chemical properties are due to this reactivity.

(b) Plutonium chlorides, bromides, and iodides

In the plutonium–chlorine system, the only stable solid compound is $PuCl_3$, which has been prepared and characterized in large quantities. The only stable higher valent chloride is $PuCl_4$, which is not stable as a solid, and only known as a gaseous species that decomposes upon condensation. For the plutonium–bromine and plutonium–iodine systems, the only stable binary compounds are the trihalides, $PuBr_3$ and PuI_3.

(*i*) *Preparation*

Plutonium trichloride

This was one of the first plutonium compounds to have been prepared and characterized in detail following the initial discovery of the element (Abraham *et al.*, 1949a). Abraham *et al.* (1949a) and Garner (1950) have provided detailed discussions on the fundamental methods for its preparation. Of the various preparative methods, the hydrochlorination of plutonium(III) oxalate hydrate was found to work best on medium-scale reactions (1–10 g) according to the general reaction:

$$Pu_2(C_2O_4)_3 \cdot 10H_2O + 6HCl \rightarrow 2PuCl_3 + 3CO_2 + 3CO + 13H_2O \qquad (7.63)$$

The direct chlorination of plutonium metal at 303–500°C and subsequent sublimation at 600–800°C yields emerald green crystals of $PuCl_3$ on the 500 mg scale (Baumgärtner *et al.*, 1965). If metallic plutonium in 100 g quantities is available, this may be converted to the hydride, which is then reacted with HCl gas at 450°C in a fluid-bed reaction. The resulting $PuCl_3$ is fused at 800°C and sparged with HCl for 45 min to remove oxychlorides. The molten $PuCl_3$ may be purified by filtering through a fritted silica disk (Bjorklund *et al.*, 1959; Reavis *et al.*, 1960).

Chlorination of PuO_2 with either phosgene or carbon tetrachloride at temperatures above 500°C can produce analytically pure samples of $PuCl_3$ (Tolley, 1953; Boreham *et al.*, 1960). This process has been used at Los Alamos to convert large quantities of PuO_2 to anhydrous $PuCl_3$ (West *et al.*, 1988).

Christensen and Mullens (1952) developed a very straightforward procedure that is applicable in most transuranium chemistry laboratories, in which plutonium(III) oxalate is reacted with hexachloropropene at 180–190°C:

$$Pu_2(C_2O_4)_3 \cdot 10H_2O + 3C_3Cl_6 \rightarrow 2PuCl_3 + 3C_3Cl_4O + 3CO_2 + 3CO + 10H_2O \qquad (7.64)$$

The oxalate is refluxed with excess hexachloropropene for 18 h, yielding $PuCl_3$ of 96–98% purity, which is separated by filtration and further purified by sublimation. The method has been applied for preparations on the 100 g scale.

A method for continuous production of 98% $PuCl_3$ at a rate of 250 g h^{-1} was reported by Rasmussen and Hopkins (1961). In this process, $Pu(C_2O_4)_2 \cdot 6H_2O$ is first precipitated from Pu(IV) solution, dried on a filter drum, and calcined to reactive PuO_2. The PuO_2 is chlorinated to $PuCl_3$ with phosgene in a vibrating Hastelloy tube furnace at 500°C.

Plutonium(III) chloride, which is obtained by evaporation of a plutonium(III) solution in HCl, followed by dehydration of the $PuCl_3 \cdot 6H_2O$ residue in a stream of HCl, is a slate-blue solid. $PuCl_3$ prepared by one of the anhydrous methods is a blue-green solid or an emerald green, fine crystalline powder. Emerald green single crystals are obtained by condensation from the vapor phase (Burns *et al.*, 1975). As for other lanthanide and actinide trihalides, sublimation in evacuated, sealed quartz tubes is advisable for purification of $PuCl_3$ (Fuger and Cunningham, 1963).

Plutonium tetrachloride

As early as 1945, Brewer *et al.* (1949) predicted that no solid binary plutonium(IV) chloride should exist. However, from their calculations, the possible existence of gaseous $PuCl_4$ in an atmosphere of Cl_2 over $PuCl_3$ was inferred. Abraham *et al.* (1949a) were the first to observe an enhanced volatility of $PuCl_3$ in a stream of chlorine. This increase in volatility was ascribed to the formation of $PuCl_4$ by the equilibrium

$$\mathrm{PuCl_3 + 0.5\,Cl_2 \rightleftharpoons PuCl_4} \tag{7.65}$$

The $PuCl_4$ gas, on condensation, decomposes again to form solid $PuCl_3$ and Cl_2 gas. Abraham *et al.* (1949a) made the first calculations of the $PuCl_4$ partial pressure over $PuCl_3$ in an atmosphere of Cl_2 and predicted values in the range 10^{-5} mmHg at 500°C to 0.3 mmHg at 800°C. Benz (1962) employed a transpiration technique to determine the equilibrium constant and free energy for the above reaction.

Gruen and deKock (1967) measured the absorption spectrum of the gas phase over solid $PuCl_3$ in 1 atm of Cl_2. The absorption spectrum observed at 928°C is shown in Fig. 7.109, and shows unequivocally the presence of a new species, which is different from Cl_2 and $PuCl_3$. This spectrum is regarded as proof of the existence of gaseous $PuCl_4$.

Even though solid $PuCl_4$ has never been prepared, a number of tetravalent chloro complexes derived from $PuCl_4$, such as Cs_2PuCl_6, have been obtained, and are stable.

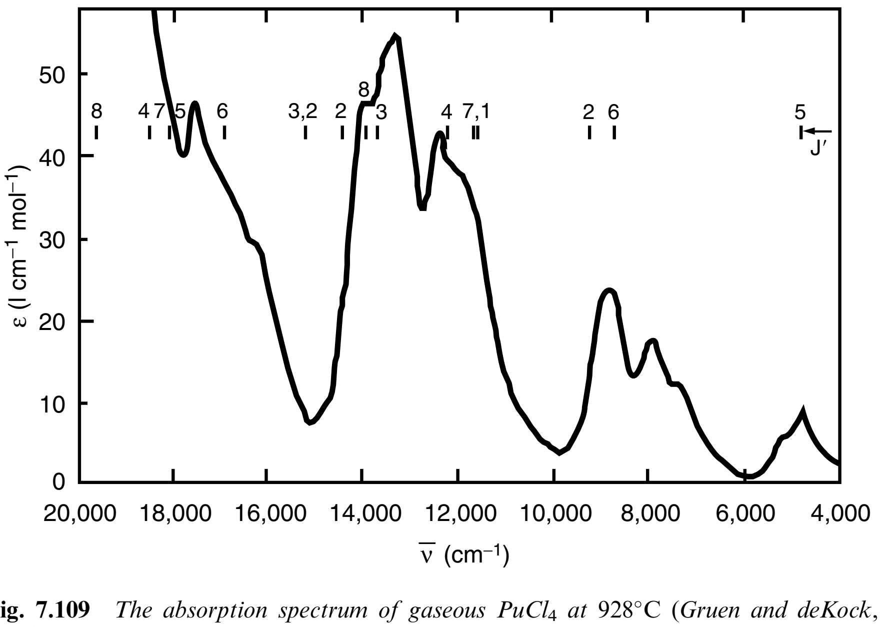

Fig. 7.109 *The absorption spectrum of gaseous* $PuCl_4$ *at* 928°C (*Gruen and deKock*, 1967).

Plutonium tribromide

This compound was first prepared by Hyde *et al.* (1944), and is a light-green solid. The methods for the preparation of $PuBr_3$ have been summarized by Bluestein and Garner (1944) and by Davidson *et al.* (1949). The two best methods for the preparation of $PuBr_3$ are the direct synthesis from the elements (Davidson *et al.*, 1949; Gruen and deKock, 1967), and the hydrobromination of the hydride at 600°C in a stream of HBr (Reavis *et al.*, 1960).

$$2Pu + 3Br_2 \rightarrow 2PuBr_3 \tag{7.66}$$

$$PuH_x + xHBr \xrightarrow{600^\circ C} PuBr_3 + xH_2 \tag{7.67}$$

Other satisfactory methods for the preparation of $PuBr_3$ include the dehydration of $PuBr_3 \cdot 6H_2O$ by controlled vacuum thermal decomposition (Brown *et al.*, 1968) and the hydrobromination of plutonium(III) oxalate at 400–600°C (Bluestein and Garner, 1944; Davidson *et al.*, 1949; Weigel *et al.*, 1982), either with pure HBr (Bluestein and Garner, 1944; Davidson *et al.*, 1949) or an HBr/H_2 mixture (Weigel *et al.*, 1982). These methods have the advantage that they do not require plutonium metal as the starting material, but make use of starting materials such as $Pu_2(C_2O_4)_3 \cdot 10H_2O$, which can be prepared from aqueous solutions (see Section 7.9.1.e.(i)).

Another method involves bromination of $Pu(OH)_4$ (dried at 70°C). This reaction proceeds satisfactorily above 600°C with HBr gas (Davidson *et al.*, 1949; Fomin *et al.*, 1958), and at 800°C with bromine and sulfur dibromide (Davidson *et al.*, 1949; Davidson and Katz, 1958). Plutonium(IV) oxalate or the tribromide hexahydrate react with HBr at 500°C and at 30–300°C, respectively, but the product of the latter reaction is usually contaminated with PuOBr. NH_4Br addition minimizes the PuOBr formation. Finally, one may convert $PuCl_3$ with HBr at 750°C (Davidson *et al.*, 1949; Bonnelle, 1976) and react PuO_2 mixed with carbon, sulfur, or phosphorus with Br_2 at elevated temperatures. Plutonium tribromide is a light green solid.

Plutonium triodide

The first attempts to prepare this compound were made by Hagemann *et al.* (1949). After initial failures, in which the oxyiodide was the reaction product, they finally succeeded in preparing PuI_3 by reacting plutonium metal with HI at 400°C. A more straightforward approach is the redox transmetallation reaction between plutonium metal and mercuric iodide, according to the reaction:

$$2Pu + 3HgI_2 \rightarrow 2PuI_3 + 3Hg \tag{7.68}$$

The plutonium metal and HgI_2 are sealed in a silica tube, and heated for 2 hours at 500°C (Asprey *et al.*, 1964). The mercury byproduct is conveniently separated by distillation away from the product. PuI_3 is extremely sensitive to moisture. Its properties have not been well characterized.

(*ii*) *Solid-state structures*

Crystallographic data on plutonium halides are summarized in Table 7.42.

$PuCl_3$. The crystal structure of $PuCl_3$ was first determined by Zachariasen (1948a) and later refined by Burns *et al.* (1975). Plutonium(III) chloride crystallizes in the hexagonal UCl_3 structure with two formula units per cell. Each plutonium atom has nine-fold coordination with a local tricapped trigonal prismatic coordination environment. Six chlorine atoms form a trigonal prism with Pu–Cl bonds of 2.886(1) Å, and the other three chlorine atoms cap the rectangular faces with Pu–Cl distances of 2.919 (1) Å (Burns *et al.*, 1975). The trigonal prisms share their triangular bases to form infinite chains along the crystallographic *c*-axis. These basic structural features are shown in Fig. 7.110.

$PuBr_3$ and PuI_3. Plutonium tribromide and triiodide are isostructural and display an orthorhombic structure known as the $PuBr_3$ structure. The structures

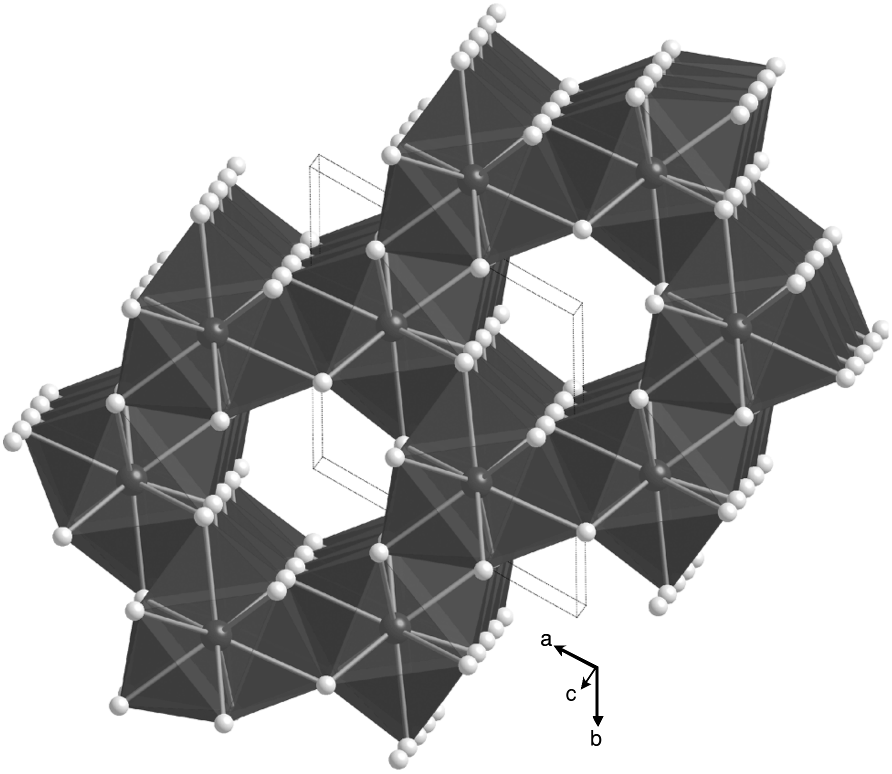

Fig. 7.110 *The solid-state crystal structure of $PuCl_3$ viewed down the c-axis and emphasizing both the hexagonal cell, and the infinite chains of tricapped trigonal prisms. Plutonium atoms are black, and chlorine atoms are light gray.*

of both $PuBr_3$ and PuI_3 were originally determined by Zachariasen (1948a), with subsequent refinements of the iodide reported by Asprey and coworkers (Asprey *et al.*, 1964). For $PuBr_3$, there are six Pu–Br bonds of 3.08 Å that form a trigonal prismatic geometry. There are two additional Pu–Br bonds that cap two of the three rectangular faces with Pu–Br distances of 3.06 Å. As in the $PuCl_3$ structure, these capped trigonal prisms stack in an infinite chain (this time along the *a*-axis) by sharing triangular bases as illustrated in Fig. 7.111. The infinite columns are now separated from each other such that the ninth bromine atom that would complete the tricapped trigonal prism is 4.03 Å away, and outside the bonding radius.

The main difference between the $PuCl_3$ and $PuBr_3$ structures is that in the $PuCl_3$ structure, each plutonium atom is nine-coordinate, while in the $PuBr_3$ structure, each plutonium atom is eight coordinate. This is surprising because the ninth bromine atom in the $PuBr_3$ structure is essentially in the correct position. The change in structure is thought to be due to the larger size of bromine and iodine (Brown, 1968), and the associated electron–electron repulsion between halogen atoms. A comparison of the column stacking between $PuBr_3$ and $PuCl_3$ structures is shown in Fig. 7.112.

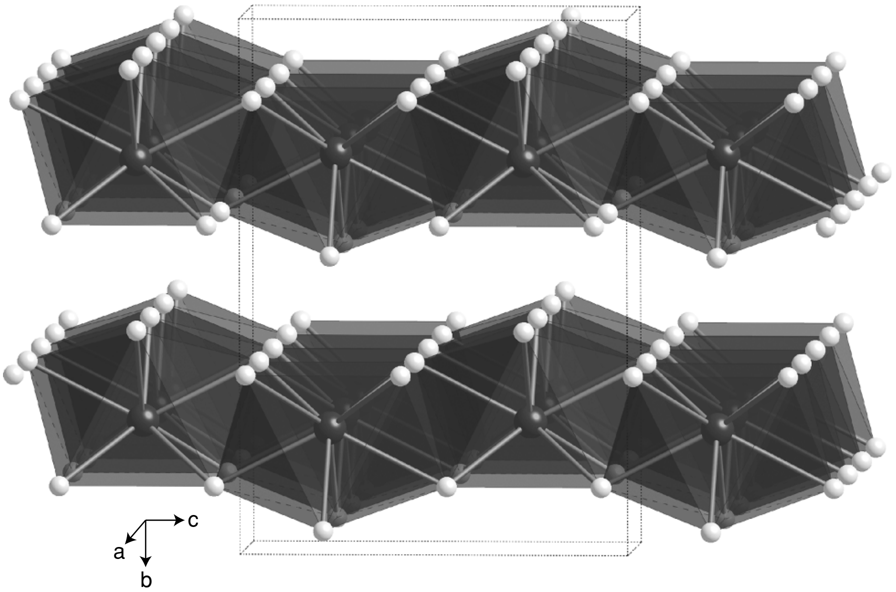

Fig. 7.111 *The solid-state crystal structure of $PuBr_3$ viewed down the a-axis and emphasizing the infinite chains of bicapped trigonal prisms. Plutonium atoms are black, and bromine atoms are light gray.*

(*iii*) *Properties*

The more important physical properties of plutonium(III) chloride are well known. Thermodynamic data are given in Table 7.43. The enthalpy of formation was first measured by Westrum and Robinson (1949a), then by Fuger and Cunningham (1963) and has been assessed by Fuger *et al.* (1983), and by Lemire *et al.* (2001). The standard free energy of formation as a function of T(K) was determined by Benz (1961), who found the following temperature dependence (958–1014 K):

$$\Delta G = -924.7 + 0.222\,92T(\text{kJ mol}^{-1}) \tag{7.69}$$

By electromotive force (EMF) measurements in fused PuCl–NaCl, Benz and Leary (1961) found the standard free energy and entropy of formation of pure solid $PuCl_3$ at 700°C to be 711 kJ mol^{-1} and 215.9 J K^{-1} mol^{-1}, respectively. From potentiometric measurements based on the Pu/$PuCl_3$ electrode, the free energy of formation of solid $PuCl_3$ in the 755–916 K temperature range was found to fit the expression

$$\Delta G = -909.6 + 0.175T(\text{kJ mol}^{-1}) \tag{7.70}$$

The optical properties of solid and gaseous $PuCl_3$ have been studied. Lipis and Pozharskii (1960) measured the absorption spectrum of $PuCl_3$ in the range 340–1000 nm. This spectrum is altered by water of crystallization, but not by absorbed or occluded water.

Conway and coworkers (Lammermann and Conway, 1963; Conway and Rajnak, 1966) measured the absorption spectrum of Pu^{3+} in an anhydrous $LaCl_3$ matrix and calculated the electrostatic, spin–orbit, and configuration-interaction parameters from these data.

The absorption spectrum of gaseous $PuCl_3$ was measured by Gruen and deKock (1967). Its energies and intensities are summarized in Table 7.45.

The magnetic susceptibility of $PuCl_3$ was measured in the range 90–600 K by Dawson *et al.* (1951). The temperature dependence of χ suggested a $5f^5$ electronic configuration for the Pu^{3+} ion.

The chemical properties of plutonium trichloride have been studied in great detail because of its application in molten-salt chemistry and metal production. $PuCl_3$ may be readily reduced to the metal by Ca, Mg, or La. The phase diagram

of the system $PuCl_3$–Pu has been studied by Johnson and Leary (1964). The metal solubility at the monotectic (740°C) was found to be 7%, but there was no indication of the formation of divalent plutonium. For the reaction of $PuCl_3$ melts with Am metal, see Mullins *et al.* (1966).

With water, $PuCl_3$ reacts to form several hydrates with 1, 2, or 6 H_2O, depending on the H_2O partial pressure (Abraham *et al.*, 1949a).

Sheft and Davidson (1949b) and Weigel *et al.* (1977) have measured the vapor-phase hydrolysis of $PuCl_3$ by determining the equilibrium constant of the reaction

$$PuCl_3(s) + H_2O(g) \rightleftharpoons PuOCl(s) + 2HCl(g) \qquad (7.71)$$

as a function of temperature. The two groups obtained nearly identical results with regard to the thermodynamic parameters of the above reaction.

With alkaline or alkaline-earth chlorides, a number of ternary chloro complexes are formed. For the individual compounds, see Section 7.8.6(d).

The optical properties of gaseous $PuBr_3$ have been studied by Gruen and deKock (1967). The energies and intensities are summarized in Table 7.45. The absorption spectrum of solid $PuBr_3$ was determined by Lipis and Pozharskii (1960) in the 340–1000 nm range. It was found to be similar to that of aqueous $PuBr_3$, but differed considerably from that of solid $PuCl_3$. This difference, together with the structural difference between $PuCl_3$ and $PuBr_3$, has been interpreted by Fomin *et al.* (1958) to indicate a change in the nature of bonding from predominantly ionic in $PuCl_3$ to predominantly covalent in $PuBr_3$.

The enthalpy of formation of $PuBr_3$ was first determined by Westrum (1949c) from its enthalpy of solution in 6 M HCl. The enthalpy of solution in O_2-free 0.1 and 1.0 M HCl, was also measured by Brown *et al.* (1977).

Sheft and Davidson (1949a) and Weigel *et al.* (1982) have measured the vapor-phase hydrolysis of plutonium(III) bromide by determining the equilibrium constant of the reaction

$$PuBr_3 + H_2O \rightleftharpoons PuOBr + 2HBr \qquad (7.72)$$

as a function of temperature. The results of both groups are in close agreement. The enthalpies of formation derived from these measurements, and reviewed by Lemire *et al.* (2001), are listed in Table 7.43.

$PuBr_3$ reacts with moisture to form the hexahydrate $PuBr_3 \cdot 6H_2O$ (Mullins *et al.*, 1966). The structural data of $PuBr_3 \cdot 6H_2O$ are listed in Table 7.42.

The enthalpy of formation of PuI_3 is reported by Brown *et al.* (1977).

(c) Oxyhalides of plutonium

Plutonium forms a number of oxyhalides in the valence states III and VI. So far, no oxyhalides of Pu(IV) or Pu(V) have been prepared. With Pu(III), the oxyhalides, PuOF, PuOCl, PuOBr, and PuOI are known.

(*i*) *Preparation and properties*

For plutonium(III) oxyfluoride, no direct method of preparation has been reported. Rather, PuOF was accidentally obtained in the attempted reduction of PuF_3 by hydrogen (Cunningham, 1954), and in an attempt to measure the melting point of plutonium metal.

Plutonium(III) oxychloride, PuOCl, was first prepared by Abraham *et al.* (1949a) by heating $PuCl_3 \cdot 6H_2O$ in a sealed tube at 400°C. The resulting preparation contained 60% PuOCl and 40% $PuCl_3$. In another similar preparation, a product containing 60–65% PuOCl and 40–35% $PuCl_3$ was obtained, which could be converted to pure PuOCl by heating in a sealed tube with 95 Torr H_2 and 55 Torr HCl at 675°C.

A preparation method yielding pure PuOCl in a one-step reaction was reported by Westrum and Robinson (1949b). They also made the first determination of the enthalpy of formation using the reaction of $PuCl_3$ with a stream of H_2, HCl and water vapor at 675°C.

The formation of PuOCl in the vapor-phase hydrolysis of $PuCl_3$ (see Section 7.8.6.b.(iii)) has been studied by several authors (Abraham and Davidson, 1949; Sheft and Davidson, 1949b; Weigel *et al.*, 1977), who have also determined the enthalpy of formation. The best values at the time of writing are given in Table 7.43.

Plutonium(III) oxybromide, PuOBr, was first observed by Davidson *et al.* (1949) as a residue from the sublimation of small amounts of $PuBr_3$ in a silica tube. It can be obtained in a pure state by treating gently heated Pu(IV) hydroxide (70°C) with moist hydrogen bromide at 750°C (Davidson *et al.*, 1949; Sheft and Davidson, 1949a), or by vapor-phase hydrolysis (Weigel *et al.*, 1982).

The enthalpy of formation of PuOBr was determined by Weigel *et al.* (1982) by measurement of the equilibrium constant of the vapor-phase hydrolysis of $PuBr_3$. Rand (1966), Fuger *et al.* (1983), and Lemire *et al.* (2001) have assessed previous values of the enthalpy of formation and the recommendations of the latter are listed in Table 7.43.

Plutonium(III) oxyiodide, PuOI, was observed to form in attempts to prepare PuI_3 (Hagemann *et al.*, 1949). In all reactions in which even traces of water are present, or are being formed in the course of the reaction, the bright-green PuOI is formed.

So far, no oxyhalides of tetravalent or pentavalent plutonium have been prepared. However, there is thermochromatographic evidence for the existence of $PuOF_3$ (Jouniaux, 1979; Jouniaux *et al.*, 1979), but this compound has not yet been isolated.

The only oxyhalides of hexavalent plutonium that have been isolated and prepared in substantial quantities are plutonyl fluoride, PuO_2F_2 (Alenchikova *et al.*, 1961a), plutonium(VI) oxytetrafluoride, $PuOF_4$ (Burns and O'Donnell, 1977), and plutonyl chloride, $PuO_2Cl_2 \cdot 6H_2O$ (Alenchikova *et al.*, 1959). $PuOF_4$ is formed when an excess of PuF_6 is condensed on a 0.23% solution of deionized water in HF, and the mixture is warmed to room temperature. After evaporation of unreacted HF and PuF_6, the $PuOF_4$ separates as a chocolate-brown solid. PuO_2F_2 is prepared by slow, low-temperature hydrolysis of PuF_6:

$$PuF_6 + 2H_2O \rightarrow PuO_2F_2 + 4HF \tag{7.73}$$

Alenchikova *et al.* (1961a) studied the system PuO_2F_2–HF–H_2O and observed $PuO_2F_2 \cdot H_2O$, $PuO_2F_2 \cdot HF \cdot 4H_2O$, and anhydrous PuO_2F_2 solids in equilibrium with the solution for 0–1.3% HF, 1.9–0.85% HF, and 87–100% HF, respectively.

Plutonyl chloride hexahydrate, $PuO_2Cl_2 \cdot 6H_2O$, has been prepared by vacuum evaporation at room temperature of Pu(VI) chloride solutions (Alenchikova *et al.*, 1959) formed by oxidation of Pu(IV) chloride solutions with chlorine. The greenish-yellow $PuO_2Cl_2 \cdot 6H_2O$ was identified by chemical and spectrophotometric analysis. $PuO_2Cl_2 \cdot 6H_2O$ is not stable, and gradually decomposes to a Pu(IV) compound.

(*ii*) *Solid-state structures*

All the PuOX compounds with heavier halides (Cl, Br, I) have the well-known PbClF structure type, and were first characterized by Zachariasen (1949d). This basic structure is built up of layers of different atom types. Each complex layer in the PuOX structure consists of a central sheet of coplanar oxygen atoms with a sheet of halogen atoms on each side, and plutonium atoms sandwiched in between. The basic layer structure is shown in Fig. 7.113(a). Within one of these complex layers, the plutonium atoms are coordinated by four oxygen and four chlorine atoms, making a local square antiprismatic coordination geometry. A view of the structure that emphasizes the square antiprismatic geometry is shown in Fig. 7.113(a).

The crystal structure of PuOF was originally reported to be cubic by Zachariasen (1949d), but a subsequent study of powder diffraction data showed that the compound was actually tetragonal (Zachariasen, 1951). In the tetragonal form, the structure fits into a class of MOF structures that display a superstructure that is related to the fluorite structure. In the tetragonal superstructure, the oxygen and fluorine atoms arrange themselves in sheets separated by a layer of plutonium atoms. The local coordination around plutonium is that of cube, with four fluorine atoms on one side, and four oxygen atoms on the opposite side. This cubic PuF_4O_4 coordination environment is compared with the square antiprismatic coordination environment found in PuOX (X = Cl, Br, I) in Fig. 7.113(b).

(d) Ternary halogenoplutonates

With ammonium, alkali, and alkaline-earth halides, and, in a few cases, with transition-metal halides, plutonium(III), (IV), (V), and (VI) halides form a large number of ternary halogenoplutonates.

The fluoroplutonates and pseudo-binary systems containing plutonium fluorides are of major interest as potential materials for molten-salt fuels in high-temperature reactors. Therefore, much work has been devoted to the individual compounds and, in some cases, to pseudo-binary phase diagrams. Leary (1962) has summarized the phase diagram work done up to 1962.

The preparation of individual fluoroplutonates depends on the nature of the compound to be prepared. The following methods are the ones usually employed.

1. A compound is precipitated from aqueous solution, and dried below 100°C.
2. Stoichiometric amounts of alkali halide and plutonium(III) or plutonium(IV) halide in HCl or HF solution(s) are evaporated to dryness. The residue is heated in a platinum boat or a sapphire dish at 300°C in a stream of HF.
3. Stoichiometric amounts of PuF_4 or PuO_2 and alkali or alkaline-earth fluoride are intimately mixed and heated at 300–600°C in a stream of HF, HF + O_2, or HF + H_2 (the latter for preparation of Pu(III) complexes).
4. Stoichiometric amounts of PuF_4 or PuO_2 and NH_4F are heated together in a closed vessel at 70–100°C. The product is pulverized and heated again in

the same manner. This procedure is repeated until a homogeneous product has been obtained.

5. Thermal decomposition of a higher complex, or treatment of another plutonium fluoro complex with elemental fluorine.
6. PuF_6 and alkali or alkaline-earth fluoride are reacted.
7. Alkali carbonate is added to plutonium nitrate solution, the solution evaporated with HF and treated with F_2.
8. PuF_4 is fused with the stoichiometric amount of the corresponding alkali fluoride.
9. PuF_4 is fused with the stoichiometric amount of alkali or metal fluoride.
10. Cooled solution of Pu(v) in dilute acid is added to ice-cold saturated RbF solution.

The known fluoroplutonate complexes have been compiled in Table 7.46. The phase diagrams of the systems LiF–PuF_3 and NaF–PuF_3 have been reported by Barton *et al.* (1961). These two systems are the only ones based on PuF_3 for which phase diagrams have been determined. No other systems, neither based on PuF_3 nor based on PuF_4, have been reported.

With the chloride systems, a different situation exists. Even though only very few compounds have been characterized as individual entities, several phase diagrams have been determined. Most of the compounds occurring in these phase diagrams have never been studied in great detail. Phase diagrams have been reported for solid–liquid equilibria in the binary systems $PuCl_3$–MCl, where M = Li (Bjorklund *et al.*, 1959), Na (Bjorklund *et al.*, 1959), K (Benz *et al.*, 1959), Rb (Benz and Douglass, 1961b), Cs (Benz and Douglass, 1961b), and $PuCl_3$–$M'Cl_2$, where M′ = Mg, Ca, Sr, and Ba (Johnson *et al.*, 1961). An excellent summary of these phase diagrams was reported by Leary (1962). Some of the systems based on $PuCl_3$ have become of practical importance in fused-salt ER of plutonium, and in the DOR and pyroredox processes (see Section 7.7.2). As a representative phase diagram of such a system, the diagram of the system KCl–$PuCl_3$ is shown in Fig. 7.114 (Benz *et al.*, 1959). In these systems based on $PuCl_3$, compounds such as $RbPu_2Cl_7$ (light blue), $CsPu_2Cl_7$ (greenish blue to deep green), $RbPuCl_5$ (brownish to greenish yellow), Cs_3PuCl_6 (green), or M_3PuCl_9 (M = Sr, Ba) (no color given) have been observed, but none of these compounds have been studied in detail.

The hexachloroplutonates M_2PuCl_6, where M = Na, Rb, Cs, $(CH_3)_4N^+$, or $(C_2H_5)_4N^+$, are obtained as pale greenish yellow (alkali compounds) or orange-yellow (alkylammonium compounds) crystals by precipitation from concentrated HCl solution. Except for Cs_2PuCl_6, the properties of these compounds are not known in detail. Cs_2PuCl_6 is sufficiently stable to be useful as a primary plutonium standard (Miner *et al.*, 1963). No bromo or iodo complexes of plutonium(IV) are known, with the sole exception of the red bromo complex, $[(C_2H_5)_4N]_2PuBr_6$, which was prepared by Ryan and Joergensen (1964) by precipitation from ethanolic HBr solution on the addition of acetone.

A number of derivatives of plutonyl chloride, PuO_2Cl_2, which is known as the hexahydrate $PuO_2Cl_2 \cdot 6H_2O$ (Alenchikova *et al.*, 1959), have been prepared. These compounds contain the anion $[PuO_2Cl_4]^{2-}$. Probably the best-known compounds of this type are the rubidium salt, $Rb_2PuO_2Cl_4$, and the cesium salt, $Cs_2PuO_2Cl_4$, which form orange-yellow crystals. The lattice constants of both compounds have been determined by Werner (1982) and are listed in Table 7.47. The lattice constants and other crystallographic properties determined for halo complexes of plutonium are listed in Table. 7.47.

7.9 SOLUTION CHEMISTRY

Descriptive solution and coordination chemistry played a key role in the discovery of plutonium and in the formulation of the actinide series concept (Seaborg and Loveland, 1990). The need to separate and purify plutonium from nuclear fuel during the Manhattan Project drove much of the early solution chemistry and included the extraction of plutonium coordinated by organic ligands, pyrochemical processing in molten salts, and the distillation or

centrifugation of volatile halide, alkoxide, and borohydride complexes (Koch, 1972, 1973a–c, 1976a,b). Solution and coordination chemistry continues to play a role in modern plutonium processing and separations, and for recycle of plutonium in closed nuclear fuel cycles. More recently, interest has grown in the chemistry of plutonium under biologically and environmentally relevant conditions, as attention has turned to understanding the long-term fate and transport of plutonium stored in geological repositories (Clark *et al.*, 1995; Neu *et al.*, 2002; Silva and Nitsche, 2002). Selected aspects of plutonium coordination chemistry have been reviewed by Cleveland (1979) and Carnall and Choppin (1983), and within broader reviews on actinide elements (Lemire *et al.*, 2001; Burns *et al.*, 2004). In this section we describe the preparation, stability, structure, and spectroscopy, of aqueous and nonaqueous molecular complexes of plutonium.

7.9.1 Aqueous solution chemistry

The chemistry of plutonium in aqueous solution is unique and rich. It is also complicated, primarily due to the small energy separations between the various oxidation states and the extreme oxophilicity of plutonium cations. Five oxidation states, Pu(III), Pu(IV), Pu(V), Pu(VI), and Pu(VII), can be readily prepared and stabilized in aqueous solution under the appropriate conditions. The lower oxidation states, Pu(III) and Pu(IV), are generally more stable in acid solution while the higher oxidation states, Pu(VI) and Pu(VII), are favored under alkaline conditions. Tetravalent plutonium is the most stable and consequently the most studied, followed by plutonium in the trivalent and hexavalent states. In the decades following the discovery of plutonium, its solution chemistry was motivated by the need to separate plutonium from mixtures of actinides and fission products in multiple oxidation states under highly acidic conditions. Processes that used oxidation and/or reduction steps in solution and condensed phases bolstered the study and understanding of aqueous Pu(III) and Pu(VI). In contrast, pentavalent plutonium is most stable in near-neutral pH solutions that are dilute in both plutonium and other ions. Although Pu(V) was identified along with the other common oxidation states, research on the solution complexes of this oxidation state was not widely pursued until the 1990s when the behavior of plutonium in environmental matrices gained importance. Heptavalent plutonium was the last oxidation state to be discovered, and it was first reported in 1967 (Krot and Gel'man, 1967). Plutonium in this oxidation state is stable only in highly alkaline solution and in the presence of strong oxidizing agents, and is therefore the least well studied. There are very recent spectroscopic studies that suggest the possibility of the existence of Pu(VIII) in alkaline solution (Nikonov *et al.*, 2004, 2005). The existence of this oxidation state is equivocal, and we look forward to future research in this area.

Under noncomplexing strongly acidic conditions, such as in perchloric or triflic acid solutions, both Pu(III) and Pu(IV) exist as the simple hydrated (or aquo) ions, $Pu^{3+}_{(aq)}$ or $Pu^{4+}_{(aq)}$, retaining their overall formal charge. In the sections that follow, we refer to the $Pu^{3+}_{(aq)}$ or $Pu^{4+}_{(aq)}$ species as simply Pu^{3+} and Pu^{4+}, or Pu(III) and Pu(IV), respectively. Pentavalent and hexavalent plutonium cations have such large positive charges that in aqueous solution they immediately hydrolyze to form a unique class of trans dioxo cations, $PuO^{+}_{2(aq)}$ and $PuO^{2+}_{2\,(aq)}$, which are commonly referred to as plutonyl ions. Under noncomplexing acid conditions (such as perchloric or triflic acid), both ions exist as the simple hydrated (or aquo) ions, $PuO^{+}_{2(aq)}$ and $PuO^{2+}_{2(aq)}$, and we refer to these as simply PuO_2^+ and PuO_2^{2+}, or Pu(V) and Pu(VI), respectively. These plutonyl cations have estimated effective charges of 2.2 and 3.3, respectively (Choppin, 1983). Heptavalent plutonium is not stable in acid solution, and can only be prepared under highly alkaline solution conditions. Under alkaline conditions, the heptavalent ion forms a tetra-oxo species PuO_4^-, which is always coordinated with hydroxide ions to give $PuO_4(OH)_2^{3-}$. We will refer to this species as Pu (VII). The OECD-NEA has evaluated thermodynamic properties for plutonium ions in aqueous solution, and a selected set of their recommended values is given in Table 7.48 (Lemire *et al.*, 2001).

(a) Stoichiometry and structure of plutonium ions

From an historical perspective, the charge and composition of plutonium ions in acid solution were inferred from solvent extraction studies. For example, plutonium(III) and plutonium(IV) are written as Pu^{3+} and Pu^{4+} in part from an interpretation of charge balances in solvent extraction studies with thenoyltrifluoroacetone (Poskanzer and Foreman, 1961), and also from the lack of hydrogen-ion dependence of the reversible Pu(IV)/Pu(III) redox couple (Rabideau, 1956). The Pu(V)/Pu(IV) redox couple on the other hand, is not rapidly reversible, nor independent of hydrogen-ion concentration, indicating that the two ions differ in degree of oxygenation. The existence of the trans dioxo ions in Pu(V) and Pu(VI) (PuO_2^+ and PuO_2^{2+}, respectively) was originally based on crystallographic data on solid compounds. For Pu(VI), XRD data for $NaPuO_2(O_2CCH_3)_3$ and $Cs_2PuO_2Cl_4$ confirmed that the compounds were isostructural with the corresponding uranium, neptunium, and americium analogs, and contained the linear PuO_2^{2+} unit (Werner, 1982). Similar structural

Table 7.48 *Selected chemical thermodynamic values for plutonium aquo ions* (*Lemire* et al., 2001).

Formula	$\Delta_f G^\circ$ (kJ mol^{-1})	$\Delta_f H^\circ$ (kJ mol^{-1})	S° (J K^{-1} mol^{-1})
Pu^{3+}	−579.0 ± 2.7	−591.8 ± 2.0	−184.5 ± 6.2
Pu^{4+}	−478.0 ± 2.7	−539.9 ± 3.1	−414.5 ± 10.2
PuO_2^+	−852.6 ± 2.9	−910.1 ± 8.9	+1 ± 30
PuO_2^{2+}	−762.4 ± 2.8	−822.0 ± 6.6	−71 ± 22

comparisons were found for other Pu(vi) compounds, and helped to assign the basic formula PuO_2^{2+} to Pu(vi) in solution. Plutonium(v), likewise, was assigned the formula PuO_2^+ because of the existence of the PuO_2^+ unit in the solid-state structure of $KPuO_2CO_3$ (Ellinger and Zachariasen, 1954), and in part because the oxidation–reduction couple Pu(vi)/Pu(v) is reversible and independent of the hydrogen-ion concentration (except for the shift in potential due to hydrolysis). This argued that there was no structural rearrangement during redox, and therefore that the oxygen content was identical in both ions.

Recent X-ray absorption and vibrational spectroscopic studies provide more direct characterization of the solution forms of the ions in all oxidation states. Under noncomplexing acid conditions, Pu(iii), Pu(iv), Pu(v), and Pu(vi) are coordinated by water molecules, resulting in hydrated cations of general formula $Pu(OH_2)_n^{3+}$, $Pu(OH_2)_n^{4+}$, $PuO_2(OH_2)_n^+$, and $PuO_2(OH_2)_n^{2+}$, respectively. Structural analysis in solution using EXAFS spectroscopy has been recently employed to determine the number of coordinated water molecules (n) and the Pu–O distances in the aquo ions (Allen *et al.*, 1997; Conradson *et al.*, 2004a). For the Pu(iii) aquo ion, $Pu(OH_2)_n^{3+}$, EXAFS studies report coordination numbers of 9 (Conradson *et al.*, 2004a) and 10 (Allen *et al.*, 1997), with Pu–O distances of 2.48(1) and 2.51(1) Å, respectively. These coordination number estimates are consistent with previous estimates of 9 that were based upon comparison with Cm(iii) from luminescence lifetime measurements (Kimura and Choppin, 1994), and Am(iii) determined from optical absorption spectroscopy (Carnall, 1989). Relativistic DFT calculations suggest eight or possibly nine water molecules for the Pu(iii) aquo ion, $Pu(OH_2)_9^{3+}$ (Blaudeau and Bursten, 2000). A recent single crystal XRD study of a salt containing the $Pu(OH_2)_9^{3+}$ unit substantiates the coordination number of 9 for the Pu(iii) aquo ion (Matonic *et al.*, 2001) in the solid state. In this compound, the $Pu(OH_2)_9^{3+}$ ion adopts a tricapped trigonal prismatic coordination environment, where all nine coordinated water molecules show a similar Pu–O distance that averages 2.51 Å (Matonic *et al.*, 2001) comparable to the values observed by EXAFS. For Pu(iv), EXAFS analysis indicates the presence of eight water molecules at a shorter Pu–O distance of 2.39(1) Å (Conradson *et al.*, 2004a). For Pu(v) and Pu(vi) aquo ions, EXAFS data reveal two short plutonyl Pu=O bonds at 1.81(1) and 1.75(1) Å (respectively) consistent with expectations for trans dioxo ions. Each plutonyl unit is coordinated by four or five water molecules with Pu–O bond distances of 2.47(1) and 2.41(1) Å, respectively (Conradson *et al.*, 2004a). Similar analyses on the aquo ions of UO_2^{2+}, NpO_2^{2+}, and NpO_2^+ indicate that a coordination number of 5 is the most common, but that this value will be affected by changes in the ionic strength of solution (Antonio *et al.*, 2001). Theoretical analysis of XANES, coupled with experimental measurements, have provided new insights on the electronic structure of these ions, especially the nature of the bonding interactions between plutonium and axial oxygen atoms in the PuO_2^+, and PuO_2^{2+} aquo ions (Ankudinov *et al.*, 1998).

Ions of Pu(vii) also contain Pu=O multiple bonds, and the preponderance of evidence indicates the presence of polyoxo ions with four or more oxo groups depending on solution conditions. The reversibility of the Pu(vii/vi) reduction, similar to the Pu(vi/v) reversible reduction supports the formulation of a polyoxo ion. A series of anionic polyoxo species that form between 0.5 and 18 molar hydroxide has been proposed and includes $PuO_4(OH_2)_2^-$, $PuO_4(OH)(OH_2)^{2-}$, $PuO_4(OH)_2^{3-}$, $PuO_5(OH)^{4-}$, or PuO_6^{5-}, depending on hydroxide concentrations (Spitsyn *et al.*, 1969; Krot, 1975; Tananaev *et al.*, 1992). Of the proposed species, only $PuO_4(OH)_2^{3-}$ has a known analog in neptunium chemistry (Grigor'ev *et al.*, 1986). The neptunium analog, $NpO_4(OH)_2^{3-}$, has a highly unusual geometry with four short Np=O bonds in a square plane, with two axial OH^- ligands (Grigor'ev *et al.*, 1986; Bolvin *et al.*, 2001; Williams *et al.*, 2001). Current research is aimed at defining conditions that favor the various forms, and at identifying their exact structure and reactivity.

Structural representations of the simple aquo ions of plutonium are given in **4**, **5**, **6,** and **7** below.

(b) Spectroscopic properties of plutonium ions

The electronic absorption spectra of plutonium ions, like those of most other actinide elements, are characterized by the presence of a few very sharp bands with relatively low molar absorptivities compared to those of d-block metal ions. The very sharp bands are strongly reminiscent of spectra of the rare-earth ions, which are attributed to electronic transitions within the shielded 4f–4f manifold of states (Edelstein, 1991). In the actinide elements, similar but relatively less shielded transitions are attributed to the 5f shell (Carnall *et al.*, 1991; Carnall, 1992; Denning, 1992, 1999). The 5f–5f transitions are more intense than the 4f–4f transitions of the lanthanides, due in part to relativistic effects that generate larger spin–orbit coupling. Energy levels for trivalent actinide ions calculated using 5f transitions compare well with experimental spectra, supporting this representation of electronic structure in plutonium (Mikheev *et al.*, 1983; Carnall, 1992). Since these transitions are forbidden by the selection rules, the absorption bands are narrow, but still not very intense.

Internal 5f–5f transitions of the plutonium ions give absorption bands in the visible and near-IR region of the electronic absorption spectrum. These absorption features are characteristic for each oxidation state and therefore frequently used for identification and quantitative analysis of plutonium ions in solution (Cohen, 1961a). Representative electronic absorption spectra of plutonium ions of common oxidation states are given in Fig. 7.115 and molar absorptivities for distinctive bands are given in Table 7.49. Plutonium ions of all oxidation states have strong absorbance in the UV region of the optical spectrum (Stewart, 1956; Cohen, 1961b). In addition to conventional electronic absorption spectroscopy, two-photon optical absorption spectroscopy has also been used to probe the electronic structure of plutonium ions isolated in host matrices and these data have provided useful extrapolations for interpreting the spectra of the solvated ions (Denning, 1991).

Photothermal spectroscopic techniques have been applied to increase the sensitivity and selectivity of the optical absorption method of plutonium analysis. For example, photoacoustic spectroscopy, in which the pressure pulse generated from absorbed light heating the solution is transduced to an electronic signal, generally has 10 to 100 times greater sensitivity (depending on the spectral region) than conventional spectrophotometry (Stumpe *et al.*, 1984; Neu *et al.*, 1994). Thermal-lensing spectroscopy has sensitivities similar to photoacoustic spectroscopy and also uses the heating of the solution due to the absorption of small amounts of energy to detect and quantify analytes. This method optically probes the gradient in the refractive index, which is generated from solution heating, as a 'thermal lens' (Moulin *et al.*, 1988). The use of fiber optics and pulsed laser diode excitation sources with either of these techniques allows for remote or in-process detection and quantification of plutonium ions (Neu *et al.*, 1994; Wruck *et al.*, 1994) in micromolar concentrations or lower. Both methods have been used in solution thermodynamic studies aimed at quantitatively evaluating complexation of plutonyl ions by chelating ligands and even by the oxo ligands of other actinyl ions (Bennett *et al.*, 1992; Stoyer *et al.*, 2000).

Vibrational spectroscopy, both infrared absorption and Raman scattering, are useful for 'fingerprint' comparisons, for structure determination, for analyzing intramolecular bond strength, and for understanding the electronic structure of plutonium ions. Comparison of infrared and Raman spectra of actinyl ions across the actinide series were used to establish that higher valent plutonium (v, vi) species in aqueous solution exist as linear trans dioxo ions with strong covalent Pu=O bonds. The hexavalent actinide ions all show an asymmetric O=An=O stretching frequency (ν_3) in the energy region 930–970 cm^{-1}, with the Pu(vi) aquo ion in noncomplexing perchlorate solution observed at 962 cm^{-1} (Jones and Penneman, 1953). These studies confirmed the symmetric and linear, or nearly linear, structures of both PuO_2^+, and PuO_2^{2+} in a more compelling way than do arguments based on similarities in the fine structure of the visible absorption spectrum. Infrared spectroscopic studies of plutonyl species in condensed phases, using very long pathlengths, powerful excitation sources, and sensitive detectors also contributed to vibrational band assignments for

ions in solution (Bovey and Steers, 1960; Vdovenko *et al.*, 1973; Kim and Campbell, 1985). Complementary Raman studies assigned the symmetric O=Pu=O stretching frequency (ν_1) for PuO_2^{2+} in 1.0 M (H,Na)ClO_4 at (834 ± 3) cm^{-1}, which compares well with ν_1 for the analogous NpO_2^{2+} and UO_2^{2+} ions at (855 ± 2) cm^{-1} and (865 ± 5) cm^{-1}, respectively. These ν_1 frequencies were assigned to ground state vibrations from both fluorescence spectra intervals and Raman shifts (Madic *et al.*, 1984; Tait *et al.*, 2004). This Raman shift also agrees with the prediction of 830 cm^{-1} based on the visible spectrum of plutonium(VI) in HCl that contains a 708 cm^{-1} frequency interval in the fine structure within the wavelength region 390–430 nm. The Raman shift of PuO_2^{+} in 1.0 M ClO_4^{-} was observed at 748 cm^{-1}. Disproportionation of PuO_2^{+} was evidenced by the decrease of the intensity of the 748 cm^{-1} PuO_2^{+} band and the increase of bands located at 833 and 817 cm^{-1} assigned to PuO_2^{2+} and $(PuO_2)_2(OH)_2{}^{2+}$, respectively (Madic *et al.*, 1984).

Correlations of vibrational frequencies to bond strength and molecular structure of the linear O=An=O moiety have been made. Recent X-ray absorption spectroscopy studies of solution and polycrystalline actinide samples allow for correlation of the energy of the symmetric ν_1 Raman frequency with measured An=O bond lengths. Clear trends can be seen within a particular oxidation state of an actinide and a general trend of heavier actinyl ions having weaker bonds has emerged. The Raman frequency for Pu(VI) is sensitive to complexation environment, showing shifts in ν_1 greater than 40 cm^{-1} between solution species for which the measured changes in the Pu=O bond length are only minimal.

Comparisons of Pu(v) with Np(v), and Pu(vi) with U(vi) and Np(vi) aquo complexes show that as nuclear charge increases across the series uranium to plutonium, the stretching frequencies actually decrease with decreasing An=O bond length. The bond shortening is clearly a result of the actinide contraction, and the weaker bonding is an indication of 5f orbital contraction across the actinide series (Tait *et al.*, 2004). The nature of chemical bonding in the plutonyl ions is discussed in Section 7.9.3 and in Chapter 17.

(c) Oxidation and reduction reactions

(*i*) *Oxidation–reduction equilibria between plutonium ions*

The oxidation–reduction (redox) relationships of the plutonium ions present one of the most complex and fascinating aspects of the aqueous solution chemistry of plutonium. The redox potentials that couple the four common oxidation states (iii, iv, v, vi) of plutonium in acid solution are all of comparable magnitude and very close to 1 V. Moreover, the kinetics of the reactions among oxidation states creates a unique situation where finite amounts of multiple oxidation states can coexist in solution under the appropriate conditions. This situation is unique for plutonium among all the elements in the periodic table. The complications arising from this unusual behavior are responsible for a considerable amount of research devoted to understanding the kinetics and mechanisms of these important reactions. We will discuss these reactions independently, and then discuss several examples to illustrate the complexity of the system. Much of this discussion follows from the excellent reviews by Cleveland (1979) and by Newton (1975, 2002).

The equilibrium concentrations of species involved in these reactions are usually determined from the potentials and the pertinent complex formation constants. Calculating standard potential values for the various couples is challenging since nearly all the data were acquired at high ionic strength, requiring extrapolation to infinite dilution. It is particularly difficult to study tetravalent plutonium independently of its hydrolysis and disproportionation. Redox reactions and corresponding electrochemical potentials that are useful for making predictions of plutonium chemistry in solution are given in Table 7.50. The constants listed for reactions in acid and some of those in base are from direct measurements, while those at pH 8 were estimated from hydrolysis data and standard potentials in acid for Pu(iii), Pu(iv), and Pu(vi) and related ions (Allard *et al.*, 1980). Electrochemical studies and reported potentials have been reviewed in recent publications (Mikheev and Myasoedov, 1985; Capdevila and Vitorge, 1995; Peretrukhin *et al.*, 1995; Lemire *et al.*, 2001) and in Chapter 19 of this work. Formal redox potential schemes for selected plutonium couples at 25°C have been derived for 1 M $HClO_4$ (Lemire *et al.*, 2001), 1 M HCl (Rabideau and Cowan, 1955; Rabideau *et al.*, 1959), and 1 M HNO_3 (Artyukhin *et al.*, 1958), and are shown in Fig. 7.116.

[d] Formal oxidation potential (Allard *et al.*, 1980).

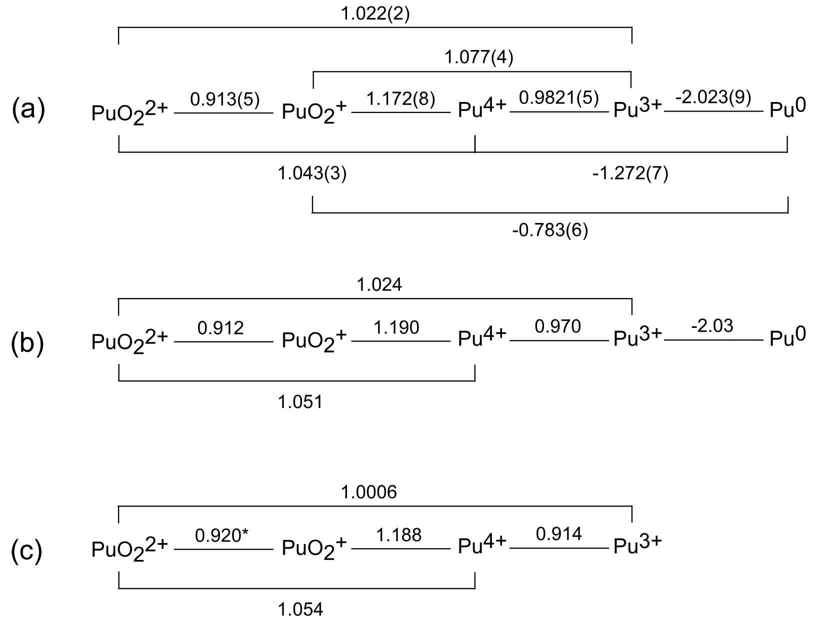

Fig. 7.116 *Formal redox potentials for selected plutonium couples at* 25°C *in V vs SHE* (*a*) *in* 1 M $HClO_4$ (*Lemire* et al., 2001), (*b*) *in* 1 M *HCl* (*Rabideau and Cowan*, 1955*; Rabideau* et al., 1959), *and* (*c*) 1 M HNO_3 (*Artyukhin* et al., 1958).

The formal potential of the Pu(VII)/Pu(VI) couple depends upon the square of the hydroxide ion concentration, and is about 0.85 V in 1 M NaOH, corresponding to the reaction (Spitsyn *et al.*, 1969; Musante and Ganivet, 1974; Krot, 1975):

$$PuO_4(OH)_2^{3-} + 2H_2O \rightleftarrows PuO_2(OH)_4^{2-} + 2OH^- + e^- \tag{7.74}$$

In voltammetric studies performed at lower hydroxide concentration (with a different proposed reaction), the Pu(VII/VI) reduction in 0.01 M hydroxide ion was observed at +1.20 V vs standard hydrogen electrode (Musante and Ganivet, 1974). Due to the instability of Pu(VII) at low hydroxide concentration (and therefore low ionic strength) it is not possible to extrapolate the potential to estimate a standard potential and other standard thermodynamic values.

The redox couples between Pu(V)/Pu(III), Pu(VI)/Pu(III), Pu(V)/Pu(IV), and Pu(VI)/Pu(IV), are quasireversible or irreversible because they involve the breaking or forming of Pu=O multiple bonds. In contrast, the redox couples between species where no Pu=O bond forming or breaking occurs, such as Pu(IV)/Pu(III), Pu(VI)/Pu(V), and Pu(VII)/Pu(VI) couples are reversible. Experimental, standard, and predicted reduction and oxidation potentials have been reported under a wide range of conditions, with the exception of those for Pu(VII). Standard redox potentials in acidic solution are described in greater detail in Chapter 19. Since the redox couples that connect the four main oxidation states (III, IV, V, VI) are relatively similar, it is possible for all four oxidation states to coexist under the appropriate solution conditions. The ability to have multiple oxidation states in solution at the same time will depend upon several key factors. The most important of these are the tendency of Pu(IV) and Pu(V) to disproportionate, and the relatively slow kinetics of reactions that involve the making or breaking of Pu=O bonds in plutonyl ions (PuO_2^+ and PuO_2^{2+}). Other factors are plutonium ion concentration, ionic strength, pH, temperature, and presence or absence of complexing ligands. Thermodynamic and activation data for redox reactions between plutonium ions are summarized in Table 7.51.

(*ii*) *Disproportionation of Pu*(*IV*)

In acid solution in the absence of complexing ligands, the disproportionation of Pu(IV) proceeds according to the following equation:

$$3Pu^{4+} + 2H_2O \rightleftharpoons 2Pu^{3+} + PuO_2^{2+} + 4H^+ \tag{7.75}$$

From this equation one can derive the equilibrium constant expression as:

$$K = \frac{[Pu^{3+}]^2[PuO_2^{2+}][H^+]^4}{[Pu^{4+}]^3} \tag{7.76}$$

Rabideau carefully determined the equilibrium constant for this reaction in $HClO_4/NaClO_4$ solution under a constant ionic strength of 1.0 M (Rabideau, 1953). Rabideau's work on this system is seminal in that it takes into account the plutonium self-reduction by α particle radiolysis, and the hydrolysis of Pu(IV) at low pH. The concentration of Pu(IV) in the equilibrium constant expression above has been corrected for both effects. The equilibrium constant, K, was determined to have a weighted average value of 0.0089 for 1.0 M ionic

strength. Rabideau and Cowan (1955) subsequently studied this same disproportion reaction in HCl solution and found the same fourth order dependence on hydrogen ion concentration. It was concluded that the mechanism of Pu(iv) disproportion was identical in both media. The fourth order dependence on hydrogen ion concentration is consistent with experimental observations of essentially no disproportionation of Pu(iv) in strongly acidic solutions. The study in HCl solution is somewhat more straightforward in that α particle reduction was essentially absent. In addition, the value of the equilibrium constant is somewhat smaller ($K = 0.00192$ in 1 M HCl) than observed in perchloric acid ($K = 0.0084$ in 1 M $HClO_4$) and this difference is attributed to stabilization of Pu(iv) ions by complexation with chloride ions in HCl solution. Rabideau and Cowan (1955) also examined the temperature dependence of the equilibria in HCl, and found that raising the temperature from 25 to 45°C increased the value of the equilibrium constant by a factor of 70 ($K = 0.00142$ at 25°C; $K = 0.0967$ at 45.16°C).

Connick studied the kinetics of the disproportionation reaction and found that the overall reaction takes place in two separate steps with a transient Pu(v) intermediate (Connick, 1949). In the first slow step (equation (7.77)), two equivalents of Pu(iv) combine to generate Pu(iii) and Pu(v). This reaction is slow because it involves the formation of a Pu=O bond in forming Pu(v). In the second step (equation (7.78)), the Pu(v) produced in the first step reacts with Pu(iv) in a rapid equilibrium.

$$2Pu^{4+} + 2H_2O \rightleftharpoons Pu^{3+} + PuO_2^+ + 4H^+ \text{ (slow)} \tag{7.77}$$

$$PuO_2^+ + Pu^{4+} \rightleftharpoons Pu^{3+} + PuO_2^{2+} \text{ (fast)} \tag{7.78}$$

Thus, the disproportionation is complete when both reactions (7.77) and (7.78) have reached equilibrium. The addition of equations (7.77) and (7.78) yields the common representation of the Pu(iv) disproportionation reaction that was given in equation (7.75). Equation (7.75) represents a reaction that comes to equilibrium in any plutonium solution, but equation (7.75) does not adequately represent the disproportionation of tetravalent plutonium because it fails to include Pu(v), even as an infinitesimally small intermediate. Silver (1971, 2003) has shown that a linear combination of equations (7.77) and (7.78) produces a new equation for the dissociation of Pu(iv) and is shown in equation (7.79), where the parameter M represents the equilibrium ratio for $[PuO_2^{2+}]/[PuO_2^+]$.

$$\begin{aligned}(2+3M)[Pu^{4+}] + (2M+2)[H_2O] &\rightleftharpoons (1+2M)[Pu^{3+}] \\ &+ [PuO_2^+] + M[PuO_2^{2+}] + (4M+4)[H^+]\end{aligned} \tag{7.79}$$

The value of M was found as the root of the cubic equation (7.80) where $K_{(7.77)}$ and $K_{(7.78)}$ are the equilibrium constants for equations (7.77) and (7.78), respectively.

$$K^2_{(7.78)}[H^+]^4 - K_{(7.77)}(M^2 + 2M^3) = 0 \qquad (7.80)$$

As the value of the ratio M increases, the coefficient of Pu(v) decreases and the stoichiometry of equation (7.79) approaches the stoichiometry of equation (7.75). In 1 M perchloric acid, the value of M is about 50.

(*iii*) *Disproportionation of Pu*(*V*)

In moderately acidic solutions Pu(v) is unstable towards disproportionation reactions. The disproportionation of Pu(v) into Pu(VI) and Pu(IV) or Pu(III) is expected to proceed by either of two possible mechanisms. From a study of the rate of the disproportionation of Pu(v) in 0.5 M HCl, Connick (1949) has shown that the actual mechanism consists of the slow reaction (7.81) coupled with the rapid equilibrium (7.78).

$$PuO_2^+ + Pu^{3+} + 4H^+ \rightleftharpoons 2Pu^{4+} + 2H_2O\,(\text{slow}) \qquad (7.81)$$

$$PuO_2^+ + Pu^{4+} \rightleftharpoons Pu^{3+} + PuO_2^{2+}\,(\text{fast}) \qquad (7.78)$$

with an overall reaction

$$3PuO_2^+ + 4H^+ \rightleftharpoons Pu^{3+} + 2PuO_2^{2+} + 2H_2O \qquad (7.82)$$

Connick (1949) pointed out that the disproportionation of Pu(v) proceeded by the mechanism of equation (7.82) under the conditions of his experiment, but that this mechanism cannot be true under all circumstances. At very low concentrations of Pu(III) the mechanism must necessarily change to that represented by equation (7.83).

$$2PuO_2^+ + 4H^+ \rightleftharpoons Pu^{4+} + PuO_2^{2+} + 2H_2O \qquad (7.83)$$

Thus equations (7.82) and (7.83) are limiting cases for Pu(v) disproportionation, and the actual reaction path depends on the plutonium species present in solution (Connick, 1949). The use of equations (7.82) or (7.83) have been widely cited in the literature, but Connick's original caveats on their intimate connection to solution conditions has not always been kept in mind. Without this understanding, equations (7.82) and (7.83) would appear to be contradictory because they do not predict the same reaction products (Pu^{3+} in (7.82), and Pu^{4+} in (7.83)). Under many solution conditions encountered in the laboratory, Pu(v) disproportionation may follow both mechanisms, in which case neither equation 7.82 or 7.83 by itself adequately describes Pu(v) disproportionation. This apparent discrepancy has been discussed in detail by Silver (1971, 1997, 2002, 2004) who has shown that the disproportionation reaction under any particular solution condition can be expressed as a linear combination of these two limiting cases. In this manner Pu(v) disproportionates in accordance with the stoichiometry of equation (7.84), where the parameter M represents the equilibrium ratio for $[PuO_2^{2+}]/[PuO_2^+]$.

$$\begin{aligned}&(3 + 2M/K_{(7.78)})[PuO_2^+] + (4 + 4M/K_{(7.78)})[H^+] \rightleftharpoons \\ &\quad [Pu^{3+}] + (M/K_{(7.78)})[Pu^{4+}] + (2 + M/K_{(7.78)})[PuO_2^{2+}] \\ &\quad + (2 + 2M/K_{(7.78)})[H_2O]\end{aligned} \tag{7.84}$$

The value of M was found as the positive, real root of equation (7.85) where $K_{(7.78)}$ and $K_{(7.77)}$ are the equilibrium constants for equations (7.78) and (7.77), respectively.

$$2K_{(7.78)}^2[H^+]^4 + (K_{(7.78)}[H^+]^4M - K_{(7.77)}M^3) = 0 \tag{7.85}$$

The mathematical details are beyond the scope of this discussion, and the interested reader should see the works of Silver (1971, 1997, 2002, 2004) for more detail.

It is noteworthy that both reactions 7.82 and 7.83 for the disproportionation of Pu(v) have equilibrium constants with a fourth order dependence on the hydrogen ion concentration. This illustrates why Pu(v) solutions are only stable at near-neutral pH where the hydrogen ion concentration is low. Many workers have used this observation to prepare solutions of Pu(v) in the absence of other oxidation states (Gevantman and Kraus, 1949; Markin and McKay, 1958; Gel'man and Zaitseva, 1965a,b; Newton, Hobart *et al.*, 1986a).

Rabideau studied the kinetics and mechanism of the Pu(v)-Pu(v) reaction in the absence of Pu(III) (Rabideau, 1957).

(*iv*) *Equilibrium between Pu*(*III*), (*IV*), (*V*), *and* (*VI*)

The reaction that describes the equilibrium between all four oxidation states has been used in the discussion of the disproportionation of Pu(IV) and Pu(v). The equilibrium constant for this reaction is given by:

$$K = \frac{[Pu(III)][Pu(VI)]}{[Pu(IV)][Pu(V)]} \tag{7.84}$$

This equilibrium constant has been determined in various media, but not all studies have corrected for the hydrolysis of Pu(IV). Rabideau and Kline (1958) determined this equilibrium constant in unit ionic strength $HClO_4/NaClO_4$ solution for various hydrogen ion concentrations. They obtained a value of $K = (13.1 \pm 0.08)$ at 25°C that is corrected for hydrolysis and is independent of H^+ concentration over the range $0.1 \leq H^+ \leq 1.0$ M. In D_2O solution, the corresponding hydrolysis-corrected value was determined to be (40.6 ± 1.0). Rabideau and Kline studied the kinetics of the reaction in both H_2O and D_2O solution, and determined that a hydrogen atom transfer process is not involved in the reaction. In complexing acids such as HCl and HNO_3, the equilibrium was found to shift to favor higher concentrations of Pu^{4+}.

Because this system is rather complicated, it is instructive to examine a series of figures that describe the system under various conditions. Equilibrium oxidation state distribution diagrams are useful for predicting the behavior of various plutonium stock solutions made up in the laboratory. Equilibrium diagrams showing the predominant oxidation state as a function of pH and average oxidation state for 1.0 M ionic strength are given in Fig. 7.117.

Fig. 7.117(a) shows the distribution for a solution with average oxidation state IV. It is seen that a solution which is initially pure Pu(IV) will contain significant concentrations of Pu(III) and Pu(VI) at equilibrium in 1 M acid. At pH 1 Pu(III) predominates and at pH 2 the solution is primarily a mixture of Pu(III) and Pu(V). The calculations that produced these plots took the first hydrolysis constant for Pu(IV) into account. It should be pointed out that the distribution in the region between pH 1 and 2 is less certain as the second hydrolysis constant was not taken into account. A small amount of irreversible hydrolysis to give colloidal Pu(IV) hydroxide is also expected at very low concentrations. Fig. 7.117(b) shows a distribution for a solution with average oxidation state V, for example an equimolar mixture of Pu(IV) and Pu(VI). Here, Pu(VI) predominates until a pH of about 1.2 is reached. At higher values, Pu(V) becomes predominant.

It is also important to know how rapidly redox equilibria will be reached in plutonium solutions. The rate constants and hydrogen ion dependences for the reactions above are known for solutions at 25°C and unit ionic strength. The kinetics of the system are somewhat complicated in that the forward and reverse

rates of all three of the reactions listed above must be considered. The disproportionation of Pu(IV) in 0.1 M acid has been calculated and the results for 1.0 M ionic strength at pH 1.0 are shown in Fig. 7.118(a). Appreciable concentrations of the other oxidation states appear after relatively short periods of time. The rates depend on the total plutonium concentration, so the time scale is given in units of M s (molar second). The time required to reach any particular distribution is found by dividing the total concentration. For example, Fig. 7.118(a) indicates that if the concentration of Pu(IV) is 0.002 M, then half of the Pu(IV) will be gone in about 3 hours. In a similar fashion, Pu(V) is quite stable at pH 3 and can be formed, for example, by mixing Pu(III) and Pu(VI). The course of this reaction at unit ionic strength is shown in Fig. 7.118(b). For a concentration of 0.001 M, equilibrium is reached in about a day and within about 10% of equilibrium within about 5 hours. Reducing the ionic strength decreases the rate. Selected oxidation and reduction rate data for different plutonium oxidation states are given in Table 7.52.

(*v*) *Preparation and stability of pure oxidation states*

Newton and coworkers have provided excellent experimental procedures for the preparation of oxidation state pure plutonium solutions. The following discussion comes essentially from Newton *et al.* (1986a).

Pu(III). Acidic solutions of Pu(III) are conveniently prepared by dissolving weighed samples of pure α-phase metal in 6 M HCl or $HClO_4$, with cooling, followed by dilution to the desired concentration. Corrosion products on the

surface of the metal may be removed electrochemically (Bergstresser, 1950) or mechanically. The standard potential for the three-electron oxidation of α-Pu metal is –(2.000 ± 0.009) V (Lemire *et al.*, 2001). Alternatively, plutonium in higher oxidation states in acid solutions may be reduced electrolytically using either a mercury or platinum cathode. The potential should be about 0.75 V (vs NHE) or less (Cohen, 1961a). Chemical reductants such as hydroxylamine or hydrazine may also be used, but these are generally less satisfactory because the oxidized form of the reducing agent is often left in the solution. The Pu(III) aquo ion imparts a blue or blue-violet color to aqueous acidic solutions and exhibits hydrolysis, complexation, and solubility properties similar to the rare-earth ion neodymium(III).

In solutions of noncomplexing acids, Pu(III) is stable with respect to reaction with the oxygen in air. However, in dilute sulfuric acid, for example, the reaction occurs at a conveniently measurable rate (Newton and Baker, 1956). At a pH of 4, Pu(III) is slowly oxidized but at pH values greater than about 4 or 5, or in 0.4 M $NaHCO_3$, Pu(III) is rapidly oxidized by atmospheric oxygen (Newton *et al.*, 1986a). For ^{239}Pu, α-particle induced oxidation occurs in $HClO_4$ solutions at a rate of about 1.5% per day, approaching a steady state containing about 10% Pu(IV) and 90% Pu(III) (Rabideau *et al.*, 1958). In HCl solutions the α-particle induced oxidation proceeds to nearly pure Pu(IV) (Newton *et al.*, 1986a).

Pu(IV). Solutions of Pu(IV) are conveniently prepared by the electrolytic oxidation of Pu(III) at about 1.2 V. At this potential Pu(VI) is thermodynamically stable, but its rate of formation is insignificant due to the slow kinetics of forming the Pu=O bond (Cohen, 1961a). Alternatively, Pu(IV) may be prepared by reacting Pu(III) with Pu(VI) according to the equation:

$$2Pu^{3+} + PuO_2^{2+} + 4H^+ \rightleftharpoons 3Pu^{4+} + 2H_2O \tag{7.86}$$

This reaction is the reverse of the Pu(IV) disproportionation reaction (equation 7.75), and the equilibrium constant is approximately 112 in 1 M $HClO_4$ solution at 25°C (Rabideau, 1953), so at equilibrium under these conditions as much as 28% of the plutonium will be in other oxidation states. Higher acid concentrations or the presence of complexing anions such as chloride will give larger fractions of Pu(IV). This is why it is a common practice to prepare and store Pu(IV) solutions in 3 M HCl (Newton *et al.*, 1986a). Acidic solutions of Pu^{4+} that are free of complexing agents are orange-brown or tan in color.

In acid solutions Pu(IV) is thermodynamically unstable with respect to reaction with oxygen, but the rate of this reaction is negligible. In $HClO_4$, α-particle induced reduction occurs to give the same steady state as described for Pu(III). In HCl solutions, however, Pu(IV) is significantly stabilized (Rabideau *et al.*, 1958). Newton *et al.* (1986a) found that stock solutions of Pu(IV) in about 3 M HCl are stable for many months. Even in 1 M acid, Pu(IV) hydrolyzes appreciably, and, at pH values greater than about 1, significant formation of green colloidal Pu(IV) hydroxide occurs. The rate of colloid formation depends on the plutonium concentration as well as the pH. Rates under specific conditions have been described (Costanzo *et al.*, 1973; Toth *et al.*, 1981; Newton and Rundberg, 1984). Complexation constants for tetravalent plutonium are among the highest for any cation of any element, being most similar to those of Th(IV), U(IV), and Np(IV).

Pu(V). Solutions of Pu(V) are conveniently prepared by the electrolytic reduction of 0.02 M Pu(VI) in $HClO_4$ solution at pH near 3. A potential close to 0.54 V (vs SCE) is suitable (Cohen, 1961a). In most preparations it is necessary to readjust the pH during electrolysis because hydrogen ions are transported from the counter electrode compartment (Newton *et al.*, 1986a). The use of a photochemically produced reducing agent in a two-phase system has also been described (Choppin and Saito, 1984). The PuO_2^+ ion imparts a pink or light purple color to aqueous solutions, has a low effective charge and undergoes hydrolysis only at higher pH (approximately $pH = 9$ for millimolar plutonium).

In acid solution Pu(V) disproportionates with the reaction rate proportional to the fourth power of the hydrogen ion concentration and the square of the Pu(V) concentration (Rabideau, 1957). Thus both the thermodynamics and the kinetics favor Pu(V) at low acidities. However, α-radiolysis effects, even at pH values greater than 3, cause fairly rapid formation of colloidal Pu(IV) and Pu(VI) (Newton *et al.*, 1986b). These effects are more pronounced at higher Pu(V) concentrations, and less pronounced at low concentrations. Pu(V) can persist in near-neutral pH solutions when the total plutonium concentration is very low ($<10^{-6}$ M), as may be the case in slightly-contaminated natural waters and some waste solutions.

Pu(VI). Solutions of Pu(VI) are conveniently prepared by oxidation with hot, concentrated $HClO_4$ (Newton *et al.*, 1986a). Plutonium ions in lower oxidation states, in the absence of coordinating anions are oxidized to Pu(VI) by fuming strongly with $HClO_4$. The remaining free acid may be estimated gravimetrically and traces of chlorine oxides can be removed by boiling the diluted solutions. Acidic solutions of PuO_2^{2+} in the absence of complexing agents are yellow or orange in color. Hexavalent plutonium nitrate can also be generated by heating nitric acid solutions of plutonium almost to dryness at about 170°C. A glassy solid results after cooling the nitrate melt that is a very stable storage form for Pu(VI) and is readily soluble in aqueous solutions (Stoll *et al.*, 1982).

In $HClO_4$ solutions Pu(VI) is unstable with respect to α-particle induced reduction. With millimolar or greater plutonium concentrations, at pH values between about 0 and 2, the rate of reduction is about 1.2 to 2% of the total plutonium per day (Rabideau *et al.*, 1958; Newton *et al.*, 1986b). At very low plutonium concentrations (2.2×10^{-5} M) the rates are much slower. It has also been reported that chloride ions inhibit the α-reduction of Pu(VI) in analogy with Pu(IV) (Rabideau *et al.*, 1958).

Pu(VII). Blue-black heptavalent plutonium is the least stable oxidation state, prepared by vigorous oxidation of highly alkaline solutions of hexavalent plutonium. In alkali solutions, ozonization, anodic oxidation or treatment with peroxydisulfate, or other strong oxidants can produce the heptavalent form (Komkov *et al.*, 1969; Krot *et al.*, 1976; Tananaev *et al.*, 1992). The high formal potential of Pu(VII) puts it outside the region of thermodynamic stability of water for hydroxide concentrations less than about 7 M, and heptavalent plutonium is instantly reduced in acid solutions. This plutonium ion is less stable than the heptavalent neptunium analog (Varlashkin *et al.*, 1984; Tananaev *et al.*, 1992).

(*vi*) *Pu(VI) oxygen exchange with solvent water*

Masters and Rabideau (1963) measured the rate of exchange between PuO_2^{2+} and ^{18}O-enriched water in dilute $HClO_4$ solution. The studies were conducted under chlorine atmosphere to ensure that Pu(VI) was the only oxidation state present. This was done because the rate of exchange was found to be accelerated by the presence of lower oxidation states of plutonium in the solutions (Rabideau and Masters, 1963). Like the exchange for the uranyl ion (Gordon and Taube, 1961), the exchange rate was found to be extremely slow with a half-time of 4.55×10^4 h at 23°C. The exchange rate was found to be the sum of the rates of two separate reaction paths that include the intrinsic $PuO_2^{2+} - H_2^{18}O$ exchange reaction and the exchange induced by the breaking of Pu=O bonds by α-particle reduction. Studies employing ^{238}Pu demonstrated that the exchange rate was much faster than with ^{239}Pu, and extrapolation of the rates to the flux conditions of ^{239}Pu solutions suggested a half-time for radiation-induced exchange of about the same order of magnitude (approximately 10^4 h). This was interpreted as indicating that in 0.15 M Pu(VI) solution, the major contribution to the exchange is from radiation-induced reaction, and that the rate of the intrinsic exchange reaction is even slower.

(*vii*) *Oxidation and reduction by actinide ions*

These reactions have been studied primarily in acidic solutions because hydrolysis and precipitation of these high-valent metal ions limit their solubility at higher pH values. Most of the actinide separations and processing technology has been developed in acid solutions motivating much of the quantitative study of plutonium redox reactions. An important subset of these reactions has been described by Newton (2002) and is given in Table 7.53. The use of catalysts to enhance the rate of reactions has also been studied for plutonium both to accomplish process steps more rapidly on an industrial scale and to determine rate constants that are otherwise difficult to determine because of back reactions, competing reactions, or other complications (Newton, 1975).

The redox reactions between plutonium and other actinides are important because they are applicable to many aqueous solutions used in separation processes and waste operations. These reactions are also useful because the reactions involving ions with similar structures but different reduction potentials can be compared. For example, the rates of reactions (reaction 3 through

[c] Calculated from the reverse reaction.

8 in Table 7.53) that involve the making of An=O bonds as An^{4+} is oxidized to AnO_2^+ differ by orders of magnitude for the different elements. Four hydrogen ions are produced in the overall reaction, but only two or three are given up in the activation processes. The rate laws for oxidation of U^{4+} and Np^{4+} by PuO_2^{2+} show consecutive rate-determining steps of which only one or two can be redox reactions. This reaction is described below for U^{4+}, as an illustration of the importance of considering multiple intermediates and pathways.

The reaction between U^{4+} and PuO_2^{2+} proceeds through AnO_2^+ intermediates, and in acid solution leads eventually to Pu^{3+} (Newton, 1958, 1975). In dilute solutions (1.8×10^{-4} M Pu(VI) and 0.62×10^{-4} M U(IV) in 1 M $HClO_4$), approximately 96% of the U(IV) reacts according to the following equation:

$$2\mathrm{Pu(VI)} + \mathrm{U(IV)} \rightarrow 2\mathrm{Pu(V)} + \mathrm{U(VI)} \tag{7.87}$$

The remaining U(IV) reacts according to

$$\frac{2}{3}\mathrm{Pu(VI)} + \mathrm{U(IV)} \rightarrow \frac{2}{3}\mathrm{Pu(III)} + \mathrm{U(VI)} \tag{7.88}$$

Equations 7.87 and 7.88 only represent the change in oxidation states of the actinides but do not account for the overall stoichiometry. The reaction rates, as studied by spectrophotometric monitoring of the concentration of Pu(VI), are consistent with the rate law:

$$-\frac{\mathrm{d[Pu(VI)]}}{\mathrm{d}t} = 2k''\mathrm{[Pu(VI)][U(IV)]} \tag{7.89}$$

This requires that the activated complexes be formed from one Pu(VI) and one U(IV), probably according to the reaction

$$\mathrm{Pu(VI)} + \mathrm{U(IV)} \rightarrow \mathrm{Pu(V)} + \mathrm{U(V)} \tag{7.90}$$

followed by the rapid reaction

$$\mathrm{Pu(VI)} + \mathrm{U(V)} \rightarrow \mathrm{Pu(V)} + \mathrm{U(VI)} \tag{7.91}$$

Steady-state calculations show that U(V) disproportionation into U(VI) and U(IV)

$$2\mathrm{U(V)} \rightarrow \mathrm{U(IV)} + \mathrm{U(VI)} \tag{7.92}$$

is too slow to account for the disappearance of U(V) and is unimportant with respect to reaction (7.91). Under these conditions (1 M $HClO_4$) the U(IV) undergoes hydrolysis, while Pu(VI) does not. Thus

$$\mathrm{[U(IV)]} = [\mathrm{U}^{4+}](1 + K/[\mathrm{H}^+]) \tag{7.93}$$

and

$$\mathrm{[Pu(VI)]} = [\mathrm{PuO}_2^{2+}] \tag{7.94}$$

where K is the first hydrolysis constant for U(IV). In terms of the species present, the rate law (7.89) becomes

$$-\frac{\mathrm{d}[\mathrm{Pu(VI)}]}{\mathrm{d}t} = 2k''\left(1+\frac{K}{[\mathrm{H}^+]}\right)[\mathrm{PuO}_2^{2+}][\mathrm{U}^{4+}] \tag{7.95}$$

The hydrogen-ion dependence as a function of temperature suggests that the most important activated complex is that formed by the prior loss of H^+, and that a second activated complex resulting from the loss of two H^+ ions may also be involved. The decrease in the apparent H^+ dependence with decreasing $[H^+]$ is not consistent with parallel rate-determining steps, but suggests consecutive reactions (6a and 6b in Table 7.53) instead.

From the linearity of $\{k''([H^+] + K)\}^{-1}$ vs $[H^+]$ for the data at each temperature (k_1 and k_2 are rate constants distinct from k' or k''). Newton arrived at the following rate law:

$$-\frac{\mathrm{d}[\mathrm{Pu(VI)}]}{\mathrm{d}t} = \frac{2[\mathrm{Pu(VI)}][\mathrm{U(IV)}]}{1+K/[\mathrm{H}^+]}\left(\frac{1}{k_1[\mathrm{H}^+]^{-1}}+\frac{1}{k_2[\mathrm{H}^+]^{-2}}\right)^{-1} \tag{7.96}$$

The rate law (7.96) governs many detailed mechanisms, all of which require a binuclear intermediate that can react to give products or dissociate to give reactants at rates that depend on $[H^+]$. A simple mechanism consistent with the rate law is:

$$\mathrm{U}^{4+} + \mathrm{H_2O} \rightarrow \mathrm{UOH}^{3+} + \mathrm{H}^+ \quad \text{(rapid equilibrium)} \tag{7.97}$$

$$\mathrm{UOH}^{3+} + \mathrm{PuO}_2^{2+} \rightleftarrows \mathrm{PuO_2(UOH)}^{5+} \quad \text{(rate-determining, reversible)} \tag{7.98}$$

$$\mathrm{PuO_2(UOH)}^{5+} \rightarrow \mathrm{PuO_2(UO)}^{4+} + \mathrm{H}^+ \quad \text{(rapid equilibrium)} \tag{7.99}$$

$$\mathrm{PuO_2(UO)}^{4+} + \mathrm{H_2O} \rightarrow \mathrm{UO}_2^+ + \mathrm{PuO}_2^+ + 2\mathrm{H}^+ \quad \text{(rate-determining)} \tag{7.100}$$

The two net activation processes required by the rate law do not depend on the details of the mechanism. The activation parameters ΔG^*, ΔH^*, and ΔS^* for these processes as determined from simultaneous treatment of the hydrogen ion and temperature data are listed in Table 7.53 under reactions 6a and 6b. For a more detailed discussion of redox reactions between plutonium and other actinide ions, the reader is referred to Newton (2002).

(*viii*) *Oxidation and reduction by nonactinide species*

Plutonium ions are well known to undergo redox reactions with ions of almost every element in the periodic table and many inorganic and organic redox reagents. Almost all of the redox reactions of aqueous plutonium ions are first order in the oxidizing or reducing agent, but some are either inhibited or catalyzed by the reaction products. The rates are often strongly influenced by the concentration of H^+ and of complexing ligands. For example, reductions using synthetic and natural organic acids, such as oxalic, ascorbic, hydroxamic, and humic acids are pH dependent with rates that generally increase with increasing $[H^+]$ (Cleveland, 1979; Choppin *et al.*, 1986; Nikitenko, 1988; Czerwinski and Kim, 1997; Ruggiero *et al.*, 2000; Moulin and Moulin, 2001; Taylor *et al.*, 2002). Common strong oxidizing agents that are relatively poor ligands for the actinides, such as dichromate, bromate, and iodate, have comparatively rapid plutonium oxidation rates (Newton, 1975). A large body of empirical observations has been accumulated on the oxidation–reduction behavior of plutonium with various reagents, while quantitative data are available for a relatively small subset. Since among plutonium ions, Pu(IV) forms the strongest complexes, redox reactions of the other ions can be interpreted using similar but simplified reactions and rate laws.

There is a broad qualitative relation between the rates of redox processes and the particular plutonium ions involved. Generally, the reactions of Pu^{4+} with single-electron reductants, such as Fe^{2+}, are rapid. The oxidation of Pu^{3+} or the reduction of Pu^{4+} with two-electron reagents is expected to be slower, although the variation in rate for different reagents varies from slow to a rate too fast to measure. A similar situation exists for one-electron reduction of PuO_2^{2+} to PuO_2^+. In contrast, reactions that make or break Pu=O multiple bonds are inherently slower. Multielectron processes, such as Pu^{4+} oxidation to PuO_2^{2+}, can proceed in one two-electron step or two one-electron steps. Oxidation of Pu^{4+} or reduction of PuO_2^+ can generally proceed by direct reaction with the oxidizing or reducing agent, or by oxidation or reduction through the disproportionation reaction. Reactions of plutonium ions are further complicated in that slight changes in solution conditions can profoundly affect the rate and even the direction of the reaction, particularly for Pu^{4+}, owing to its tendency to form multiple stable molecular complexes. For example, reactions in sulfuric acid or carbonate media may take a different course or proceed at a different rate compared to those in perchlorate solutions. Early observations on the redox behavior of plutonium that were made on tracer level concentrations before all of the oxidation states had been well established cannot be applied directly to higher concentrations without reservations. Many of those experiments were qualitative, designed to determine whether reactions were complete or not, and will not be discussed here. A few important systems that relate to plutonium processing and also illustrate particular details of plutonium chemistry will be described here, including reactions with ferrous ion, nitrate, nitrite, hydroxylamine, and hydrogen peroxide. For additional detailed information or lists of reactions and rates, the reader is directed to reviews by Newton (2002) and Cleveland (1979), and general references that contain oxidation and reduction potentials (Wick, 1980).

The multistep reduction of Pu(VI) by Fe(II) is important in fuel reprocessing and has complicated mechanisms and rate laws that were described by Newton (1958, 2002).

When Fe(II) is added to an excess of Pu(VI), the predominant reaction is

$$\mathrm{PuO_2^{2+} + Fe^{2+} \rightarrow PuO_2^{+} + Fe^{3+}} \tag{7.101}$$

Using a 60% excess of Pu(VI), Newton (1958) found that for each mole of Fe(II) oxidized approximately one mole of Pu(VI) was reduced as the acid concentration was varied from 2.0 to 0.05 M. Although Fe(II) is capable of reducing Pu(VI) all the way to Pu(III), appreciable amounts of Pu(IV) are observed, even if an excess of Fe(II) is used.

In addition to $\mathrm{Pu^{4+}}$ disproportionation, the following reactions were found to be important:

$$\mathrm{PuO_2^{+} + Fe^{2+} + 4H^{+} \rightarrow Pu^{4+} + Fe^{3+} + 2H_2O} \tag{7.102}$$

$$\mathrm{Pu^{4+} + Fe^{2+} \rightarrow Pu^{3+} + Fe^{3+}} \tag{7.103}$$

From sets of individual reactions in which the pH, then ionic strength, then metal ion concentrations were varied, Newton and Baker (1963) found the following rate law:

$$-\frac{\mathrm{d}[\mathrm{PuO_2^{2+}}]}{\mathrm{d}t} = \{A + (B + C[\mathrm{H^+}])^{-1}\}[\mathrm{PuO_2^{2+}}][\mathrm{Fe^{2+}}] \tag{7.104}$$

The necessity of three parameters in the rate law equation indicates three rate-determining steps and three important activated complexes. The above three-parameter equation may be rearranged to give

$$\begin{aligned} -\frac{\mathrm{d}[\mathrm{PuO_2^{2+}}]}{\mathrm{d}t} &= A[\mathrm{PuO_2^{2+}}][\mathrm{Fe^{2+}}] \\ &\quad + \left(\frac{1}{B^{-1}[\mathrm{PuO_2^{2+}}][\mathrm{Fe^{2+}}]} + \frac{1}{C^{-1}[\mathrm{PuO_2^{2+}}][\mathrm{Fe^{2+}}]/[\mathrm{H^+}]}\right)^{-1} \end{aligned} \tag{7.105}$$

In this equation, parameter A is associated with the path that leads directly to products, and the B and C terms involve consecutive reactions that parallel the direct reaction. Newton and Baker found several mechanisms that were consistent with the data. All involve the same three activated complexes formed in both consecutive and parallel paths, as well as $\mathrm{PuO_2^{2+}}$ hydrolysis.

Plutonium reduction and oxidation reactions in nitric acid solutions have been extensively studied. Descriptions of Pu(IV) oxidation and reduction in nitrate solutions benefited from recent spectroscopic studies that measured the formation constants for two Pu(IV) nitrate species, $\mathrm{Pu(NO_3)_n^{4-n}}(n = 1, 2)$ (Berg *et al.*, 2000). Complexation of Pu(IV) by nitrate can decrease the concentration of aquo $\mathrm{Pu^{4+}}$, and thereby slow down the rates of some reactions, or it can provide additional reaction pathways for other reactions. For example, reactions involving Pu(IV) either as a reactant or product with pentavalent metal ions are much faster in nitrate solutions than in perchlorate solutions. Conversely, oxidation of Pu(IV) by Ce(IV) or Np(VI) are both slower in HNO_3. Reductions of Pu(IV) are also generally slower in HNO_3 than in $HClO_4$ (Newton, 2002).

A great deal of information is available for Pu(IV) redox involving nitrous acid, hydroxylamine, and hydrazine in HNO_3, systems that are important for processing applications. Nitrous acid is commonly used to adjust the oxidation state of plutonium, both as a pure reagent and inadvertently as a contaminant in nitric acid. The key to understanding plutonium redox reactions in nitric and nitrous acid is that small equilibrium concentrations of NO_2 are present in HNO_2–HNO_3 mixtures. For example, although Pu(III) is quite stable in dilute nitric acid solutions, in the presence of HNO_2 it is readily oxidized to Pu(IV) by the following reaction:

$$2Pu^{3+} + 3H^+ + NO_3^- \rightleftarrows 2Pu^{4+} + HNO_2 + H_2O \qquad (7.106)$$

An empirical rate law and a plausible mechanism for the reaction were derived by Koltunov and Marchenko (1973). The oxidation may be retarded by the addition of a "holding reductant" to react with the HNO_2 as soon as it is formed. Effective reductants include sulfamic acid, ferrous sulfamate or hydrazine (Cleveland, 1979).

Plutonium(V) is reduced very slowly by nitrous acid (Koltunov *et al.*, 1982b). These studies consistently show that NO_2, formed by reaction of HNO_2 with HNO_3, is the important oxidant in the Pu(III) or Pu(V) oxidation by HNO_3. The rate of the following equilibrium reaction involving Pu(V) and Pu(VI) has been measured in both directions (Koltunov and Ryabova, 1980).

$$2PuO_2^{2+} + HNO_2 + H_2O \rightleftarrows 2PuO_2^+ + NO_3^- + 3H^+ \qquad (7.107)$$

Hydroxylamine and hydrazine are very useful reducing agents for all of plutonium's higher oxidation states, because they are nonmetallic, yield volatile oxidation products, and tend to react rapidly. These reactants are two-electron reducing agents, so one-electron oxidation leads to radical intermediates that can either decompose to stable products or be oxidized by plutonium and therefore influence the overall stoichiometry and the rate law. If the two one-electron oxidations occur at approximately the same rates, the stoichiometry will change during the course of the overall reaction and the rate laws will be very complicated. Additional redox agents and mechanistic complexity are added when the reduction of plutonium by these reagents is conducted in nitric acid solutions.

When hydroxylamine is oxidized by plutonium(IV), the two limiting overall reactions are (Barney, 1976):

$$2Pu^{4+} + 2NH_3OH^+ \rightleftarrows 2Pu^{3+} + N_2 + 4H^+ + 2H_2O \qquad (7.108)$$

and

$$2Pu^{4+} + NH_3OH^+ \rightleftarrows 2Pu^{3+} + 3H^+ + 0.5N_2O + 0.5H_2O \qquad (7.109)$$

The empirical rate law for the plutonium reduction by hydroxylamine in 2.5 M [(H, Na) (NO_3, ClO_4)] was found to be

$$-\mathrm{d}[\mathrm{Pu(IV)}]/\mathrm{d}t = [\mathrm{Pu}^{4+}]^2[\mathrm{NH_3OH^+}]^2/[\mathrm{Pu}^{3+}]^2[\mathrm{H}^+]^4(1+\beta_1[\mathrm{NO_3^-}])^2 \quad (7.110)$$

The factor $(1+\beta_1[\mathrm{NO_3^-}])$ is consistent with the formation of a nitrate complex. An independent investigation using 3 M (H,Na)NO_3 and large excess amounts of NH_3OH^+ gave results at 30°C that agreed reasonably well with the rate law and stoichiometries (Koltunov and Zhuravleva, 1978), yet the rate law does not account for higher nitrate complexes that are known to form when the $[\mathrm{NO_3^-}]$ is greater than ~2–3 M (Berg *et al.*, 1998).

Yarbro *et al.* (1998) recently summarized past studies of Pu(IV) reduction by hydroxylamine and reported results with hydroxylamine nitrate (HAN) in the presence of excess plutonium. Rather than define the kinetic expression in terms of concentrations (although plausible mechanisms and complex stoichiometries were discussed), the following fractional conversion was defined:

$$X = 1 - (N_{\mathrm{A}}/N_{\mathrm{A}^0}) \quad (7.111)$$

where X is the fraction of compound reacted, N_{A^0} is the initial number of moles of the reactant A and N_{A} is the number of moles of reactant A at some time t. If acid and nitrate concentrations are constant, then the fractional conversion of HAN can be described as follows:

$$\begin{aligned}-\mathrm{d}X/\mathrm{d}t = {} & (kk_{\mathrm{H}}^{0.44}/C_{\mathrm{Pu}^0}[\mathrm{H}^+]^{0.56})([\mathrm{H}^+]^{0.65} \\ & + k_{\mathrm{a}}[\mathrm{NO_3^-}])[(1-X)/X]^2([\mathrm{HAN_0}] - C_{\mathrm{Pu}^0}X)^{0.44}\end{aligned} \quad (7.112)$$

where k is the kinetic constant; k_{H} is the dissociation constant for HAN; k_{a} is the dissociation constant for HNO_3; C_{Pu^0} is the initial plutonium molar concentration and [HAN_0] is the initial HAN molar concentration. This expression is useful at low HAN to plutonium molar ratios.

An improved understanding of this system and more broadly applicable rate law requires additional research, including quantitative evaluation of multiple plutonium nitrate complexes (beyond the 1:1 complex), the oxidation of HAN by nitric acid, the reoxidation of Pu(III) by nitrous acid, the disproportionation of Pu(IV), and, for solutions concentrated in Pu, radiolytic oxidation of Pu(III) and reduction of Pu(IV). The Pu(IV) hydroxylamine reaction has also been studied in perchlorate solutions using relatively high $[\mathrm{Pu(IV)}]_o/[\mathrm{NH_3OH^+}]_o$ ratios (Koltunov and Zhuravleva, 1978). These conditions favor the path in which the radical intermediate is oxidized to N_2O. Kinetic studies of Pu(IV) reduction by a derivatized hydroxylamine, where the reducing agent was present in molar excess of plutonium, showed similar dependencies on hydrogen ion and hydroxylamine concentrations (Anyun *et al.*, 2002).

The reduction of Pu(VI) by NH_3OH^+ has been studied in 3 M perchlorate solutions at temperatures near 60°C (Koltunov *et al.*, 1981b). When $[\mathrm{H}^+]$ is

<0.55 M, the disproportionation of Pu(V) is relatively slow and the net reaction is probably as follows:

$$2PuO_2^{2+} + NH_3OH^+ \rightleftarrows 2PuO_2^+ + 3H^+ + 1/2N_2O + 1/2H_2O \qquad (7.113)$$

This reaction requires that a radical intermediate be oxidized by Pu(VI). The rate law was found to be

$$-d[Pu(VI)]/dt = 2k_0[PuO_2^{2+}][NH_3OH^+]/[H^+] \qquad (7.114)$$

This rate law is much simpler than the one for the reduction of Pu(IV), and shows that the rate-determining step is the initial formation of the radical intermediate. At higher $[H^+]$, the disproportionation of Pu(V) becomes important. The Pu(IV) formed is rapidly reduced by NH_3OH^+ to Pu(III), which in turn reacts rapidly with Pu(VI). These steps lead to the catalytic reduction of Pu(VI) by Pu(III). Thus, during the course of the reaction, the concentration of Pu(V) will increase to a maximum, then decrease as the concentration of Pu(III) increases. The complex rate laws for this system have been integrated numerically and give concentrations that are in good agreement with the experimental results (Koltunov *et al.*, 1981b).

The reduction of Pu(IV) by hydrazine has been studied in 2 M $(H,Na)NO_3$ (Koltunov and Zhuravleva, 1974). The limiting overall reactions are probably the following:

$$Pu^{4+} + N_2H_5^+ \rightleftarrows Pu^{3+} + NH_4^+ + H^+ + 1/2N_2 \qquad (7.115)$$

and

$$4Pu^{4+} + N_2H_5^+ \rightleftarrows 4Pu^{3+} + N_2 + 5H^+ \qquad (7.116)$$

The stoichiometric ratio was found to depend on the initial reactant concentrations, just as with hydroxylamine. At 50°C with a $[H^+]$ range between 0.5 and 1.9 M, the rate law for the Pu(IV)–hydrazine reaction was found to be

$$-d[Pu(IV)]/dt = k[Pu^{4+}][N_2H_5^+]/(K_h + [H^+]) \qquad (7.117)$$

This rate law shows that the rate-determining step is the formation of the radical intermediate $(N_2H_4\cdot)$, not its subsequent reaction. The parameter K_h was interpreted as the hydrolysis constant for Pu(IV), but the 1:1 Pu(IV)–nitrate complex should be included in the rate law. An alternative explanation involves the formation of low steady-state concentrations of a plutonium–hydrazine intermediate (Newton, 2002). Additional kinetic studies of the reduction of Pu(IV) have been reported for substituted hydrazines, with similar overall reactions and small changes in reaction rates (Koltunov *et al.*, 1989).

The reduction of Pu(VI) by $N_2H_5^+$ was shown to have features similar to the reduction of Pu(IV) (Koltunov and Zhuravleva, 1973). The initial reaction is most probably

$$PuO_2^{2+} + N_2H_5^+ \rightleftarrows PuO_2^+ + NH_4^+ + 1/2N_2 + H^+ \qquad (7.118)$$

The final reaction product is Pu(III), which arises from the reduction of Pu(IV) described above. The reduction of Pu(V) to Pu(IV) occurs by two parallel pathways: direct reaction of Pu(V) with hydrazine, and comproportionation of Pu(VI) with Pu(III) to give Pu(IV). The kinetics of the reduction of Pu(V) by hydrazine as well as the use of the overall reductions in the nuclear fuel cycle have been described (Koltunov and Baranov, 1993). The rate law in 2 M Na (NO_3,ClO_4) was found to be approximately

$$-\mathrm{d}[\mathrm{Pu(VI)}]/\mathrm{d}t = k[\mathrm{PuO_2^{2+}}][\mathrm{N_2H_5^+}]/[\mathrm{H^+}] \qquad (7.119)$$

The nitrate dependence was found to be zero in the range from 0.15 to 2 M at constant ionic strength. The reduction of Pu(VI) by substituted hydrazines has been shown to proceed with similar overall reactions, some differences in the exponents of the reactants in the rate equation, and small changes in reaction rates (Koltunov *et al.*, 2004).

Both fundamental research and process application of plutonium redox reactions with hydrogen peroxide are complicated by the incomplete characterization of molecular Pu(IV) and Pu(VI) complexes that form with peroxide, and the chemical and radiolytic complexities of plutonium–hydrogen peroxide mixtures. Recent studies indicate the utility of hydrogen peroxide reduction of Pu(VI) and mixtures of Pu(VI) and Pu(IV) on the mM scale by 0.3% H_2O_2 in the presence of extraction resins (Morgenstern *et al.*, 2002). Hydrogen peroxide is more commonly used to reduce Pu(VI) in nitrate solutions. Maillard and Adnet (2001) studied effects of acidity and plutonium and H_2O_2 concentrations on the kinetics of Pu(VI) reduction. The kinetics results generally showed an induction period where the [Pu(VI)] does not change, followed by a linear decrease of [Pu(VI)]. The length of the induction period depends on temperature, $[HNO_3]$, and $[H_2O_2]$, but not on the H_2O_2/Pu(VI) ratio. Total reduction time decreases with increasing [Pu(VI)] and $[HNO_3]$ from 0.5 to 6 M $[HNO_3]$, but increases when $[HNO_3]$ varies from 6 to 8 M. Red-brown peroxo complexes were observed and PuO_2^+ was an intermediate in these reductions.

The kinetics of the reduction of ~1 mM PuO_2^+ by $[H_2O_2]$ has been studied in 1.0 M NaCl solutions at near-neutral pH. The reduction was found to be first order with respect to $[H_2O_2]$ and inverse first order with respect to $[H^+]$ and described by the rate equation (7.119) with $k = 3.59$ to 1.79×10^{-9} min^{-1} (Morgenstern and Choppin, 1999).

$$\mathrm{d}[\mathrm{Pu(V)}]/\mathrm{d}t = k\,[\mathrm{PuO_2^+}][\mathrm{H_2O_2}]/[\mathrm{H^+}] \qquad (7.120)$$

(*ix*) *Autoradiolysis*

When plutonium isotopes undergo radioactive decay in aqueous solution they deposit a great deal of energy (approximately 5 MeV per α particle) in α particle tracks that both heat the solution and produce ions, radicals, and solvated electrons. The predominant products generated by water radiolysis in the bulk solution are H, OH, HO_2, and H_2O_2 (Spinks and Woods, 1990; Vladimirova and Kulikov, 2002). Under plutonium process conditions α radiation generates concentrations of these reactive species that can significantly affect individual stages of reactions as well as the final products. If solute concentrations (most commonly plutonium and nitrate) are less than approximately 1 M, then there will be little direct reaction between the α particles or the transient species and the solute within the tracks.

Reactive species that diffuse out of the alpha-tracks can act as either oxidizing or reducing agents for plutonium and other solutes. For example, in 0.4 M H_2SO_4, 0.53 μmol of Fe(II) is oxidized to Fe(III) per joule of deposited energy (Spinks and Woods, 1990), expressed as $G[\mathrm{Fe(III)}] = 0.53$ μmol J^{-1}; whereas Ce(IV) is reduced with $G[\mathrm{Ce(III)}] = 0.33$ μmol J^{-1} (Spinks and Woods, 1990). The G-values for the reduction of Pu(IV) or Pu(VI) in 1 M $HClO_4$, 0.36 – 0.03 μmol J^{-1}, are similar (for either oxidation state) to those for Fe(II) or Ce(IV) (Kasha, 1949; Newton, 2002). The reduction of Pu(IV) reaches a steady state in which its rate equals the rate of oxidation of Pu(III). At 4°C, the mean oxidation number was found to depend slightly on the total plutonium concentration and/or the dose rate, e.g. 3.05 in 0.022 M Pu, which corresponds to an energy deposition rate of 0.01 Sv L^{-1} (Rabideau *et al.*, 1958).

Plutonium radiolysis in nitrate solution was reviewed by Miner and Seed (1967). Recent research has emphasized the behavior of plutonium in HNO_3 solutions that have much higher dose rates. The results are complicated due to the formation of HNO_2, volatile NO_x, and H_2O_2. Andreichuk *et al.* (1990) studied the oxidation of Pu(III) to Pu(IV) in HNO_3 solutions by using radiation from *in situ* ^{244}Cm. This group first studied the formation of HNO_2 from HNO_3 by ^{244}Cm irradiation in the absence of plutonium (Andreichuk *et al.*, 1984b). These studies, where nitric acid concentrations and dose rates ranged up to 8.6 M and 11.5 W L^{-1}, respectively, showed initial rates of HNO_2 formation to be closely proportional to dose rate, with a yield of 0.21 μmol J^{-1} in 1.89 M HNO_3. A steady-state concentration of 6 mM HNO_2 was reached after 30 h with a dose rate of 3.2 W L^{-1}. In subsequent measurements of Pu(III) oxidation from a dose rate of 3.2 Gy s^{-1}, where $[\mathrm{Pu(III)}]_0 = 10$ mM, and $[HNO_3] < 0.5$ M, steady state was reached within 1 h and approximately 15% of the plutonium had been oxidized. Small concentrations of a Pu(IV) · H_2O_2 complex were observed. At higher acid concentrations, the peroxide complex was not detected and oxidation to Pu(IV) was complete. The reaction was observed to be autocatalytic; that is, initial rates were low but increased to a maximum when approximately one-half the Pu(III) had been oxidized. The corresponding radiation yields of Pu(IV) ranged up to approximately 5 μmol J^{-1} in 2.9 M acid. These yields were relatively high because Pu(III) is readily oxidized in the presence of HNO_2. Plutonium was oxidized further to Pu(VI), but only after no Pu(III) remained. The initial rates for the alpha-radiolytic oxidation of Pu(IV) were similarly found to be proportional to the concentration of the Pu(IV) multiplied by the dose rate

(Andreichuk *et al.*, 1979). For example, for 0.01 M $[\mathrm{Pu(IV)}]_0$, the yield in 6 M HNO_3 is 0.00044 μmol W^{-1}.

The alpha-radiolytic reduction of Pu(VI) is much more complicated. Small steady-state concentrations of Pu(V) are formed initially, followed by the formation of HNO_2. Further reaction is autocatalytic because the Pu(V) disproportionation is catalyzed by both HNO_2 and Pu(IV) (Vladimirova, 1982). The Pu(VI)/Pu(IV) steady-state ratios were found to vary widely, depending on total plutonium concentration, HNO_3 concentration, and dose rate (Andreichuk *et al.*, 1979, 1984a,b). For example, a dose rate of 3.46 W L^{-1} in 1 M HNO_3 for plutonium concentrations of 2.1 and 14.8 mM yielded Pu(VI)/Pu(IV) ratios of 5.1 and 0.047, respectively. For 10 mM Pu in 6 M HNO_3, the dose rates of 1.4 and 13.8 W L^{-1} yielded Pu(VI)/Pu(IV) ratios of 0.76 and 3.15, respectively. Kinetic models for the rates of the radiolytic oxidation of Pu(IV) and the reduction of Pu(VI) have been presented by Vladimirova (1990, 1998) and Frolov *et al.* (1990). In a study designed to mimic conditions of dissolved nuclear fuel in nitric acid, Rance and Zilberman (2002) found that the addition of U and fission products to Pu(VI) solutions eliminates the induction periods for reduction. This study reported *G*-values of 0.6–1.1 for 3 g L^{-1} ^{239}Pu solutions that contained from 0.12 to 9.2% ^{238}Pu.

Haschke and Oversby have proposed an alternate disproportion reaction to explain the instability of Pu(VI) in aqueous solution that does not require water radiolysis (Haschke and Oversby, 2002; Haschke, 2005):

$$\mathrm{PuO_2^{2+}} + 1/2\mathrm{H_2O} \rightleftarrows \mathrm{PuO_2^{+}} + \mathrm{H^+} + 1/4\mathrm{O_2} \tag{7.121}$$

Their proposed mechanism invokes the disproportionation of PuO_2^{2+} to produce PuO_2^{+} and heptavalent PuO_2^{3+}, followed by the water oxidation by PuO_2^{3+} to produce oxygen. The fact that PuO_2^{3+} has never been observed makes this mechanism doubtful. In a subsequent report, Newton and Hobart (2004) reiterate that below pH 6 the instability of Pu(VI) clearly results from reactions with reducing species produced by alpha radiolysis of water.

Chlorine is formed by radiolysis of HCl solutions, counteracting the processes that reduce plutonium, such that neither Pu(IV) nor Pu(VI) appear to be reduced in 1 M HCl (see discussion in Section 7.9.1.c(ii)). However, at lower chloride concentrations, alpha-reduction of ^{239}Pu(IV) does take place. Rabideau and Kline (1958) showed that *G*[Pu(III)] decreases from 0.36 in 1 M $HClO_4$ μmol J^{-1} to approximately 0.077 in 0.5 M HCl–0.5 M $HClO_4$. More recent experiments by Büppelmann *et al.* (1988) using higher chloride concentrations, more nearly neutral acid concentrations, and ^{238}Pu to give higher dose rates, show that Pu(IV) can be oxidized to Pu(V) or Pu(VI). With NaCl concentrations less than 3 M and dose rates of 0.15 W L^{-1}, the product is primarily Pu(V). Higher concentrations of NaCl and/or higher dose rates give Pu(VI). These reactions involve the oxidation of Pu(IV) hydroxide by HClO or ClO^-. The effect of dose rate on the reduction of Pu(VI) in $HClO_4$ is illustrated by the

Table 7.54 *Alpha-induced reduction of Pu*(*VI*) (*Newton,* 2002).

Pu(VI) (mM)	*Dose rate* (W L^{-1})	*Yield* (μeq J^{-1})	*Radiation source*	*References*
<2	<0.002	0.33–0.38	^{239}Pu	Rabideau *et al.* (1958)
1.1	0.15	0.04	^{238}Pu	Büppelmann *et al.* (1988)

results of experiments using ^{239}Pu, ^{238}Pu, and ^{239}Pu–^{244}Cm mixtures as summarized in Table 7.54. From the Table it is clear that the yield decreases as the dose rate increases.

(d) Hydrolytic stability of plutonium ions

The hydrolytic behavior of the plutonium ions has been the subject of many studies. This interest has been intensified by the practical importance of hydrolysis in the manipulation of plutonium solutions. This class of solution phenomena is as important in the chemistry of plutonium as it is for the actinide elements generally because of the existence of highly charged positive ions in aqueous solution. Hydrolysis leads to the formation of ionic species or precipitates by the action of water as illustrated in equation (7.122) for trivalent plutonium. While hydrolysis reactions are often written as in equation (7.122), hydrolysis is actually a complexation reaction with the hydroxide ion. Therefore, it is also common to express hydrolysis as a complex formation as indicated in equation (7.123). The hydrolysis constant $^*\beta$ (corresponding to equation (7.122)) is related to the formation constant β (equation (7.123)) by the ion product of water, K_w (Grenthe *et al.*, 1997).

$$Pu^{3+} + H_2O \rightleftharpoons Pu(OH)^{2+} + H^+ \tag{7.122}$$

$$Pu^{3+} + OH^- \rightleftharpoons Pu(OH)^{2+} \tag{7.123}$$

Characterization of the hydrolysis behavior of plutonium is the cornerstone of understanding its aqueous coordination chemistry, particularly the thermodynamic stability of complexes. The tendency to undergo hydrolysis increases with the charge/size ratio of the ion. Therefore hydrolysis is most pronounced for Pu^{4+}, and the least pronounced for PuO_2^+. The tendency for hydrolysis follows the general order

$$Pu^{4+} > PuO_2^{2+} \approx Pu^{3+} > PuO_2^+$$

Plutonium ions hydrolyze readily and thereby limit both the stability fields of individual aquo ions and the overall solubility of plutonium ions in aqueous solution. At the extreme end of the spectrum, Pu(IV) hydrolyzes even in pH 1 solutions and can form complicated polymeric (or colloidal) hydroxides and precipitates (Lemire *et al.*, 2001; Neck and Kim, 2001; Rothe *et al.*, 2004), making even the first hydrolysis product of Pu(IV) difficult to characterize. Each of the other common oxidation states forms more soluble and discrete hydroxide species, although Pu(VI) also forms both monomeric and polymeric hydroxide species. The coordination numbers and structures of all of the pure hydroxides can be inferred from the hydration numbers, the stoichiometry of the hydroxo species, and X-ray structures of corresponding solids. X-ray absorption spectroscopy has been used to determine the bond lengths and coordination numbers more directly. Selected hydrolysis constants for plutonium ions are given in Table 7.55 and follow the usual hydrolysis equilibrium expression and associated hydrolysis constant, $^*\beta_n$ (Lemire *et al.*, 2001).

$$\mathrm{Pu}^{x+} + n\mathrm{H_2O} \rightleftharpoons \mathrm{Pu(OH)}_n^{(x-n)+} + n\mathrm{H}^+ \tag{7.124}$$

$$^*\beta_n = \frac{[\mathrm{Pu(OH)}_n^{(x-n)+}][\mathrm{H}^+]^n}{[\mathrm{Pu}^{x+}]} \tag{7.125}$$

A complete review of hydrolysis products and the solubility of plutonium hydroxides is available in the NEA compilation of the chemical thermodynamics of neptunium and plutonium (Lemire *et al.*, 2001) and its most recent update (Guillaumont *et al.*, 2003). Hydration and hydrolysis of plutonium are compared with that of the other actinide elements in Chapter 23.

Pu(III) The tendency of an ion to displace a proton from water increases with charge and, for a given charge, with decreasing ionic radius. The acidity of the tripositive actinide ions, then, should follow the order

$$\mathrm{Pu}^{3+} > \mathrm{Np}^{3+} > \mathrm{U}^{3+}$$

with Pu^{3+} being the strongest acid and therefore the trivalent actinide ion of this triad that undergoes the most extensive hydrolysis. On the basis of its ionic radius, Pu^{3+} should have an acidity similar to the lanthanide ions, and should have a first hydrolysis constant lying between those of Ce^{3+} and Pr^{3+}.

The hydrolysis of Pu^{3+} can be studied only with careful control of the plutonium solubility and maintenance of an inert or reducing atmosphere to avoid oxidation to Pu^{4+}, which is increasingly favored as the solution pH is raised. The first hydrolysis product, $\mathrm{Pu(OH)}^{2+}$, has been inferred from solvent extraction, potentiometric and spectrophotometric titration studies in acid solutions up to pH ~3 (where it accounts for ca. 70% of plutonium present). Kraus and Dam (1949) have studied the hydrolysis of trivalent plutonium according to equation (7.122). From titration curves of plutonium(III) chloride and perchlorate solutions with alkali, Kraus and Dam (1949) identified the first hydrolysis species $\mathrm{Pu(OH)}^{2+}$ and reported the first hydrolysis constant $^*\beta_1$.

$2PuO_2^{2+} + 4H_2O \rightleftarrows (PuO_2)_2(OH)_4 + 4H^+$	0.1	−19.3	–	Okajima and Reed (1993) and Reilly *et al.* (2000)

[a] Asymmetric uncertainties (+0.5, −1.5).

Later studies reported the same species stoichiometry and contributed to the recommended hydrolysis constant of $\log_{10} {}^*\beta_1 = -7.0$ (Baes and Mesmer, 1976; Lemire *et al.*, 2001). The overall formula for $\mathrm{Pu(OH)^{2+}}$ is likely to be $\mathrm{Pu(OH)(OH_2)_8^{2+}}$ based upon the coordination number 9 observed for the $\mathrm{Pu^{3+}}$ aquo ion (see Section 7.9.1(a)) (Matonic *et al.*, 2001). Quantitative evaluation of the formation of higher hydrolysis products is inhibited by oxidation and precipitation of Pu(III/IV) hydroxides. Based on the hydrolysis of other trivalent actinides the second hydrolysis constant for formation of $\mathrm{Pu(OH)_2^+}$ via equation (7.122) is approximately $\log_{10} {}^*\beta_2 = -15.0$ (Baes and Mesmer, 1976; Fuger, 1992).

The solid trivalent plutonium hydroxide that precipitates from aqueous solutions is presumed to be $\mathrm{Pu(OH)_3 \cdot \mathit{n}H_2O}$, by analogy with the known $\mathrm{Am^{3+}}$ hydroxide. Solubility studies that were performed as a function of ionic strength provide a solubility product of $\log_{10} K_{\mathrm{sp}} = -(15.8 \pm 1.5)$ under standard conditions (Felmy *et al.*, 1989).

Pu(IV). On the basis of size and charge, the plutonium(IV) ion should undergo much more extensive hydrolysis than does plutonium(III). For the same reasons as in the case of the III state, the tendency to undergo hydrolysis should be greater in plutonium than for its predecessors in the actinide series:

$$\mathrm{Pu^{4+} > Np^{4+} > U^{4+} > Pa^{4+} > Th^{4+}}$$

In the early stages of hydrolysis, only monomeric species such as $\mathrm{Pu(OH)^{3+}}$ are important. It is likely that $\mathrm{Pu^{4+}}$ hydrolyzes in a stepwise manner to yield monomeric $\mathrm{Pu(OH)}_n^{4-n}$ ($n = 1, 2, 3, 4$); however, the intermediate hydrolysis products ($2 \leq n \leq 4$) undergo irreversible polymerization with the formation of large colloidal aggregates (see below).

The first hydrolysis product for the formation of $\mathrm{Pu(OH)^{3+}}$, has been determined from solution complex formation studies.

$$\mathrm{Pu^{4+} + H_2O \rightleftharpoons Pu(OH)^{3+} + H^+} \tag{7.126}$$

Reported hydrolysis constants for this reaction vary widely, with limited correlation between the experimental technique used and the resulting value of the hydrolysis constant (Baes and Mesmer, 1976; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003). From the many reported values, several are considered the most accurate. Rabideau (1957) carefully measured the pH dependence of the $\mathrm{Pu^{4+}}$/$\mathrm{Pu^{3+}}$ redox couple and calculated a hydrolysis constant of $\log_{10} {}^*\beta_1 = -1.41$ at $I = 0.1$ M using the Nernst equation. Compared with directly measuring the formation of the hydrolysis product, for example, by quantifying the shift in the optical absorption bands for $\mathrm{Pu^{4+}}$ as the hydroxide forms, or calculating a constant to best model the solubility of (oxy)hydroxide solids, this approach explicitly considers the formation and subsequent hydrolysis of $\mathrm{Pu^{3+}}$ at low pH. The 2003 NEA review recommended the value of $\log_{10} {}^*\beta_1 = (0.60 \pm 0.20)$ under standard conditions ($I = 0$) (Guillaumont *et al.*, 2003), which is based on values proposed in recent studies by Knopp *et al.* (1999) and Neck and Kim (2001). The constant for the second hydrolysis product was originally estimated to be $\log_{10} {}^*\beta_2 = -3.7$ at $I = 0.1$ M (Kraus and Nelson, 1950). The 2003 NEA review recommended $\log_{10} {}^*\beta_2 = (0.60 \pm 0.30)$ for $I = 0$ based on the most recent studies (Guillaumont *et al.*, 2003). The overall formulae for $Pu(OH)^{3+}$ and $Pu(OH)_2^{2+}$ are likely to be $Pu(OH)(OH_2)_7^{3+}$ and $Pu(OH)_2(OH_2)_6^{2+}$ based upon the coordination number 8 observed for the Pu^{4+} aquo ion (see Section 7.9.1(a)).

$$Pu^{4+} + 2H_2O \rightleftharpoons Pu(OH)_2^{2+} + 2H^+ \qquad (7.127)$$

Characterization of subsequent third and fourth hydrolysis species [$Pu(OH)_3^+$ and $Pu(OH)_4$] is frustrated by the propensity of these hydroxides to polymerize, as discussed below. The direct observation of the solution species and definitive determination of the constants are prevented by the detection limits of current techniques coupled with the sparing solubility of the (hydr)oxide phases. Attempts to accurately determine these constants from solubility data are focused on the following: identifying discrete solution ion and colloidal species, improving the quantification of the Pu^{4+} ion, refining the operational definitions of the solid/solution phase (commonly delineated by the phase separation method), and better characterizing and controlling the solid phase [crystalline PuO_2, hydrated PuO_2, crystalline or amorphous $Pu(OH)_4$]. Based on the most recent work by Knopp *et al.* (1999), and by Neck and Kim (2001), the 2003 NEA review proposed the value of $\log_{10} {}^*\beta_3 = -(2.3 \pm 0.4)$, and $\log_{10} {}^*\beta_4 = -(8.5 \pm 0.5)$ for the third and fourth hydrolysis constants at $I = 0$, respectively (Guillaumont *et al.*, 2003).

The published solubility product of amorphous Pu(IV) hydroxide, $Pu(OH)_4(s)$, is $\log_{10} K_{sp} = -(58 \pm 1)$ (Capdevila and Vitorge, 1998; Lemire *et al.*, 2001; Neck and Kim, 2001). This value gives a calculated Pu(IV) solution concentration near pH 7 of 10^{-11} M, while observed solubilities span a range of 10^{-8}–10^{-13} M due to interactions with other simple ligands, formation of other hydroxide species, redox instability, and the formation of colloidal species (Neck and Kim, 2001; Rothe *et al.*, 2004).

Pu(IV) polymerization. It has been known for half a century that aqueous solutions of Pu(IV) will form colloidal polymers under the appropriate solution conditions (Kraus and Nelson, 1950; Kraus, 1956). Early emphasis focused on avoiding Pu(IV) polymer because of its intractability and potential for interference in plutonium process chemistry. Newer concerns involve retention of plutonium in nuclear waste repositories where radioactive heating and low acidity of ground waters favor Pu(IV) colloid formation and thus could provide a potential transport pathway for migration of plutonium away from the repository. Radiocolloids are very fine, well-dispersed, intrinsic particles of radioactive compounds, whose formation in the case of the actinides is intimately connected to their hydrolysis chemistry.

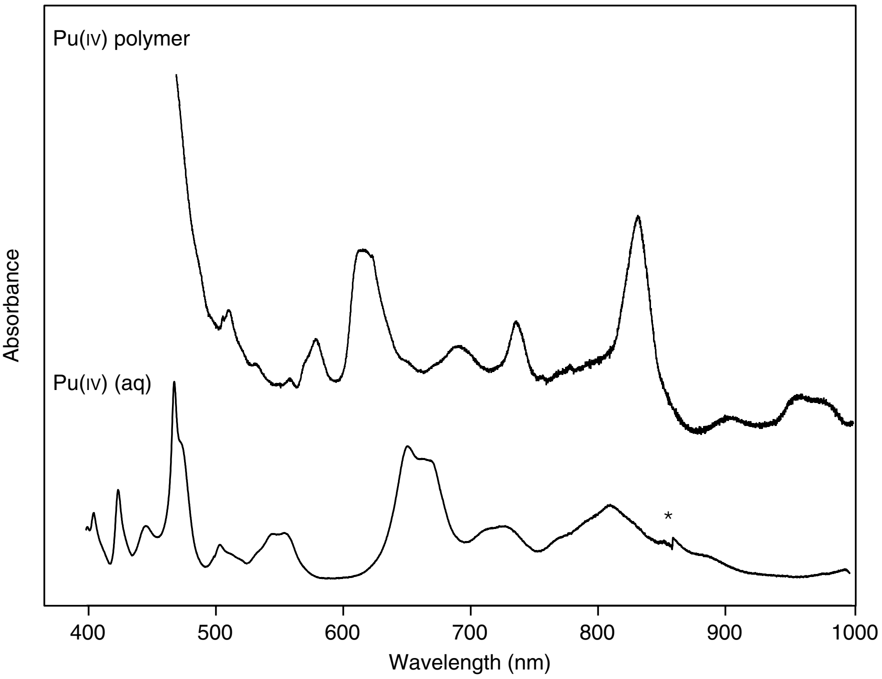

Fig. 7.119 *Electronic absorption spectra of Pu(IV) polymer compared to the Pu(IV) aquo ion. Plutonium(IV) polymer recorded on* 9.0 mM *solution; plutonium(IV) aquo ion recorded on* 2.91 mM *solution in* 1 M *$HClO_4$ using* 1 cm *cell. The asterisk indicated a spectrometer grating change (spectra courtesy of P. D. Palmer of Los Alamos).*

For plutonium (IV) the colloid can form green solution-like sols that are optically clear, display a characteristic absorption spectrum (Fig. 7.119), and do not settle on long-standing (Ockenden and Welch, 1956; Lloyd and Haire, 1978). Under the appropriate conditions, these colloids may decompose or disaggregate into soluble ionic species, or age into relatively insoluble materials (Newton *et al.*, 1986b).

The formation of colloidal Pu(IV) polymer was first reported by Kraus, and much of the early information on it is based on the work of Kraus and his coworkers (Kraus and Nelson, 1950; Kraus, 1956). Pu(IV) polymer can be prepared by a number of methods (Hobart *et al.*, 1989). Precipitation methods include the partial neutralization of Pu(IV) solutions, addition of water to 'dried' acid samples, or precipitation with alkali followed by peptization in dilute acid (90°C). Redox methods include slow oxidation of Pu(III) by oxygen and/or alpha irradiation products, or the reduction of Pu(V). The polymer formation depends on acidity, Pu(IV) concentration, presence of other ions, and temperature (Rainey, 1959). Solutions of Pu(IV) polymer can be very readily obtained when plutonium(IV) hydroxide is treated with less than four equivalents of hydrogen ion per mole of plutonium; when plutonium(IV) hydroxide is dissolved in dilute acid, plutonium polymer forms. Likewise, if a solution of plutonium(IV) in moderately concentrated acid is poured slowly into boiling water, polymeric plutonium is obtained. It is also formed when a plutonium nitrate solution is depleted of nitric acid by extraction with *n*-hexanol. The colloid polymer is ideally formed in nitrate solution in about 0.8 mole per mole of plutonium(IV) (Lloyd and Haire, 1978). This colloidal polymer may be isolated as a solid, which shows the electron diffraction pattern typical of an amorphous substance and has a practical size of up to 20 Å. This colloid can easily be redissolved. On standing or artificial aging, the particle size increases, and the solid becomes finely crystalline and exhibits the XRD pattern of PuO_2. The colloidal character of plutonium(IV) polymer is manifested by the strong absorption of the polymer on glass and on substances such as paper, cotton, and silica, which acquire a negative surface charge when immersed in water.

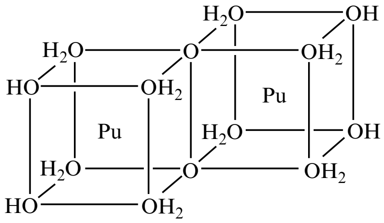
Until recently, the characterization of plutonium(IV) colloid has met with only limited success. Thiyagarajan *et al.* (1990) measured the structures of Pu(IV) hydrous polymers by small-angle neutron scattering (SANS) in aqueous media and after solvent extraction into an organic phase. The SANS data indicate long, thin, rod-like particles that measured (4.7 ± 0.2) by (190.0 ± 20.0) nm. XRD was consistent with a fcc crystal system similar to that found in crystalline PuO_2 (see Section 7.8.5.a(iii)).

Light scattering methods have also be used to characterize macromolecular Pu(IV) hydroxide solutions. Rundberg *et al.* (1988) and Triay *et al.* (1991) employed autocorrelation photon spectroscopy (APS) to determine the size distribution of Pu(IV) colloidal suspensions that were prepared by dilution, peptization, and autoxidation of Pu(III). The plutonium(IV) colloids measured by APS were assumed to be spherical particles in order to utilize the Stokes–Einstein relationship to calculate a particle diameter. In the initial study by Rundberg *et al.* (1988) the average size of the colloid diameter was measured to be (2.9 ± 0.2) nm. The diameter of a plutonium colloid sample measured over a period of 2 years resulted in reproducible diameters of 180 nm. Subsequently, Triay *et al.* (1991) examined colloid diameters as a function of preparation method, and found that the size of the colloids varied from 1 to 370 nm depending on method of preparation. Small colloid diameters on the order of 1.5 nm were found when the colloid was prepared by the method of Savage and Kyffin (1986) by heating a plutonium nitrate solution with hydrogen peroxide, neutralizing most of the free acid with sodium hydroxide, and diluting to known volume to give 2.5 g L^{-1} solutions. Dilution of a well-characterized Pu(IV) stock solution using distilled water yields colloids in the range of 2–6 nm in diameter (Triay *et al.*, 1991). Peptization gave a mixture of two different sizes (14 and 370 nm). Autoxidation of Pu(III) yielded the largest single-sized colloid.

More recently, Rothe *et al.* (2004) investigated Pu(IV) colloid growth using a combination of laser-induced breakdown detection (LIBD) and X-ray absorption fine structure (XAFS) spectroscopy. LIBD measurements gave colloid sizes ranging from 12 to 25 nm depending on solution conditions.

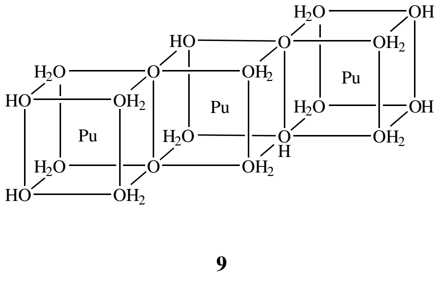
Rothe *et al.* proposed a model for colloid formation that is consistent with their XAFS, LIBD, and UV-Vis spectroscopic data, based on the stepwise buildup of polynuclear species and loss of water, in analogy to a mechanism proposed by Fujiwara and coworkers (Fujiwara *et al.*, 2001). In this model, they propose hydrolysis of aquo Pu^{4+} to form an eight coordinate monomer $Pu(OH)_2(OH_2)_6^{2+}$ followed by condensation of two monomers to form a dimer of cubic units connected at their edges. The condensation of $Pu(OH)_2^{2+}$ units as reactants satisfies a –2 slope dependency on LIBD data, and the eight coordinate monomer $Pu(OH)_2(OH_2)_6^{2+}$ satisfies the coordination environment from XAFS data. This basic condensation model is described in equation (7.128), and the structural model for the resulting dimer is illustrated in **8**.

$$
\begin{aligned}
2Pu(OH)_2(H_2O)_6^{2+} + xH_2O \rightleftharpoons{}& Pu_2O_p(OH)_{8-2p}(OH_2)_{6+p} \\
&+ 4H^+ + (2+x)H_2O
\end{aligned}
\tag{7.128}
$$

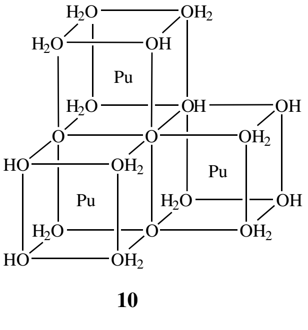


8

In rationalizing the formation of higher order polymers, a trimeric species could be envisioned as forming through the subsequent condensation of monomeric $Pu(OH)_2(OH_2)_6^{2+}$ with the dimer **8**. To be consistent with XAFS data, the new trimer must retain an essentially fcc Pu sublattice with an approximately 3.87 Å distance between Pu centers. This is possible through condensation of the third monomeric $Pu(OH)_2(OH_2)_6^{2+}$ unit along cube edges to form a chain, or by condensing a third monomeric unit along two edges of neighboring cubes of the dimer to form a trimer of cubes sharing one common corner. Examples of these proposed trimeric units are shown in **9** and **10**.



9



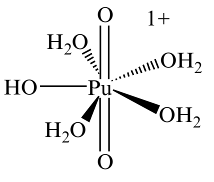
10

The fundamental components of this polymerization mechanism are to grow oligomeric units that maintain a Pu–Pu separation near 3.87 Å, maintain a Pu: OH ratio of 2, and keep the overall cluster size small enough to be consistent with UV-Vis results. Polymerization to larger units can proceed by subsequent condensation of dimers or trimers with each other, or with monomeric units.

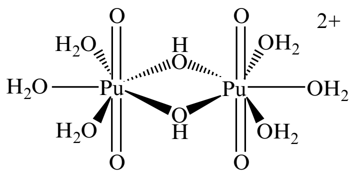
The XAFS data from Rothe *et al.* reveal the presence of several different Pu–O distances between 2.20 and 2.42 Å consistent with different coordinating oxygen atoms (–O, –OH, and OH_2). Similarly, the XAFS data show a Pu–Pu distance between 3.86 and 3.89 Å. The fcc cubic environment and the 3.8 Å Pu–Pu separation gives a basic structural unit that is similar to that observed in fcc PuO_2 (see Section 7.8.5(a)). These workers also observed a small feature in their XAFS data near 1.9 Å, and they argued that this feature was too short to be reconcilable with a Pu(IV)–O bond. As this feature had also been observed in ThO_2 XAFS spectra (Rothe *et al.*, 2002), and in XAFS reported by other workers, it was concluded that this feature was most consistent with multiple electron excitation. Essentially identical structural features were observed in XAFS data of Pu(IV) colloid samples reported by Conradson and coworkers (Conradson *et al.*, 2004b). The primary focus of the Conradson study was to examine the structural features of solid PuO_{2+x} materials (see Section 7.8.5(a)). The XAFS data from PuO_{2+x} solids show many remarkable structural similarities to the Pu(IV) colloid samples studied by Rothe *et al.* (2004) and Conradson *et al.* (2004b). Both studies show a range of Pu–O distances consistent with different coordinating oxygen atoms (–O, –OH, and OH_2). In the oxide of stoichiometry of $PuO_{2.26}$, the short interatomic distance near 1.9 Å is no longer a small feature, but has become a dominant spectroscopic feature (see Fig. 7.94). Conradson also reported XAFS data on a number of Pu(IV) colloid samples whose XAFS spectra vary as a function of preparation and aging. Conradson's data show that both Pu(IV) polymers and solid PuO_{2+x} compounds share structural features, and are consistent with an fcc arrangement of plutonium atoms with a 3.8 Å separation. The difference between the two studies is that in solid PuO_{2+x} compounds, the XANES data were consistent with a mixture of Pu(IV) and Pu(V). Conradson *et al.* suggested that the short internuclear distance that averaged 1.86 Å was consistent with the presence of Pu(V), where solution measurements show a distance of 1.85 Å for PuO_2^+. In the freshly prepared samples studied by Rothe *et al.* (2004) this feature was quite small. In the aged samples studied by Conradson *et al.* (2004b) this feature was quite pronounced. These two XAFS studies remind us of the complex nature of the Pu(IV) polymer, and suggest that the elegant polymerization mechanism proposed by Rothe *et al.* may need to be expanded. We look forward to future advances in this area.

Pu(V). Of the common oxidation states of plutonium only Pu(V) is not hydrolyzed until the solution pH becomes basic. Because of the tendency of pentavalent plutonium to disproportionate or be reduced by even weak agents there are very few studies on the hydrolysis of this plutonium ion. Similarly, the presence of inorganic and organic ligands will generally favor the formation of Pu(IV)–ligand complexes in accordance with their relative formation constants. Early conventional spectrophotometric studies showed that Pu(V) hydrolyses above pH 9 to form stepwise products, $PuO_2(OH)$ and $PuO_2(OH)_2^-$ (Baes and Mesmer, 1976; Madic *et al.*, 1984; Fuger, 1992). By analogy with Np(V) hydroxides, which have been studied in detail by optical absorption and Raman spectroscopy (Madic *et al.*, 1984; Sullivan *et al.*, 1991), Pu(V) hydroxide complexes $PuO_2(OH)$ and $PuO_2(OH)_2^+$ likely have two or three inner-sphere water molecules in the equatorial plane and pentagonal bipyramidal coordination geometry. The monohydroxide hydrate solid is amorphous and has not been structurally characterized. Attempts to increase the crystallinity of the $NpO_2(OH)$ analog have produced Np_2O_5 (Runde *et al.*, 2002). Bennett and coworkers used photoacoustic spectroscopy to perform spectrophotometric titrations of millimolar and submillimolar PuO_2^+, which provided a formation constant for the first hydrolysis product of $\log_{10} {}^*\beta_1 = -(9.73 \pm 0.10)$ (Bennett *et al.*, 1992). Mixed hydroxo carbonato complexes, such as $PuO_2(OH)(CO_3)_2^{4-}$ or $PuO_2(OH)_2(CO_3)^{3-}$ may form (by analogy with Np(V) chemistry) but they have not been characterized. In addition, there is some evidence that the superstoichiometric Pu(IV) oxide (PuO_{2+x}) contains Pu(V) (Conradson *et al.*, 2003, 2004b). Thus, Pu(V) hydroxides may be much more important in plutonium chemistry and material science than was previously thought.

Pu(VI). Plutonium(VI) hydrolysis is intermediate between that of Pu(III) and Pu(IV), corresponding to its effective charge of ~3.2. Similar to Pu(IV), low solubility and polymerization challenge the characterization of products above neutral pH. The first hydrolysis products, $PuO_2(OH)^+$ and $PuO_2(OH)_2$ have hydrolysis constants of $\log_{10} {}^*\beta_1 = -(5.5 \pm 0.5)$ and $\log_{10} {}^*\beta_2 = -(13.2 \pm 1.5)$ at $I = 0$, respectively (Lemire *et al.*, 2001), comparable to the analogous U (VI) species (Grenthe *et al.*, 1992). Structurally, these monomeric species likely have three or four water molecules in addition to hydroxide in the equatorial plane and a pentagonal bipyramidal geometry with respect to inner-sphere oxygen atoms as indicated in **11**. There is substantial data from potentiometric, optical absorption, and Raman studies that indicates that at higher plutonium concentrations (estimated to be $\sim 5 \times 10^{-4}$ M) the first hydrolysis product is the dimer, $(PuO_2)_2(OH)_2^{2+}$, with two bridging hydroxides and pseudo-pentagonal bipyramidal coordination as shown in **12** (Madic *et al.*, 1984; Okajima and Reed, 1993; Reilly *et al.*, 2000). The hydrolysis constant for the dimer is estimated to be $\log_{10} {}^*\beta_{22} = -(7.5 \pm 1.5)$ at $I = 0$ (Lemire *et al.*, 2001). Polymerization is less pronounced for Pu(VI) than for U(VI) and there is no evidence for the trimeric hydroxide complexes that have been well characterized for uranyl, e.g. $(UO_2)_3(OH)_5^+$, (Grenthe *et al.*, 1992; Palmer and Nguyen-Trung, 1995). Solids precipitated from these systems have been formulated based on stoichiometry as $PuO_2(OH)_2$ or various hydrated phases, but neither their structures nor solubility products have been determined.



11



12

Under alkaline solution conditions of 1 M LiOH, Tananaev (1989) presented data to suggest the formation of $PuO_2(OH)_4^{2-}$ that converts to $PuO_2(OH)_3^{-}$ upon lowering the hydroxide concentration. The single crystal XRD structures (Clark *et al.*, 1999a) and solution XAFS data (Wahlgren *et al.*, 1999; Clark *et al.*, 1999a; Moll *et al.*, 2000; Bolvin *et al.*, 2001) have been reported on the $UO_2(OH)_4^{2-}$ and $NpO_2(OH)_4^{2-}$ analogs.

Pu(vii). Heptavalent plutonium has only been studied in strongly alkaline solutions, given its immediate reduction to Pu(vi) under all other conditions. Interest in the coordination environment of Pu(vii) in solution has been renewed because highly alkaline conditions could be technologically useful in nuclear waste processing, and because Pu(vii) hydroxides provide an opportunity to examine structure/bonding relationships in actinide systems with an unusual number of Pu–O multiple bonds. Pu(vii) appears to be analogous to Np(vii) for which many more studies have been reported. A series of anionic polyoxo species that form between 0.5 and 18 M hydroxide has been proposed and includes the following, $PuO_4(OH_2)_2^{-}$, $PuO_4(OH)(OH_2)^{2-}$, $PuO_4(OH)_2^{3-}$, $PuO_5(OH)^{4-}$, or PuO_6^{5-}, depending on hydroxide concentrations (Spitsyn *et al.*, 1969; Krot, 1975; Tananaev *et al.*, 1992). Of the proposed species, only $PuO_4(OH)_2^{3-}$ has a proven analog in neptunium chemistry, and its likely structure is shown in **7** (see Section 7.9.1.a) (Grigor'ev *et al.*, 1986). No hydrolysis constants are known. Crystalline samples of analogous Pu(vii) compounds have been prepared (Zakharova *et al.*, 1972).

(e) Complex ions

In this section we describe the preparation, stability, structure, and in selected cases the spectroscopy and solid-state forms, of molecular complexes of plutonium in aqueous solution. The little information that is available on the nonaqueous coordination and organometallic chemistry of plutonium will be described in Section 7.9.2. The stoichiometry and stability of aqueous plutonium complexes has generally been determined indirectly from proton, ligand, and metal titrations, including the following approaches: measured plutonium extraction efficiencies as a function of extractant ligand concentrations, pH titrations of protic ligands in the absence and presence of plutonium, pH/ligand/plutonium titrations monitored by optical spectroscopy, and less frequently from multinuclear NMR and vibrational spectroscopic analysis. The structures of solution species have also been inferred from the characterization of corresponding solids. More direct methods, including electrospray mass spectroscopy and X-ray absorption spectroscopy, are increasingly being applied to characterize molecular plutonium complexes. Fluorescence spectroscopy has the potential to be used to characterize plutonium species, similar to its application in uranyl chemistry, as emission from plutonium ions has been observed, albeit under very special conditions.

The coordination chemistry of plutonium ions is generally characteristic of exceptionally 'hard' Lewis acids, those that show preference for complexation by hard (i.e. first row donor atom) ligands. Weak Lewis bases, such as HS^- form weak complexes with plutonium and strong Lewis bases, such as CO_3^{2-}, F^-, and PO_4^{3-} form very stable complexes. Plutonium ions have relatively large ionic radii and therefore form complexes with high coordination numbers (8–14). For a given ligand the strength of complexation (the stability of the Pu–ligand complex) and the tendency of ions to hydrolyze decrease following the effective charges:

$$Pu^{4+} > PuO_2^{2+} \approx Pu^{3+} > PuO_2^{+}$$

Overall, the bonding in plutonium complexes can generally be described as ionic, where the geometry of coordination complexes is primarily governed by steric considerations (ligand–ligand repulsions). Plutonium–ligand orbital overlap is considered to be important in some types of complexes, and comparatively more important than in corresponding complexes of lanthanides and lighter actinides with similar ionic radii. Ligand exchange in plutonium complexes is facile, and reaction rates are generally fast.

Complexation in this chapter generally refers to inner-sphere coordination, where the ligand is directly bonded to plutonium and displaces more weakly bound ligands and/or solvent water. Outer sphere complexation and ion pairing are also important interactions, particularly in high ionic strength and otherwise complicated solutions. Equilibrium constants for the reactions of plutonium ions with ligands reflect the competition between protons and plutonium for ligand atom bonding and are experimentally determined. Formation constants are pH independent values calculated from equilibrium constants, ligand pK_as, and plutonium hydrolysis constants and therefore more directly reflect the strength of interaction between the plutonium ion and the deprotonated ligand. For weaker ligands it is important to note that this interaction may be on the order of plutonium–solvent interactions, a factor not easily separated out to provide a quantitative pure plutonium–ligand interaction constant. In the text that follows, we will use K for the consecutive or stepwise formation constants, and β for the cumulative or overall formation constants (Lemire *et al.*, 2001). In cases where complex formation involves a deprotonation of a ligand, the equilibrium constant (K) or formation constant (β) will be denoted by an asterisk as indicated below.

$$\mathrm{PuL}_{n-1} + \mathrm{L} \rightleftharpoons \mathrm{PuL}_n, \quad K_n = \frac{[\mathrm{PuL}_n]}{[\mathrm{PuL}_{n-1}][\mathrm{L}]} \tag{7.129}$$

$$\mathrm{PuL}_{n-1} + \mathrm{HL} \rightleftharpoons \mathrm{PuL}_n + \mathrm{H}^+, \quad {}^*K_n = \frac{[\mathrm{PuL}_n][\mathrm{H}^+]}{[\mathrm{PuL}_{n-1}][\mathrm{HL}]} \tag{7.130}$$

$$\mathrm{Pu} + n\mathrm{L} \rightleftharpoons \mathrm{PuL}_n, \quad \beta_n = \frac{[\mathrm{PuL}_n]}{[\mathrm{Pu}][\mathrm{L}]^n} \tag{7.131}$$

$$\mathrm{Pu} + n\mathrm{HL} \rightleftharpoons \mathrm{PuL}_n + n\mathrm{H}^+, \quad {}^*\beta_n = \frac{[\mathrm{PuL}_n][\mathrm{H}^+]^n}{[\mathrm{Pu}][\mathrm{HL}]^n} \tag{7.132}$$

Selected formation constants and equilibrium constants will be defined and conditions specified in summary tables. The emphasis is on describing the types of molecular plutonium complexes that form and highlighting specific chemical, structural, and physical properties. For a more comprehensive discussion of stability constant determinations and analysis done to compute thermodynamic constants under standard conditions the reader is referred to specialized critical reviews (Grenthe *et al.*, 1997; Lemire *et al.*, 2001; Guillaumont *et al.*, 2003). Comparisons across the actinide series and a fine description of the details of plutonium complexation in solution are given in Chapter 23. Selected formation and equilibrium constants for plutonium complexes are given in Table 7.56.

(*i*) *Oxoanions*

Plutonium ions are oxophilic and therefore readily form complexes with oxo ligands, as exemplified by high hydration numbers and extreme hydrolysis described in Section 7.9.1(d). Anionic inorganic oxo ligands effectively complex plutonium to form complexes whose stability depends on the charge and basicity of the ligand. For a given plutonium ion the order of complexation strength for common oxoanions is: $\mathrm{ClO_4^-}<\mathrm{IO_3^-}<\mathrm{NO_3^-}<\mathrm{SO_4^{2-}}<<\mathrm{CO_3^{2-}}<\mathrm{PO_4^{3-}}$. Perchlorate is often referred to as a noninteracting counter ion, but does coordinate to plutonium at very high concentrations. Nitrate complexes are much more stable than analogous perchlorate species and slightly more stable than chloride complexes of the same stoichiometry. Phosphate is an exceptionally strong ligand for plutonium. These ions usually chelate plutonium ions in a bidentate fashion. The stability of plutonium oxoanionic complexes follow the general trends of Pu(IV) being the strongest and Pu(V) being the weakest.

The coordination numbers of plutonium oxoanion complexes ranges from 7 for $\mathrm{PuO_2^+}$ to up to 12 for $\mathrm{Pu^{4+}}$, where water is successively displaced from the inner coordination sphere by chelating ligands. Water that remains bonded to the Pu center can hydrolyze to form mixed-ligand complexes that contain one or more bidentate oxoanion and one or more hydroxide ligand. These species are favored at near-neutral pH and lower oxoanion concentrations. Solution complex formation constants and solid-state structures are known for relatively few of these species, such as Pu(IV) hydroxo oxalates. It is difficult to distinguish mixed-ligand complexes from the coexistence of individual complexes, which explains the uncertainty in, for example, plutonium(IV) carbonate speciation and thermodynamic stability.

Carbonate

Plutonium carbonates are of interest because of their fundamental chemistry and environmental behavior, including aspects of actinide mineralogy and nuclear waste isolation. Separation schemes based on carbonate that utilize the pH-dependent complexing properties of this ligand have been proposed as alternatives to acid-based or organic extraction processes for used nuclear fuels (Asanuma *et al.*, 2001). Some features are common to the carbonate complexation of plutonium ions. Carbonate binds plutonium in a bidentate fashion and has a small bite angle so that coordination numbers of resulting complexes are generally quite high, 7–10. The actinyl ions, PuO_2^+ and PuO_2^{2+} have pentagonal and hexagonal bipyramidal structures in which the linear triatomic O=An=O unit forms the axis of a pentagonal or hexagonal bipyramidal coordination polyhedron with respect to carbonato and aquo oxygen atoms bound to the metal center. In addition to chelating the plutonium ion, carbonate ligands often hydrogen bond to outer sphere waters or counter ions to produce chains and layers and other less regular hydrogen bond networks in the solid-state structures. For all of the oxidation states the stability constant for the initial monocarbonato complex is known with the greatest accuracy and precision because they can be determined spectrophotometrically from the reduction/shift in the characteristic absorption band for the aquo ion. Thermodynamic constants of the limiting carbonato complexes are better known from the solubility and carbonate titration studies than are those corresponding to intermediate species because the former usually have large stability fields. And the limiting molecular complexes are usually isostructural with the solution species from which they are precipitated. Intermediate carbonate complexes are not well characterized for any of the oxidation states. Several reviews on actinide carbonate and environmental chemistry describe plutonium carbonato complexes in detail (Grenthe *et al.*, 1986b; Newton and Sullivan, 1986; Fuger, 1992; Clark *et al.*, 1995; Choppin and Wong, 1998).

Trivalent plutonium carbonato complexes generally oxidize rapidly to tetravalent species. In aqueous Pu(III) solutions there is evidence for the stepwise formation of the carbonato complexes, $Pu(CO_3)^+$ and $Pu(CO_3)_2^-$. Additional carbonato and hydroxocarbonato complexes may form, but are immediately oxidized to Pu(IV) species. Formation constants of $\log_{10}\beta_1 = 7.5$ and $\log_{10}\beta_2 = 12.4$ have been estimated at low ionic strength (0.1–0.5 M) (Cantrell, 1988). These values have not been verified, but are consistent with well-known constants of Am(III) carbonato complexes (Silva *et al.*, 1995).

Table 7.56 *Formation constants for plutonium oxo anions.*

Reaction stoichiometry	I (M)	$\log_{10}\beta_n$	$\log_{10}\beta_n^\circ$	*References*
carbonate				
$Pu^{3+} + CO_3^{2-} \rightleftarrows PuCO_3^+$	0.1–0.5	7.5		Cantrell (1988)
$Pu^{3+} + 2CO_3^{2-} \rightleftarrows Pu(CO_3)_2^-$	0.1–0.5	12.4		Cantrell (1988)

[a] NEA Update Vol 5 (Guillaumont *et al.*, 2003).

[b] Species may not exist, based on later studies of Pu(IV) carbonates (Capdevila *et al.*, 1996).

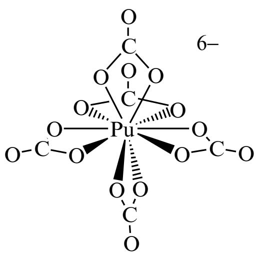
Tetravalent plutonium probably forms stepwise complexes, $Pu(CO_3)_n^{4-2n}$, $n = 1–5$, with increasing solution pH and carbonate concentration (Newton and Sullivan, 1986; Clark *et al.*, 1995). The end members of this series and the tetracarbonato complex have been characterized, while the bis- and tris-species are inferred from studies of other actinide(IV) carbonates. Monocarbonato Pu(IV) of formula $Pu(CO_3)^{2+}$ is prepared by addition of carbonate to acidic solutions of the ion or from carbonate-mediated dissolution of hydroxide or oxide solids. The formation constant for $Pu(CO_3)^{2+}$ is reported to be $\log_{10} \beta_1 = (17.0 \pm 0.7)$ (Nitsche and Silva, 1996; Rai *et al.*, 1999). Given the generally accepted hydration number of eight for Pu(IV), this complex likely has six additional water molecules in the inner coordination sphere. In concentrated carbonate solutions, $Pu(CO_3)_4^{4-}$ is in equilibrium with $Pu(CO_3)_5^{6-}$. The formation constants for these individual species are highly correlated with each other and with the lower carbonate species.

Capdevila *et al.* (1996) studied the formation of the limiting carbonato complex of formula $Pu(CO_3)_5^{6-}$ by electronic absorption spectroscopy with varying ionic strength. From the study of the equilibrium in equation (7.133), they were able to determine an equilibrium constant for the reaction of $\log_{10} K_5 = -(1.36 \pm 0.09)$, and the formation constant for the limiting complex of $\log_{10} \beta_5 = (35.8 \pm 1.3)$ in 3 M $NaClO_4$ solution. The NEA review recommended a zero ionic strength value of $\log_{10} \beta_5 = (36.65 \pm 1.13)$ (Lemire *et al.*, 2001). By combining the value for β_5 with the equilibrium constant K_5 for equation (7.133), the formation constant for $Pu(CO_3)_4^{4-}$ at zero ionic strength was recommended to be $\log_{10} \beta_4 = (37.0 \pm 1.1)$ (Lemire *et al.*, 2001).

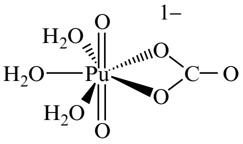
$$Pu(CO_3)_4^{4-} + CO_3^{2-} \rightleftarrows Pu(CO_3)_5^{6-} \qquad (7.133)$$

Recent conventional spectrophotometric and electrochemical studies have focused on refining the thermodynamic constants for the carbonato species and determining the stability field and stoichiometry of mixed hydroxo/carbonato Pu(IV) complexes (Capdevila and Vitorge, 1999). The NEA critical review of thermodynamic data suggests that spectroscopic signatures and solubility characteristics that have been attributed to mixed hydroxo/carbonato complexes are in fact explained by the simultaneous and independent formation of hydrolysis products and carbonato complexes (Lemire *et al.*, 2001). Counter arguments are that colloidal Pu(IV) polymer formation is suppressed by carbonate complexation, and that absorption spectra of Pu(IV) in carbonate solutions over the entire pH range are wholly reproduced by linear combinations of known individual hydroxide and carbonate spectra.

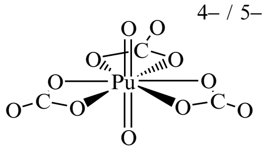
Plutonium(IV) carbonato solids of general formula $M_xAn(CO_3)_y \cdot nH_2O$ have been prepared with a variety of cations ($M = Na^+, K^+, NH_4^+, C(NH_2)_3^+$; $y = 4$, 5, 6, 8) by precipitating or crystallizing the solution species. For example, $[Na_6Pu(CO_3)_5]_2 \cdot Na_2CO_3 \cdot 33H_2O$ was crystallized from 2.5 M Na_2CO_3 solution and characterized by single-crystal XRD (Clark *et al.*, 1998). The structure contains the discrete $Pu(CO_3)_5^{6-}$ ion, which can be viewed as a pseudo-hexagonal bipyramid with three CO_3^{2-} ligands in an equatorial plane and two in axial positions as shown in **13**. Solution XAFS data for Pu(IV) in 2.5 M Na_2CO_3 solution gave bond distances and coordination numbers that corresponded extremely well with the average Pu–O, nonbonding Pu- -C, and distal Pu- -O distances of 2.42(1), 2.87(1), and 4.12(1) Å, respectively, found in the solid-state structure for the $Pu(CO_3)_5^{6-}$ ion. A peak-by-peak correspondence of the optical absorption spectra of the solution and diffuse reflectance spectrum of the ground crystalline solid, together with the solution XAFS data provide conclusive evidence that the $Pu(CO_3)_5^{6-}$ ion is the limiting species in high carbonate solutions. Depending on reaction conditions, green amorphous powders of compositions $K_4Pu(CO_3)_4{\cdot}nH_2O$, $K_6Pu(CO_3)_5{\cdot}nH_2O$, $K_8Pu(CO_3)_6{\cdot}nH_2O$, and $K_{12}Pu(CO_3)_8{\cdot}nH_2O$ have all been reported (Gel'man and Zaitsev, 1958). Since Clark *et al.* identified the $Pu(CO_3)_5^{6-}$ ion as the limiting species, it is reasonable to assume that the latter two solids are more realistically formulated as $[K_6Pu(CO_3)_5][K_2CO_3]{\cdot}nH_2O$ and $[K_6Pu(CO_3)_5][K_2CO_3]_3{\cdot}nH_2O$. Sodium salts of formula $Na_4Pu(CO_3)_4{\cdot}3H_2O$, $Na_6Pu(CO_3)_5{\cdot}2H_2O$, and $Na_6Pu(CO_3)_5{\cdot}4H_2O$ have also been claimed as light green crystalline compounds that appear to dehydrate in air (Gel'man and Zaitsev, 1958). Similarly, the $(NH_4)_4Pu(CO_3)_4{\cdot}4H_2O$ and $[Co(NH_3)_6]_2Pu(CO_3)_5{\cdot}5H_2O$ salts have been reported (Ueno and Hoshi, 1970).



13



14

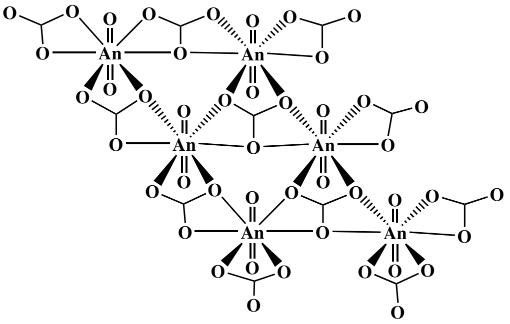


15

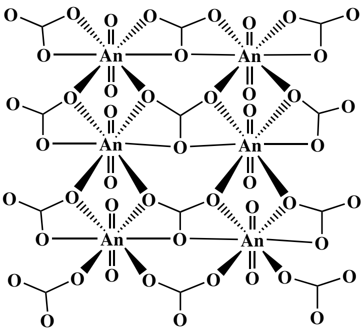
Pentavalent plutonium carbonato complexes are prepared by addition of alkali metal carbonate solutions to mildly acidic solutions of PuO_2^+, or by the one-electron reduction of Pu(VI) carbonato complexes. The mono- and triscarbonato complexes, $PuO_2(CO_3)^-$ and $PuO_2(CO_3)_3^{5-}$, have been observed directly by optical absorption spectroscopy, and their formation constants have been determined. In contrast, the biscarbonato complex $PuO_2(CO_3)_2^{3-}$ has not been observed directly, and is only inferred. Sensitive laser photoacoustic spectroscopy was used to determine the formation constant of $\log_{10}\beta_1 = (4.6 \pm 0.04)$ for $PuO_2(CO_3)^-$ (Bennett *et al.*, 1992). Using the Nernst equation, the measured reversible reduction of hexavalent $PuO_2(CO_3)_3^{4-}$ at 339 mV vs SHE in 1 M Na_2CO_3 and comparisons with Np(V) carbonato formation constants, the formation constant for $PuO_2(CO_3)_3^{5-}$ can be estimated to be $\log_{10}\beta_3 = 7.5$

(Wester and Sullivan, 1983; Capdevila *et al.*, 1992). These solution species are likely isostructural with the corresponding $NpO_2(CO_3)(OH_2)_3^-$, and $NpO_2(CO_3)_3^{5-}$ complexes which have been characterized by EXAFS spectroscopy, and illustrated in **14** and **15** (Clark *et al.*, 1996). These complexes have the general actinyl carbonate structure with axial O=An=O units at a bond distance of 1.85 Å and bidentate carbonato and water oxygen atoms arrayed about the equatorial plane to form a pentagonal or hexagonal bipyramidal coordination polyhedron at average bond distances of 2.45 and 2.42 Å, respectively. Optical absorption spectra do not suggest that the biscarbonato complex $PuO_2(CO_3)_2^{3-}$ is ever a predominant solution species, consistent with the small difference between the stability constants for the mono- and tris-species that suggest a very small stability field for this intermediate species. Mixed hydroxo carbonato complexes have been proposed for Np(v) (Sullivan *et al.*, 1991), but the identification and existence of analogous Pu(v) species is questionable.

Solids corresponding to the Pu(v) carbonate solution species have been prepared as microcrystalline powders via precipitation and the orthorhombic solid-state structure of $KPuO_2CO_3$ has been determined (Ellinger and Zachariasen, 1954). Much more data is available for analogous salts of Np(v) carbonates, $MNpO_2CO_3$, and $M_3NpO_2(CO_3)_2$, where M is an alkali metal or ammonium ion (Simakin *et al.*, 1974; Volkov *et al.*, 1974a,b, 1981). These structure types have been reviewed by Clark *et al.* (1995). These compounds show interesting structural changes due to the size similarity of hydrated ions such as K^+ and NpO_2^+, and the extent of hydration. For example, for $MNpO_2CO_3$ where M = Cs^+, Rb^+, NH_4^+, K^+, Na^+, and Li^+, a hexagonal-to-orthorhombic phase change is observed within the NpO_2CO_3 layer at the potassium–sodium boundary. The solids both contain actinyl carbonate layers and the hexagonal and orthorhombic sheets are related by displacement of the chains of actinyl units through half a translation along the crystallographic *a*-axis. These basic layers are illustrated qualitatively in **16** and **17**. The orthorhombic structure **17** is more open than the hexagonal structure **16**, which appears to allow for the closer contacts necessary for the smaller sodium and lithium cations.

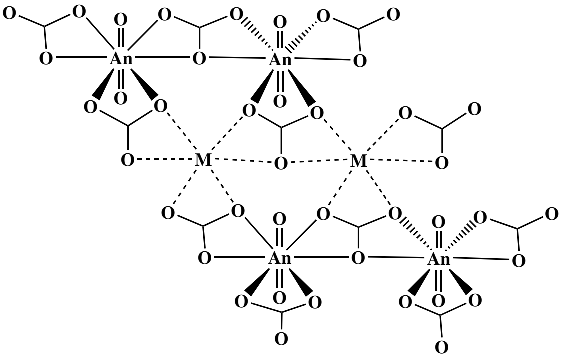


16



17

The biscarbonato solid $M_3NpO_2(CO_3)_2$ displays an overall orthorhombic structure, but exhibits a pseudo-hexagonal layer similar to **16**, except that one half of the AnO_2^+ ions in the anionic carbonate layer have been replaced by alkali metal cations. One can envision that M^+ and AnO_2^+ cations form alternating chains within the hexagonal sheet and give rise to the approximate composition $[M_{0.5}(AnO_2)_{0.5}(CO_3)]$ within the layer. This arrangement is illustrated qualitatively in **18**. The cation and anion layers are oriented such that an alkali metal cation, M^+, lies directly above and below the linear AnO_2^+ ion of adjacent sheets. The anionic carbonate layer and the cationic potassium layers line up such that they are parallel to the crystallographic *c*-axis, and this allows for an M–O=An interaction between layers and yields a maximally ordered structure (Clark *et al.*, 1995).



18

Hexavalent plutonium carbonato complexes have been studied primarily as an extension of uranyl carbonate chemistry. Uranyl carbonato complexes are very important in uranium geochemistry actinide contaminant environmental transport, uranium mining, and nuclear fuel production and reprocessing, owing to their high solubility and stability in aqueous solution. Substitution of the plutonyl ion in uranyl phases has the potential to form solid solutions.

Carbonate complexation of Pu(VI) increases with pH and carbonate concentration. Pashalidis *et al.* (1997) studied the solubility of both UO_2CO_3 and PuO_2CO_3 in aqueous carbonate solutions and determined equilibrium constants for the formation of $PuO_2(CO_3)$, $PuO_2(CO_3)_2^{2-}$, and $PuO_2(CO_3)_3^{4-}$. These results are in good agreement with earlier studies on $AnO_2(CO_3)$ solids of uranium, neptunium, and plutonium by Ullman and Schreiner (1988), and $PuO_2(CO_3)$ solids by Robouch and Vitorge (1987). The most recent NEA review recommends $\log_{10}\beta_1 = (9.5 \pm 0.5)$, $\log_{10}\beta_2 = (14.7 \pm 0.5)$, and $\log_{10}\beta_3 = (18.0 \pm 0.5)$ for the corresponding formation constants (Guillaumont *et al.*, 2003).

Both $PuO_2(CO_3)_{(aq)}$ and $PuO_2(CO_3)_3^{4-}$ have been spectroscopically observed. In contrast, while the $AnO_2(CO_3)_2^{2-}$ species has been spectroscopically observed for U(VI) and Np(VI), the stability field of the corresponding $PuO_2(CO_3)_2^{2-}$ analog appears to be so small that it has not been directly observed. Spectrophotometric and calorimetric studies of the formation of the monocarbonato complex from the Pu(VI) hydroxide illustrated that carbonate can outcompete hydroxide to coordinate to plutonium, and provided the first formation constants (Sullivan *et al.*, 1982). Subsequent solubility studies and additional spectrophotometric data provide a formation constant of $\log_{10} \beta_1 = (8.7 \pm 0.3)$ for $PuO_2(CO_3)$ in 0.1 M $NaClO_4$ (Pashalidis *et al.*, 1997). X-ray powder diffraction and XAFS studies of the corresponding $PuO_2(CO_3)$ solid show that it is isostructural with rutherfordine, $UO_2(CO_3)$ (Reilly *et al.*, 2000). This solid has a layered structure where the local coordination environment of the plutonyl ion is a hexagonal bipyramidal arrangement of oxygen atoms with the plutonyl units perpendicular to the orthorhombic plane (Clark *et al.*, 1995). Each plutonium atom forms six equatorial bonds with the oxygen atoms of four carbonate ligands, two in a bidentate manner and two in a monodentate manner. The orthorhombic plane is identical to that shown in **17**. The orthorhombic plane of hexagonal bipyramidal plutonyl units forms infinite, two-dimensional layers.

Solution EXAFS and single crystal XRD studies show the limiting $PuO_2(CO_3)_3^{4-}$ is isostructural with the uranyl analog, which has pseudo-hexagonal pyramidal coordination geometry as illustrated in **15**. The Pu=O distance was found to be 1.74 Å with an average Pu–O distance to carbonate ligands of 2.45 Å (Clark *et al.*, 1999b; Neu *et al.*, 2000; Conradson *et al.*, 2004a). The stability constant for $PuO_2(CO_3)_3^{4-}$ has been determined from solubility, calorimetry, and spectrophotometric studies to be $\log_{10} \beta_3 = (18.2 \pm 0.4)$ in 0.1 M electrolytes (Robouch and Vitorge, 1987; Ullman and Schreiner, 1988). Pashalidis *et al.* determined a value of (17.8 ± 0.2) in 0.1 M $NaClO_4$ solution, and the recent NEA assessment recalculated their value to correct for a systematic error and obtained (18.4 ± 0.2) (Guillaumont *et al.*, 2003). This species can be readily precipitated to form salts with monovalent cations.

In contrast with uranyl carbonate chemistry where the bis carbonato $UO_2(CO_3)_2^{2-}$ and its trimeric oligomer $(UO_2)_3(CO_3)_6^{6-}$ are major species (Allen *et al.*, 1995; Banyai *et al.*, 1995), the bis carbonato plutonyl complex, $PuO_2(CO_3)_2^{2-}$, has a small stability field and neither it nor the trimer $(PuO_2)_3(CO_3)_6^{6-}$ have been characterized. Similar to the hexavalent hydroxides, oligomerization reactions appear to decrease dramatically across the series from uranium to plutonium. Mixed actinyl trimers, $(UO_2)_2(PuO_2)(CO_3)_6^{6-}$ and $(UO_2)(PuO_2)_2(CO_3)_6^{6-}$ have been proposed based on optical absorption and emf studies (Grenthe *et al.*, 1986b). Similarly, additional polymeric species known for uranyl $(UO_2)_2(CO_3)(OH)_3^-$, $(UO_2)_3O(OH)_2(HCO_3)^+$, and $(UO_2)_{11}(CO_3)_6(OH)_{12}^{2-}$ under conditions of high metal ion concentration or high ionic strength (Grenthe *et al.*, 1992) have not been observed for plutonyl.

Nitrate

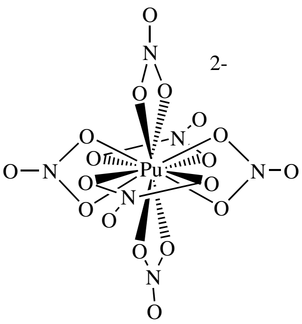
Nitrates were among the first complexes studied for plutonium and are very important in plutonium processing (Cleveland, 1979). The effectiveness of solvent extraction and ion-exchange processes in nitric acid, for example, depends strongly on the stoichiometry, stability, molecular geometry and molecular charge of nitrate complexes. Nitrate tends to bind plutonium in a bidentate fashion and to retain its planar molecular geometry, similar to carbonate. But it is a much weaker ligand. Because nitric acid solutions of plutonium and nitrate solids of Pu(IV) and Pu(VI) are both prevalent forms in process and synthetic chemistry, a tremendous number of mixed-ligand complexes are known that contain one or more mono- or bidentate nitrates in the inner coordination sphere.

Trivalent nitrate species have been prepared in nitric acid solution, but they are unstable with respect to oxidation.

Aqueous Pu(IV) nitrate complexes are very well studied because of their use in solvent extraction methods and ion-exchange chromatography. The solution species, $Pu(NO_3)_n^{4-n}$ ($n = 1$–6), have been studied in detail. There is evidence from numerous ion exchange and extraction studies and more recent NMR and EXAFS experiments that the mono-, bis-, tetra, and the hexanitrato complexes are significant, but the tris- and pentanitrato complexes are not (Veirs *et al.*, 1994). X-ray absorption data for the system suggest aquo ligation decreases in the inner sphere even before sequential bidentate nitrates bind the metal center. Solution EXAFS data gives coordination numbers of 11–12 for the first coordination sphere, with average Pu–O bond distances of 2.49 and 2.38 Å for nitrate and water ligands, respectively (Allen *et al.*, 1996b). Formation constants measured for the mononitrato complex, $Pu(NO_3)^{3+}$, were critically evaluated by the NEA reviewers, who recommend the constant $\log_{10}\beta_1 = (1.95 \pm 0.15)$ at $I = 0$ (Lemire *et al.*, 2001). A recent spectrophotometric study in 2 molal $HClO_4$ and extensive analysis by Monte Carlo methods sheds new light on the relative importance of the $Pu(NO_3)^{3+}$ and $Pu(NO_3)_2^{2+}$ complexes, and reported the constants $\log_{10}\beta_1 = (0.51 \pm 0.05)$ and $\log_{10}\beta_2 = (1.05 \pm 0.08)$ (Berg *et al.*, 2000).

Cation exchange resins have a strong affinity for the hexanitrato species, $Pu(NO_3)_6^{6-}$. This nitrate-based purification method is used to separate plutonium from most of the elements in the periodic table, and is used on an industrial scale (Section 7.5.5). There has been some discussion over whether the limiting Pu(IV) nitrate in solution is the penta- or hexanitrato species and some experiments suggest that the hexanitrate is only a major species in the presence of resins or in concentrated salt solutions that favor ion pairing (Veirs *et al.*, 1994; Clark and Delegard, 2002).

Plutonium(IV) nitrate solids are readily formed in nitric acid by dissolution of hydroxides or carbonates followed by precipitation or crystallization. Crystalline orthorhombic $Pu(NO_3)_4{\cdot}5H_2O$ can be obtained in this way and also by heating a Pu(VI) nitrate salt (Staritzky, 1956). Hexanitrato complexes, $M_2Pu(NO_3)_6{\cdot}2H_2O$, where M = Rb, Cs, NH_4, and pyridinium, are obtained from moderately concentrated (8 to 14 M) nitric acid. A single crystal XRD study was performed on $(NH_4)_2Pu(NO_3)_6$ by Spirlet *et al.* (1992). In the solid state the icosohedral $Pu(NO_3)_6^{2-}$ unit is characterized by three mutually perpendicular planes formed by the trans NO_3^- ligands giving virtual T_h symmetry as illustrated in **19**. The 12 Pu–O bond distances average 2.487(6) Å.



19

Numerous additional solution studies on Pu(IV) mixed ligand-nitrate complexes have been performed in the development and performance testing of extractants. Most notably these include TBP and phosphine oxides. As other examples, a variety of mixed amide-nitrate complexes have been proposed based upon NMR, IR, and extraction behavior (Berthon and Chachaty, 1995; Preston and du Preez, 1995; Romanovski *et al.*, 1999).

No inner-sphere Pu(V) nitrate complexes have been characterized. The existence of the solid nitrates of Np(V) and Pa(V), $NpO_2(NO_3){\cdot}xH_2O$ ($x = 1, 5$), $RbNpO_2(NO_3)_2{\cdot}H_2O$, and $PaO(NO_3)_3{\cdot}xH_2O$ ($x = 1$–4) suggests that it might be possible to isolate solid Pu(V) nitrates if the oxidation state could be stabilized in nitrate solution. Pu(VI) nitrates are weak complexes and only the mononitrate, $PuO_2(NO_3)^+$, species is significant in solution. Mixed TBP-nitrate complexes have been widely studied, including a recent EXAFS study of the structural changes as the actinyl species are reduced to An(IV) (Den Auwer *et al.*, 1999). The hydrated solid, $PuO_2(NO_3)_2{\cdot}xH_2O$, $x = 3{,}6$, has been characterized.

Sulfate

Trivalent plutonium forms at least two stepwise complexes, $PuSO_4^+$ and $Pu(SO_4)_2^-$ in acid solutions according to equations below (Fardy and Buchanan, 1976; Rao *et al.*, 1978; Nash and Cleveland, 1983).

$$\mathrm{Pu^{3+} + HSO_4^- \rightleftharpoons PuSO_4^+ + H^+} \tag{7.134}$$

$$\mathrm{Pu^{3+} + 2HSO_4^- \rightleftharpoons Pu(SO_4)_2^- + 2H^+} \tag{7.135}$$

The NEA reviewers recalculated the formation constants for these species according to the reactions above, extrapolated to zero ionic strength and recommended $\log_{10} {}^*\beta_1 = (1.93 \pm 0.61)$ and $\log_{10} {}^*\beta_2 = (1.74 \pm 0.76)$ (Lemire *et al.*, 2001). The fact that higher order anions such as $Pu(SO_4)_4^{5-}$ are found in solids such as $K_5Pu(SO_4)_4{\cdot}4H_2O$ suggests that higher order ions of formula $Pu(SO_4)_n^{3-2n}$ must form to a small extent in solution (Mudher *et al.*, 1995). There is some evidence for the formation of solid $Pu_2(SO_4)_3{\cdot}xH_2O$. The Pu(III) solid is likely isostructural with $Am_2(SO_4)_3{\cdot}8H_2O$, which is comprised of eight coordinate Am(III) (Bullock *et al.*, 1980). The ternary salts of $MPu(SO_4)_2{\cdot}H_2O$, where M is an alkali metal, are isostructural with the Nd(III) analog (Iyer and Natarajan, 1989, 1990). Similarly, the $(NH_4)Pu(SO_4)_2{\cdot}4H_2O$ is isomorphous with the corresponding Sm(III) compounds; and all of these structures contain nine coordinate metal centers containing water and bidentate sulfate ligands. Salts of other complex anions, such as $K_5Pu(SO_4)_4$, which is isostructural with $K_5La(SO_4)_4$, are also known (Mudher *et al.*, 1995).

Sulfate has high affinity for plutonium(IV). The stability of the complexes has been studied both to understand the properties of the complexes themselves and to evaluate how sulfate competes with extractants (Laxminarayanan *et al.*, 1964; Sokhina *et al.*, 1978; Solovkin and Rubisov, 1983). As for Pu(III), formation constants for Pu(IV) sulfato complexes are accurately expressed as solution reaction constants from bisulfate addition to Pu^{4+} according to reactions (7.136) and (7.137).

$$\mathrm{Pu^{4+} + HSO_4^- \rightleftharpoons PuSO_4^{2+} + H^+} \tag{7.136}$$

$$\mathrm{Pu^{4+} + 2HSO_4^- \rightleftharpoons Pu(SO_4)_{2\,(aq)} + 2H^+} \tag{7.137}$$

The data are most consistent with the formation of two complexes, $PuSO_4^{2+}$ and $Pu(SO_4)_2$, but higher order species $Pu(SO_4)_n^{4-2n}$ are implied by the existence of salts such as $K_4Pu(SO_4)_4{\cdot}2H_2O$. The NEA review recommends the constants $\log_{10} {}^*\beta_1 = (2.75 \pm 0.01)$ and $\log_{10} {}^*\beta_2 = (4.43 \pm 0.01)$ in 2.2 molal $(H, Na)_2SO_4$ solutions (Lemire *et al.*, 2001). Extrapolation to zero ionic strength gives $\log_{10}{}^*\beta_1 = (4.91 \pm 0.22)$ and $\log_{10}{}^*\beta_2 = (7.18 \pm 0.32)$ (Lemire *et al.*, 2001). Based upon the crystal structure of $Pu_2(OH)_2(SO_4)_3(H_2O)_4$, mixed hydroxo sulfato complexes are also thought to form in solution at higher pH (Wester, 1983).

The neutral hydrates can be precipitated as $Pu(SO_4)_2{\cdot}nH_2O$ ($n = 9, 8, 6, 4$), and subsequently dehydrated up to 400°C. The red tetrahydrate Pu(IV) phase is noteworthy because of its high purity (Cleveland, 1979). The common bicapped square antiprismatic geometry of four sulfates and four waters is adopted by the

Pu(IV) centers in the tetra- and octahydrates. Each sulfate group is shared by two Pu(IV) ions, and sulfates not bonded to plutonium are hydrogen bonded to water molecules (Kierkegaard, 1956; Jayadevan *et al.*, 1982). Two orthorhombic polymorphs of the tetrahydrate differ only by hydrogen bonding in the structures (Jayadevan *et al.*, 1982). The octahydrate loses four water molecules at relatively low temperature, and can be fully dehydrated. Ternary salts have also been characterized, such as the green Pu(IV) compounds $M_4Pu(SO_4)_4 \cdot xH_2O$ and $M_6Pu(SO_4)_5 \cdot xH_2O$ ($M = K, NH_4$) (Sood *et al.*, 1992). The structure of the anion in $K_4Pu(SO_4)_4 \cdot 2H_2O$ consists of chains of plutonium atoms linked by pairs of bridging sulfate groups, and the plutonium atom exhibits a tricapped trigonal prismatic coordination geometry. The structure of the Pu(IV) mixed hydroxo-sulfato complex, $Pu_2(OH)_2(SO_4)_3(H_2O)_4$, has been determined and is isomorphous with the hydroxosulfates of Zr, Hf, and Ce (Wester, 1983).

Sulfate complexes of Pu(V) have not been characterized, but they may be important environmental species since sulfate can be a major component of natural waters and minerals. Therefore research on these types of complexes is merited.

Mono- and bis-sulfato complexes of plutonyl(VI), $PuO_2(SO_4)$ and $PuO_2(SO_4)_2^{2-}$, are generally prepared from acidic solutions. Solution equilibrium constants derived in terms of formation constants for the reactions listed below have been measured (Patil and Ramakrishna, 1976; Ullman and Schreiner, 1986).

$$PuO_2^{2+} + SO_4^{2-} \rightleftharpoons PuO_2SO_4(aq) \tag{7.138}$$

$$PuO_2^{2+} + 2SO_4^{2-} \rightleftharpoons PuO_2(SO_4)_2^{2-} \tag{7.139}$$

The NEA reviewers evaluated these results and recommended the zero ionic strength formation constants of $\log_{10} \beta_1 = (3.38 \pm 0.20)$ and $\log_{10} \beta_2 = (4.4 \pm 0.2)$ (Lemire *et al.*, 2001). Changes in the electronic structure of hexavalent plutonium and neptunium as a function of sulfate, selenate, and chromate complexation have been studied by optical and IR spectroscopy and attributed to covalence variation in An=O bonding or distortions in the ligand arrangement (Budantseva *et al.*, 2000).

Plutonyl sulfate solids of formula $M_2PuO_2(SO_4)_2$ have been prepared and are likely isostructural with the neptunyl analogs. The solid state layered structure of $Cs_2NpO_2(SO_4)_2$ is built up by anionic layers $[NpO_2(SO_4)_2]_n^{2n-}$, linked together by Cs^+ ions. Each NpO_2^{2+} ion in the anionic layer is linked via the sulfate ions to three other atoms to form an hexagonal net similar to the actinyl(V) carbonate structures (Fedosseev *et al.*, 1999).

Phosphate

Because of their very low solubility as exemplified by stable minerals and ore bodies, actinide phosphates have been proposed as potential radioactive waste forms (Boatner and Sales, 1988). Phosphate has multiple protonation states, PO_4^{3-}, HPO_4^{2-} and $H_2PO_4^-$, and related condensed phosphate anions such as $P_2O_7^{4-}$ and $(PO_3)_n^{n-}$ with many coordination modes that can lead to intricate three-dimensional structures in the solid state, making the plutonium phosphate compounds particularly challenging to characterize. The limited information that is available for plutonium phosphate solution species comes from solubility studies and X-ray and optical absorption spectroscopic studies. In the solid state, the major classes of actinide phosphate are phosphates, hydrogenphosphates, dihydrogen phosphates, diphosphates (pyrophosphates), and polytrioxophosphates (metaphosphates). In addition there are numerous ternary compounds, mixed valent uranium phosphates, halophosphates, organophosphates, and more recently, open framework and templated phases.

Plutonium(III) phosphate solution species are proposed to have the formula $Pu(H_2PO_4)_n^{3-n}$ ($n = 1$–4), but they have not been spectroscopically or structurally characterized (Moskvin, 1971a). For Pu(III), the blue, hexagonal $PuPO_4 \cdot 0.5H_2O$ has been prepared by precipitation from relatively dilute HNO_3/H_3PO_4 solution, then heated to yield the anhydrous compound (Bamberger, 1985). Anhydrous plutonium pyrophosphate PuP_2O_7 has been prepared by the thermal decomposition of plutonium oxolatophosphates (Bjorklund, 1957; Bamberger, 1985).

By considering the protonation behavior of phosphoric acid (Grenthe *et al.*, 1992) the following plutonium(IV) complexes may form: $Pu(H_3PO_4)_x(H_2PO_4)_y^{(4-y)+}$ ($x = 0, 1$; $y = 0, 1, 2$) under acidic conditions; $Pu(HPO_4)_3(H_2PO_4)_x^{(2+x)-}$ ($x = 1, 2$) at neutral pH; and $Pu(HPO_4)_x^{4-2x}$ ($x = 1$–3) under basic conditions. All of the known Pu(IV) solids have such low solubilities that only experiments with $Pu(HPO_4)_2 \cdot xH_2O$ have yielded solution speciation information. The solution complex in equilibrium with the solids, $Pu(H_3PO_4)^{4+}$, has a formation constant of $\log_{10}\beta_1 = 2.3$ in 2 M $(H,Na)NO_3$ (Denotkina *et al.*, 1960), and the NEA reviewers recommended the value $\log_{10}\beta_1 = (2.4 \pm 0.3)$ at zero ionic strength (Lemire *et al.*, 2001).

The chemistry of tetravalent actinide phosphates has been recently reviewed and a new classification system proposed for these compounds (Brandel and Dacheux, 2004a,b). New characterization data indicates that a number of previously reported actinide phosphate phases appear to be polyphase mixtures, particularly the "$M_3(PO_4)_4$" group of compounds. Solid Pu(IV) phosphates can be considered a subset of known Th(IV) and U(IV) compounds. Plutonium(IV) polytrioxophosphate, $Pu(PO_3)_4$, can be crystallized by dissolving PuO_2 in polyphosphoric acid (Douglass, 1962). The hydrogenphosphate, $Pu(HPO_4)_2 \bullet xH_2O$, is reported to precipitate as a gelatinous solid upon addition of phosphoric acid to nitric acid solutions of Pu(IV) and can be used as precursor for other phosphate phases. Anhydrous plutonium diphosphate PuP_2O_7, has been prepared by the thermal decomposition of plutonium oxolatophosphates or by heating a mixture of PuO_2 and BPO_4 (Bjorklund, 1957; Bamberger, 1985). Additonal Pu(IV) phosphates and diphosphates are likely based on the growing list of thorium and uranium phosphate phases reported. For example, Bénard *et al.* reported two distinct thorium types in $Th_4(PO_4)_4(P_2O_7)$, one eight-coordinate with oxygen from five phosphate and one diphosphate group and around the thorium atom (Bénard, Brandel *et al.*, 1996). Thorium(IV) can be replaced by Pu(IV) up to a maximum value of x = 1.67 for $Th_{4-x}M_x(PO_4)_4(P_2O_7)$ (Dacheux, Brandel *et al.*, 1998). Ternary compounds of the general formula $M(I)Th_2(PO_4)_3$ and $M(II)Th(PO_4)_2$ with M(I) = alkali cation, Tl, Ag, Cu, (Louer, Brochu *et al.*, 1995; Bénard, Brandel *et al.*, 1996) and M(II) = Ca, Sr, Cd, Pb, (Merigou, Genet *et al.*, 1995) are also known for U(IV).

Plutonium(V) phosphate, $NH_4PuO_2HPO_4{\cdot}4H_2O$, was precipitated from solutions of PuO_2^+ in nitric acid with the addition of $(NH_4)_2HPO_4$ (Gel'man and Zaitseva, 1964). There is evidence for $PuO_2HPO_4^-$ from adsorption studies of PuO_2^+ on iron oxides in phosphoric acid, but it has not been fully characterized (Moskvin and Poznyakov, 1979; Morgenstern and Kim, 1996). Its formation constant has been reported to be $\log_{10}\beta_1 = (2.39 \pm 0.04)$ in 1 M NH_4Cl (Moskvin and Poznyakov, 1979). It is likely that additional complexes are formed, but their stoichiometries are not certain.

Denotkina *et al.* reported the first studies of Pu(VI) phosphates (Denotkina, Shevchenko *et al.*, 1965; Denotkina and Shevchenko, 1967). This work was later revised and augmented by Fischer *et al.* who prepared a series of compounds of Pu(VI) with phosphates and arsenates with the general formulas, $MPuO_2XO_4{\bullet}yH_2O$ and $M'(PuO_2XO_4)_2{\bullet}zH_2O$ (X = P, As; M = H^+, K^+, Rb^+, NH_4^+; M′ = Ca^{2+}, Sr^{2+}), and compared the characterization data with analogous uranium and neptunium compounds (Fischer, Werner *et al.*, 1981). The hydrogenphosphate compounds, $PuO_2(HXO_4){\bullet}yH_2O$ (X = P, As), were prepared by reacting Pu(VI) hydroxide with aqueous solutions of H_3PO_4 and H_3AsO_4. The compounds $MPuO_2(PO_4){\bullet}yH_2O$ (M = K^+, NH_4^+) precipitated from aqueous solutions of Pu(VI) in dilute nitric acid upon addition of K_2PO_4 and $(NH_4)_2PO_4$. The acidic proton in the solid arsenate hydrogenarsenate complex was partially exchanged by mixing the solid with a solution of the Group 1 or 2 metal chloride. Weger *et al.* reported preliminary data on the solubility and speciation of Pu(VI) in phosphate solutions and observed evidence for colloid formation from filtration data and for three complexes between pH 2.7 to 12 in the visible–near infrared absorption spectra (Weger, Okajima *et al.*, 1993). Further work is needed to determine if the absorption features are due to soluble or colloidal species.

Iodate

The precipitate of Pu(IV) iodate, $Pu(IO_3)_4$, was one of the first forms of ^{239}Pu isolated and is a common end product in low pH actinide/lanthanide separations (Cleveland, 1979). This useful solid has not been characterized, but likely has the same stoichiometry as the thorium perchlorate analog that forms upon reaction of thorium hydroxide with perchloric acid, $Th(ClO_4)_4{\cdot}4H_2O$. Attempts to prepare Pu(IV) iodates by hydrothermal methods have produced Pu(VI) phases (described below).

Similarly, most conditions that would be used to attempt to prepare Pu(V) iodates have yielded Pu(VI) or Pu(IV) solids. The solid-state structure of $NpO_2(IO_3)$ was recently determined by single crystal XRD (Albrecht-Schmitt *et al.*, 2003). Its structure consists of neptunyl(V) cations linked to one another by $O_2Np{-}O{=}Np{=}O$ bonds and bridging iodate anions, creating a pentagonal bipyramidal NpO_7 unit.

The binary plutonyl(VI) iodate, $PuO_2(IO_3)_2{\cdot}H_2O$, has been prepared under hydrothermal conditions and has a layered structure with PuO_7 pentagonal bipyramids linked by iodate anions. By contrast, $UO_2(IO_3)_2$ is one-dimensional, and contains chains of edge-sharing UO_8 hexagonal pyramids. A second actinyl (VI) compound with water in the inner coordination sphere, $AnO_2(IO_3)_2(H_2O)$, has been characterized for uranyl and neptunyl, but not for the slightly smaller plutonyl ion (Bean *et al.*, 2001; Runde *et al.*, 2003b). The addition of cations to the starting solution for these hydrothermal preparations produces ternary phases where the cations are located between chains and layers in the three-dimensional structure (Shvareva *et al.*, 2005). A dimeric plutonyl hydoxo iodate $(PuO_2)_2(IO_3)(\mu\text{-}OH)_3$ was isolated from a hydrothermal reaction of Pu(IV) in a mixed hydroxide, H_5IO_6 solution. In this structure hydroxide bridges are the primary structural element and seven-coordinate plutonium atoms are bridged by iodate and hydroxide (Bean *et al.*, 2005).

Perchlorate

Because perchlorates and perchloric acid solutions (similar to nitrates) are very common starting materials in actinide chemistry there are numerous examples of perchlorate containing plutonium compounds. However, pure binary plutonium perchlorates have not been characterized in the solution or solid state. Perchlorate is such a weak ligand that it most likely does not form inner-sphere complexes in aqueous solution, but acts as a simple counter ion. For comparison, crystals of uranyl perchlorate, $UO_2(ClO_4)_2{\cdot}nH_2O$ have been obtained with 6 and 7 hydration water molecules. The uranyl is coordinated with 5 water molecules in the equatorial plane with a distance of U–O(aquo) of 2.45 Å. The complex is best formulated as $[UO_2(H_2O)_5][ClO_4]_2{\cdot}nH_2O$ (Alcock and Esperas, 1977).

Oxalate

Oxalates have been widely used in plutonium separations and processing (Cleveland, 1979; Wick, 1980). The rapid formation of microcrystalline phases that are easily filtered from solution is the basis for the large-scale recovery of plutonium from concentrated solutions. In addition, the low solubility of the oxalates makes them useful in 'polishing' or 'finishing' steps where minor amounts of material are recovered. Plutonium oxalates may also be important in environmental chemistry since oxalate is a major byproduct of plant metabolism and can be concentrated in some soils. The stoichiometry for the oxalate complexes has been determined from a combination of thermogravimetric analyses and XRD on solid compounds. The oxalate ligand $\left(C_2O_4^{2-}\right)$ generally binds actinide ions in a mono- or bidentate fashion, and can also bridge metal centers to produce a variety of chains, layers, and intricate three-dimensional structures with high coordination numbers. Solution species are only poorly studied, as expected given their low solubilities.

The solid trivalent plutonium oxalate system is dominated by two hydrates of formula $Pu_2(C_2O_4)_3{\cdot}10H_2O$ and $Pu_2(C_2O_4)_3{\cdot}6H_2O$ that are readily precipitated from solution in the presence of reducing agents, such as hydroxylamine. The blue, monoclinic decahydrate $Pu_2(C_2O_4)_3{\cdot}10H_2O$ forms in concentrated solutions and can be dehydrated or fired to produce highly pure finely divided PuO_2 (Rao *et al.*, 1963). This stoichiometric oxalate is isostructural with lanthanide (III) oxalate decahydrate, which includes nine-coordinate metal centers (Jenkins *et al.*, 1965). A single crystal XRD structure of a nonahydrate $Pu_2(C_2O_4)_3{\cdot}9H_2O$ has been recently reported (Runde *et al.*, 2005a). This two-dimensional solid consists of tricapped trigonal prismatic PuO_9 units that are linked by $C_2O_4^{2-}$ groups and a network of interstitial water molecules. The plutonium atom is coordinated to six oxygen atoms from three bidentate oxalate ligands and three oxygen atoms from coordinated water. The Pu–O distances range from 2.47 to 2.56 Å (Runde *et al.*, 2003a). Complex plutonium(III) oxalates of general formula $MPu(C_2O_4)_2{\cdot}xH_2O$ ($M = Na, K, Cs, NH_4$) have also been prepared (Runde *et al.*, 2005a).

Solution oxalate complexes are mainly of the form, $Pu(C_2O_4)_n^{3-2n}$, $n = 2$–4. The bis-oxalate species is the most important, while the latter complexes have very narrow ranges of stability (Cleveland, 1979; Hasilkar *et al.*, 1994). Numerous mixed-ligand Pu(III) oxalate complexes have been postulated to form but have not been studied in detail.

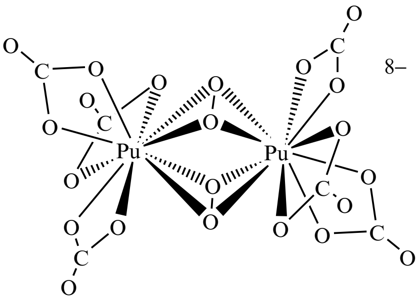
Tetravalent plutonium oxalates have been prepared with 2, 4, and 5 oxalate ligands bound to plutonium. The binary oxalate hydrates, $Pu(C_2O_4)_2{\cdot}xH_2O$ ($x = 0$, 1, 2, or 6), can be prepared from Pu(III) solutions in the presence of peroxide or other mild oxidizing agents, or precipitated directly from Pu(IV) solutions. Detailed structural analyses of these solids have not been reported. They are likely isostructural with the related binary Th(IV) and U(IV) oxalates, which generally have a coordination number of eight, comprised of bidentate and bridging oxalate and water molecules in the inner sphere arranged in irregular cubic and square antiprismatic coordination geometries. Complex salts of the tetra- and pentaoxalates, including $Na_4[Pu(C_2O_4)_4]{\cdot}5H_2O$, $(NH_4)_6[Pu(C_2O_4)_5]{\cdot}5H_2O$, and $K_6[Pu(C_2O_4)_5]{\cdot}5H_2O$ have been prepared. Uranium and thorium analogs of the tetraoxalate contain a ten-coordinate actinide (IV) atom in an irregular bicapped square antiprism linked to other metal centers by oxalato or aquo bridges (Favas *et al.*, 1983; Harrowfield *et al.*, 1983). Hydrothermal synthesis produced single crystals of $KPu(C_2O_4)_2(OH){\cdot}2H_2O$ (Runde, 2005a). The single-crystal structure of $KPu(C_2O_4)_2(OH){\cdot}2H_2O$ shows a three-dimensional framework built up from oxalate-linked PuO_9 polyhedra. Each PuO_9 polyhedron consists of eight oxygen atoms from four chelating oxalate ligands and one hydroxide ligand. This finding is suggestive that $Pu(C_2O_4)_4(OH)^{5-}$ may be the limiting Pu(IV) solution complex under high oxalate concentrations (Runde, 2005a).

Plutonium(V) in the presence of oxalate disproportionates to a mixture of oxidation states under most conditions (Nikitenko, 1988). Plutonium(V) oxalates (such as $NH_4PuO_2(C_2O_4) \cdot xH_2O$) can be isolated by rapid precipitation from neutral pH solutions and have been identified by optical absorption spectroscopy and chemical analyses (Zaitseva *et al.*, 1973). Plutonium(VI) oxalates that are isostructural with uranyl oxalates have been prepared (Jenkins *et al.*, 1965; Bessonov *et al.*, 1996). The simple binary, $PuO_2(C_2O_4) \cdot 3H_2O$, is the most studied and was recently employed in an EPR study to show the evidence for the participation of 5f electrons in plutonium chemical bonding (Bhide *et al.*, 2000).

Peroxide

Hydrogen peroxide is commonly used to reduce Pu(V) or Pu(VI) to Pu(IV) and to precipitate Pu(IV) from acidic solution, often in the presence of other anions (Balakrishnan and Ghosh Mazumdar, 1964; Hagan and Miner, 1980). Efficient separation and purification processes have been developed from this chemistry (see Section 7.5.3(b)) even though the exact nature of species in solution is not definitively known (Cleveland, 1979; Wick, 1980). Plutonium(IV) can also be reduced by hydrogen peroxide to form Pu(III) or Pu(III)/Pu(IV) mixtures, depending upon the acidity, presence of sulfate, and total plutonium concentration (Balakrishnan and Ghosh Mazumdar, 1964; Koltunov, 1982a).

Connick and McVey (1949) spectroscopically identified two Pu(IV) peroxide complexes in acidic solution. Small amounts of peroxide produced a brown complex with absorption bands at 495 ($\epsilon = 266$ L mol^{-1}cm^{-1}) and 540 nm, with a suggested peroxo-bridged formula of $[Pu(O_2)(OH)Pu]^{5+}$ and corresponding formation constant of 8.8×10^6 in 0.5 M HCl. As more peroxide is added, the brown complex converts to a red complex with an absorption maximum at 513 nm. The equilibrium between these two solution complexes (equilibrium constant of 145 in 0.5 M HCl) suggests intermediates of general composition $[Pu(\mu\text{-}O_2)_2Pu]^{4+}$. While there is no structural information to confirm the proposed solution complex stoichiometries, Runde (2005b) has recently isolated single crystals containing the $Pu_2(\mu\text{-}O_2)_2(CO_3)_6^{8-}$ ion, that confirms the presence of a doubly bridged $Pu_2(\mu\text{-}O_2)_2$ core as illustrated in **20**. When the peroxide concentration is increased, two green precipitates form with different oxygen to plutonium ratios that also incorporate other anions present in the solution, e.g. sulfate, nitrate, and chloride (Leary *et al.*, 1959). The hexagonal form ($a = 4.00$ Å) precipitates preferentially at high acidity and high ionic strength and has an oxygen to plutonium ratio of 3.0–3.4 depending on whether the solid is dry or wet, respectively. At less than 2 M acidity a fcc form ($a = 16.5$ Å) of higher purity and with an oxygen to plutonium ratio of 3.0 is obtained (Hagan and Miner, 1980) regardless of whether the solid is wet or dry.



20

Less is known about the complexation of plutonyl ions by peroxide in alkaline media. Nash *et al.* (1980) reported that Pu(VI) in a 3 mM H_2O_2/0.05 M $NaHCO_3$ solution is reduced to Pu(V) via an intermediate reddish-brown colored complex, which was assumed to be a 1:1 Pu(VI) peroxo complex. The rate of formation of this complex was determined to be $(6.9 \pm 0.8) \times 10^3\ M^{-1}\ s^{-1}$ in 0.05 M $NaHCO_3$ (Nash *et al.*, 1980).

(*ii*) *Carboxylate and polyaminocarboxylate complexes*

Plutonium complexes with carboxylates and polyaminocarboxylic acids are important in separations, decontamination, and environmental migration. They have also been studied to achieve a better understanding of fundamental aqueous actinide chemistry. Owing to their multiple anionic chelating oxygen donor atoms, these ligands form highly stable and soluble complexes with plutonium ions. Solution complex formation constants for the plutonium species follow the usual trend where Pu(IV) complexes are the most stable and Pu(V) complexes the least stable. These ligands and other multidentate chelating organic acids stabilize Pu(IV) complexes to such a great extent, that under most conditions plutonium ions of the other oxidation states are rapidly oxidized/reduced to the tetravalent state.

Many studies have been reported for plutonium complexes with citrate, tartrate, malonate, glycine, and other carboxylates and amino acids, most recently by researchers at the Russian Academy of Sciences. Among these the acetate complexes are arguably the most comprehensively studied. The solution chemistry of plutonium complexes of other similar ligands can be inferred by considering the acetate complexes and the comparative basicity of the ligands; hence, only the acetate complexes will be discussed in this section. Among plutonium complexes of the amino polyacetates, iminodiacetate (IDA), nitrilotriacetate (NTA), ethylenediaminetetraacetate (EDTA), diethylenetriamine pentaacetate (DTPA), and derivatives, the EDTA complexes have been studied most extensively and used most broadly in applications. The pentaacetate analog, DTPA, has special application for treatment of internal human plutonium contamination through chelation therapy. The stoichiometry and stability of plutonium polyacetate solution complexes are generally known from spectrophotometric and potentiometric titration experiments. Solution and solid-state structures have been proposed by inference. The chemistry of the lower valent ions, Pu^{3+} and Pu^{4+} is comparative and will be described first, followed by that of the higher oxidation state ions, PuO_2^+ and PuO_2^{2+}. Formation constants for selected carboxylate and aminocarboxylate ligands are given in Table 7.57.

Pu(III) and (IV). Acetate complexes of Pu(III) have been studied primarily for stabilization with respect to oxidation to Pu(IV). Each of the stepwise complexation species from the mono- to pentaacetate has been reported. The formation constants for the first two species are $\log_{10}\beta_1 = 2.02$ and $\log_{10}\beta_2 = 3.34$ in 0.3 M $NaClO_4$ (Moskvin, 1969; Nair and Joshi, 1981). These constants have been reported from independent studies and compare well with values reported for acetate complexes of trivalent lanthanides. The limiting pentaacetate complex has an estimated formation constant of $\log_{10}\beta_5 = 16.7$ (Cleveland, 1979), which is high relative to the formation constants for the mono- and bis complexes and may therefore be considered an upper limit. Similarly, stepwise constants for Pu(IV) have been reported. Values for the first and limiting (penta) species are known with the greatest certainty, $\log_{10}\beta_1 = 5.31$ and $\log_{10}\beta_5 = 22.6$ (Cleveland, 1979). Solid-state structures of the lower valent plutonium acetate complexes are not known.

Plutonium(III) complexes of NTA^{3-} and $EDTA^{4-}$ have been studied directly by optical spectroscopy, voltammetry, and cation exchange, as well as indirectly in the study of Pu(IV) EDTA complexes at very low pH. Multiple species have been identified from pH and ligand titration experiments. In solutions with pH > 5, Pu(III) complexes are rapidly oxidized to Pu(IV). Studies at low pH have yielded the formation constant for the Pu(NTA) complex of $\log_{10}\beta_1 = 10.26$ (Merciny *et al.*, 1978; Anderegg, 1982). The protonated species Pu(EDTA)H forms in strong acid solutions and is deprotonated to $Pu(EDTA)^-$ above pH 3, and then to the mixed EDTA hydroxo complex, $Pu(EDTA)(OH)^{2-}$. Solution formation constants for the first complex and protonated forms have been reported from multiple independent studies (Cauchetier and Guichard, 1973; Merciny *et al.*, 1978). A value for the stability constant of the binary, deprotonated species, $Pu(EDTA)^-$, $\log_{10}\beta_1 = 16.1$ is reported in a critical review of EDTA thermodynamic data (Anderegg, 1977). $DTPA^{5-}$, with an additional bidentate acetate group, forms a more stable 1:1 complex with Pu^{3+}, $\log_{10}\beta_1 = 21.5$ (Merciny *et al.*, 1978).

Tetravalent plutonium–EDTA complexes are important because EDTA stabilizes Pu^{4+} over all other oxidation states sufficient for use in chemical processing, and because the complexes may promote the transport of plutonium contamination in the environment. Studies of Pu–EDTA complexation are challenging because of the extreme hydrolysis of Pu^{4+} and low solubility of

plutonium hydroxides, inherent limits of analytical and spectrophotometric techniques, large number of potential species, precipitation of EDTA in strong acid solution, and uncertainties in experimental proton concentrations. Despite these limitations, solubility, potentiometric, spectrophotometric, and electrochemical studies provide species formulations that are consistent between techniques (Cauchetier and Guichard, 1973; Rai *et al.*, 2001; Boukhalfa *et al.*, 2004).

In acidic solution ($pH < 4$) and at 1:1 ligand to metal ratio, Pu(EDTA) is the predominant species, with an overall formation constant of $\log_{10} \beta_1 = 26.44$ in 1 M (Na,H)ClO_4. The absorption maximum of the binary complex is at 496 nm. At higher pH the hydrolysis species $Pu(EDTA)(OH)^-$ and $Pu(EDTA)(OH)_2^{2-}$ form with the corresponding overall stability constants of $\log_{10} \beta = 21.95$ and 15.29, respectively. The reduction potential of the complex Pu(EDTA) at $pH = 2.3$ is reported to be $E_{1/2} = 342$ mV (vs SHE). It was recently determined that under conditions of neutral pH and excess EDTA relative to Pu^{4+}, a second ligand coordinates to the ion. The formation of such species, as well as mixed-ligand EDTA complexes, can be anticipated knowing that the Pu^{4+} ions may accommodate up to 12 ligand donor atoms in their inner coordination sphere as in the hexanitrato structure, **19**. The bis chelate complex, $Pu(EDTA)_2^{4-}$, forms with an overall formation constant of $\log_{10} \beta = 35.39$ (Boukhalfa *et al.*, 2004). In the presence of ancillary ligands, mixed-ligand complexes form, as exemplified by the citrate and carbonate complexes $Pu(EDTA)(citrate)^{3-}$ and $Pu(EDTA)(CO_3)^{2-}$ (Boukhalfa *et al.*, 2004).

Dissolution of Pu(IV) hydrous oxides, PuO_2, $PuO_2 \cdot xH_2O$, and '$Pu(OH)_4$' in the presence of EDTA has been studied both to understand how EDTA may promote plutonium solubility in waste and the environment and as a method to determine the thermodynamic stability of the resulting Pu–EDTA solution complexes. Dissolution rates of 0.0074 and 0.42 μmol g^{-1} day^{-1} Pu in the presence of 10 mM EDTA were measured for the oxide and hydroxide, respectively, in a study that measured the solubility over months (Ruggiero *et al.*, 2002). A faster dissolution rate for the oxide has been reported in a study of shorter duration (Rai *et al.*, 2001).

DTPA solution complexes have been studied in pure solutions using the same methods as those employed for the EDTA and NTA complexes. The formation constants are less accurately known because they have been studied by fewer researchers, but mostly because they form in highly acidic solutions where there is uncertainty in the proton concentration and the protonation state of DTPA. The constant, $\log_{10} \beta_1 = 29.5$, can be considered a best estimate (Moskvin, 1971b). Given the high stability constant and positive results from plutonium complexation in aqueous solution, DTPA has been studied as a plutonium decontamination agent (Stradling *et al.*, 1989). It is highly effective in chelating plutonium in complex media that mimic physiological environments, and is the standard against which other potential therapeutic agents are measured. The efficacy of plutonium solubilization and complexation by DTPA has been studied in blood, urine, and cells (Rosenthal *et al.*, 1975). Most mammalian studies are done with Zn and Ca salts ($CaNa_3DTPA$ or $ZnNa_3DTPA$) since early chelation therapy studies indicated that these essential metals were scavenged and depleted in the body. For a more detailed account of *in vivo* actinide chelation, the reader is referred to chapter 31 of this work.

Pu(v) and (vi). Plutonium(vi) acetate complexes have been well studied in solution, and characterized in detail in the solid state. Plutonium(v) acetate complexes are not stable with respect to oxidation or reduction, depending on the solution conditions. Spectrophotometric and potentiometric studies have yielded the following average formation constants for plutonium(vi) acetates $\log_{10}\beta_1 = 2.2$, $\log_{10}\beta_2 = 3.6$, and $\log_{10}\beta_3 = 5.0$, in 1.0 M $(Na,H)ClO_4$ (Magon *et al.*, 1968; Moskvin, 1969; Eberle and Wade, 1970; Cleveland, 1979). In the presence of alkali ions, triacetate complexes of the form $MAnO_2(CH_3COO)_3$ precipitate from solutions containing Pu(vi). The cubic pink sodium plutonyl acetate and the analogous cesium salt are the most studied (Jones, 1955).

Plutonium(v) and plutonium(vi) aminocarboxylate complexes have been identified in electrochemical and pH titration studies (Cauchetier and Guichard, 1975). A stability constant for the complex of Pu(v) with NTA^{3-} was reported to be $\log_{10}\beta_1 = 6.8$ in 0.1 M $(Na,H)ClO_4$ (AlMahamid *et al.*, 1996) consistent with a number of previous studies (Eberle and Wade, 1970). The related iminodiacetate (IDA^{2-}) complex has a reported formation constant $\log_{10}\beta_1 = 6.2$ (Eberle and Wade, 1970), which as expected is somewhat lower than the constant for the Pu(v) complex with NTA^{3-}. A stability constant for a Pu(v) complex with $EDTA^{4-}$ has been estimated to be $\log_{10}\beta_1 = 12.3$ from spectrophotometric titrations (Cauchetier and Guichard, 1975). The reduction to Pu(iv) proceeds at a rate that depends on pH, plutonium concentration, and the ligand to metal ratio. At neutral pH and submicromolar plutonium

[a] Data from Lemire *et al.* (2001).

concentrations, the higher oxidation states can persist in the presence of excess NTA and EDTA for weeks (AlMahamid *et al.*, 1996). For Pu(VI), stability constants have been reported for the complexes with IDA^{2-} and $EDTA^{4-}$, $\log_{10}\beta_1 = 8.5$ (Cassol *et al.*, 1973), $\log_{10}\beta_1 = 14.6$ (Cauchetier and Guichard, 1975), respectively. Comparable constants reported for uranyl aminocarboxylates and for other ligand complexes of Pu(VI), suggest that these constants, while not yet confirmed by multiple independent studies, accurately describe the stability of the solution species.

(*iii*) *Halides*

Halide complexes were among the first complexes studied for plutonium and the fluorides and chlorides are of particular importance in plutonium purification and metal production as discussed in Sections 7.5 and 7.7.1. The formation constants for aqueous halide complexes of plutonium(III, IV, and VI) that have been critically evaluated by the NEA reviewers are listed in Table 7.58 (Lemire *et al.*, 2001; Guillaumont *et al.*, 2003). Only the addition of one or two halide ligands to any plutonium aqueous species is considered reliably established by these reviewers.

Many double salts of plutonium(III–VI) fluorides and chlorides have been reported (see Tables 7.46 and 7.47) and these salts have been prepared by aqueous or high temperature methods or combinations of these methods as described in Section 7.8.6(d). Where XRD data are available, the plutonium salts are usually observed to be isostructural with analogous compounds for thorium, uranium, neptunium, or the early lanthanides. For example, K_2PuCl_5 is isostructural with K_2PrCl_5 (Axler *et al.*, 1992) and $[K(18\text{-Crown-}6)]_2PuO_2Cl_4$ is isostructural with $[K(18\text{-Crown-}6)]_2UO_2Cl_4$ (Danis *et al.*, 2001; Clark, in preparation).

(*iv*) *Cation–cation complexes*

Owing to the linear structure and primary ionic bonding in the equatorial plane of actinyl ions AnO_2^{2+} and AnO_2^{+} (see Section 7.9.3), the oxygen atoms within these ions have a negative charge and can form bonds with a second metal center to produce 'cation–cation' complexes. This type of interaction was first characterized for UO_2^{2+} and NpO_2^{+} (Sullivan *et al.*, 1961), and is most well known for NpO_2^{+} (Stout *et al.*, 1993). For example, the structure of $NpO_2(ClO_4)\cdot 4H_2O$ consists of layers of NpO_2^{+} cations where axial O=Np=O units link to the equatorial plane of adjacent NpO_2^{+} units (Grigor'ev *et al.*, 1995). Interactions of this type have also been observed for the plutonyl ions. Newton and Burkhart (1971) oxidized Pu(IV) with Cr(VI) in dilute $HClO_4$ solution to form a $CrOPuO^{4+}$ cation, and recovered the complex by ion exchange. Photoacoustic spectroscopy was used to estimate an equilibrium constant of $K = (2.2 \pm 1.5)$ L mol^{-1} for the interaction between UO_2^{2+} and PuO_2^+ in a 6.0 M perchlorate solution (Stoyer *et al.*, 2000).

7.9.2 Nonaqueous and organometallic chemistry

There is an extensive literature on the nonaqueous and organometallic coordination chemistry of the light actinide elements thorium and uranium. A good deal of this chemistry should, in principle, be accessible to plutonium. Extending this chemistry to plutonium and other transuranium elements would be of great value in elucidating trends in structure and bonding across the actinide series. Unfortunately, the corresponding plutonium chemistry is virtually unexplored, clearly due to the extreme difficulty associated with handling plutonium isotopes, the paucity of synthetic laboratories equipped to conduct this kind of chemical research, and the scarcity of suitable starting materials. The known chemistry has been summarized in several excellent reviews by Ephritikhine (1992), Burns and Sattelberger (2002), Burns *et al.* (2005), and Burns and Eisen in Chapter 25 of this work.

(a) Sigma-bonded ligands

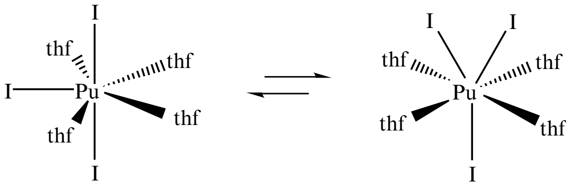
(*i*) *Organic-solvent soluble halides*

As discussed in Section 7.8.6(b), the binary trihalides, PuX_3 (X = F, Cl, Br, I) are polymeric solids that are insoluble in polar organic solvents. Therefore, the PuX_3 compounds have not been particularly useful starting materials for the nonaqueous preparation of other inorganic or organometallic complexes. Over the last two decades, there has been considerable effort to develop organic-solvent soluble forms of plutonium trihalides. Karraker (1987) reported the reaction between alpha plutonium metal and 1,2-diiodoethane in tetrahydrofuran (THF) solvent to give the solvated triiodide complex $PuI_3(THF)_x$, and suggested that such complexes would be useful synthetic starting materials for preparation of nonaqueous inorganic and organometallic compounds. Zwick, Avens and coworkers subsequently reported that stoichiometric amounts of elemental iodine would oxidize plutonium metal in aprotic, coordinating solvents such as THF, pyridine (Py), or dimethylsulfoxide (DMSO) to give hydrocarbon soluble Lewis base adducts of formula PuI_3L_4 in extremely high yields (Zwick *et al.*, 1992; Avens *et al.*, 1994). Unlike the corresponding reaction between uranium metal and iodine, there is no need to rigorously remove any oxide coating from the surface of plutonium metal. The reaction is exothermic, however, and will cause the solvent to boil if the rate of iodine addition is too rapid.

$$2Pu + 3ICH_2CH_2I \xrightarrow[THF]{} 2PuI_3(THF)_x + 3C_2H_4 \qquad (7.140)$$

$$2\text{Pu} + 3\text{I}_2 \underset{\text{L}}{\longrightarrow} 2\text{PuI}_3\text{L}_4, \quad (\text{L} = \text{THF, Py, DMSO}) \qquad (7.141)$$

Infrared spectra of PuI_3L_4 compounds are virtually identical to their UI_3L_4 counterparts, and show vibrational bands characteristic of coordinated ligands. Thermogravimetric analysis demonstrated that upon heating PuI_3L_4, all four coordinated solvent molecules are displaced between 56 and 180°C to give anhydrous PuI_3. Room temperature ^1H NMR spectra of $PuI_3(THF)_4$ in $CDCl_3$ solution shows a single THF ligand environment, consistent with the spectra of the $NpI_3(THF)_4$ and $UI_3(THF)_4$ analogs (Avens *et al.*, 1994). Unlike the uranium and neptunium analog spectra, $PuI_3(THF)_4$ shows reasonably sharp ^1H NMR resonances ($\Delta v_{1/2} = 11.4$ Hz). Subsequent variable temperature ^1H NMR experiments in CD_2Cl_2 solution revealed a dynamic solution process that generates equivalent THF ligand resonances at room temperature, but freezes out a static structure at –90°C with two types of coordinated THF ligand consistent with the solid-state structure of $UI_3(THF)_4$ (**21**). The NMR data were interpreted in terms of the dynamic equilibrium between **21** and **22** shown below. Therefore, while no crystallographic data have been presented for $PuI_3(THF)_4$, the detailed characterization of the series of $AnI_3(THF)_4$ complexes (An = U, Np, Pu) leaves little doubt that in the solid state, the molecule displays the pentagonal bipyramidal coordination geometry, with two trans iodide ligands occupying apical coordination sites, and the third iodide and four THF ligands lying in the equatorial plane as shown in **21** below.

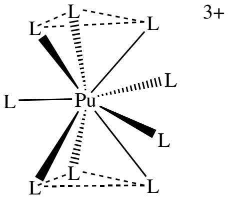


21 **22**

In a variation of the oxidative dissolution of plutonium metal, Enriquez *et al.* (2003) found that plutonium metal will also dissolve in acetonitrile solvent in the presence of three equivalents of thallium or silver hexafluorophosphate as the oxidant to give a blue solution containing $Pu(NCMe)_9^{3+}$. Filtration and cooling gives crystals of $[Pu(NCMe)_9][PF_6]_3 \cdot MeCN$.

$$\text{Pu} \xrightarrow[\text{MeCN}]{3\text{MPF}_6} [\text{Pu(NCMe)}_9][\text{PF}_6]_3 \cdot \text{MeCN}, \quad (\text{M} = \text{Ag, Tl}) \qquad (7.142)$$

The solid-state crystal structure reveals a $Pu(NCMe)_9^{3+}$ cation surrounded by three noncoordinating PF_6^- anions. The $Pu(NCMe)_9^{3+}$ ion displays a nine-coordinate tricapped trigonal prismatic coordination environment as shown in **23**. There is little variation in the Pu–N bond distances between apical and capping ligands, which span the narrow range between 2.554(4) and 2.579(5) Å.



23

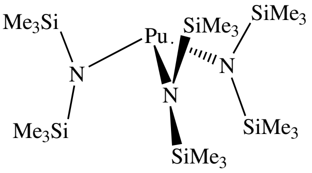
While binary $PuCl_4$ is unstable in the solid state (see Section 7.8.6(b)), it can be stabilized by formation of Lewis base adducts. Bagnall and coworkers showed that the reaction of Cs_2PuCl_6 with amide ($RCONR'_2$) or phosphine oxide (R_3PO) ligands in dichloromethane or acetonitrile solvent gives the Lewis base adducts $PuCl_4L_2$ or $PuCl_4L_3$, depending on the steric demands of the Lewis base (Bagnall *et al.*, 1961, 1985a). These adducts were characterized by IR, diffuse reflectance, and X-ray powder diffraction. In many cases, the solids were reported to be isostructural with thorium or uranium counterparts. The $PuCl_4L_2$ complexes were presumed to contain a pseudo-octahedral plutonium center, with trans Lewis base ligands. These Lewis base adducts have the potential to serve as good synthetic starting materials, though their general utility has yet to be explored.

(*ii*) *Amides*

The Lewis base adducts of plutonium triiodide have proven to be useful starting materials for the preparation of a number of trivalent organometallic and nonaqueous coordination compounds. A THF slurry of $PuI_3(THF)_4$ reacts smoothly at room temperature with three equivalents of $NaN(SiMe_3)_2$ to give an air-sensitive yellow-orange $Pu[N(SiMe_3)_2]_3$ in 93–95% yield (Zwick *et al.*, 1992; Avens *et al.*, 1994).

$$PuI_3(THF)_4 + 3NaN(SiMe_3)_2 \xrightarrow{THF} Pu[N(SiMe_3)_2]_3 + 3NaI \qquad (7.143)$$

The tris silylamide complex sublimes at 60°C under reduced pressure, gives an elemental analysis consistent with the formulation of $Pu[N(SiMe_3)_2]_3$, and shows a single ^1H NMR resonance at $\delta = 0.7$ ppm. The infrared spectra display vibrational features nearly identical to the uranium counterpart, and reveal the asymmetric $\nu(PuNSi_2)$ stretch at 986 cm^{-1}. Based on the similarity in spectroscopic properties, it is presumed that this compound will display the well-established pyramidal structure that is shared by the uranium and lanthanide analogs as indicated in **24**.



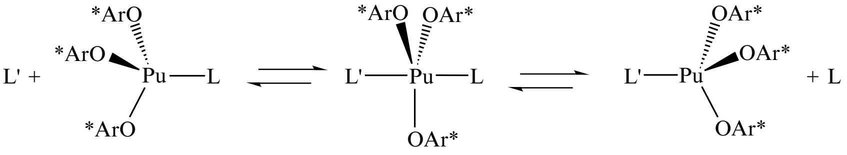
24

(*iii*) *Alkoxides*

Zwick and coworkers reported that the alcoholysis of $Pu[N(SiMe_3)_2]_3$ with the sterically demanding $2,6\text{-}Bu^t_2C_6H_3(OH)$ gives the tan, air-sensitive tris aryloxide derivative $Pu(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_3$ in 70% yield (Zwick *et al.*, 1992). The structural formulation as a monomeric compound is based on the similarity of spectroscopic data (^1H NMR and IR) to the well-characterized uranium analog which shows a monomeric structure in the solid state (Van der Sluys *et al.*, 1988).

$$Pu[N(SiMe_3)_2]_3 + 3HO\text{-}2,6\text{-}Bu^t_2C_6H_3 \xrightarrow{\text{hexane}} Pu(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_3 + 3HN(SiMe_3)_2 \qquad (7.144)$$

The tris aryloxide complex will coordinate Lewis bases to form $LPu(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_3$ complexes (shown in **25**), where L is triphenylphosphine oxide, 4,4′-dimethoxybenzophenone, or *N*,*N*-di-isopropyl-benzamide (Oldham *et al.*, 2000). The relative binding affinities were found to correspond with that observed in process extraction chemistry (see Section 7.5.4), with the phosphine oxide and benzamide showing similar binding affinities, which were much larger than that of the benzophenone. Kinetic investigations of the self-exchange process probed by ^{31}P NMR spectroscopy yielded activation parameters indicative of an associative process, with a five-coordinate $L_2Pu(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_3$ intermediate (**26**).



25 **26** **25**

Bradley and coworkers prepared aliphatic alkoxide complexes of general formula $Pu(OR)_4$ using $(Hpy)_2PuCl_6$ and benzene/alcohol solutions containing ammonia (Bradley *et al.*, 1957). With excess isopropanol, the reaction mixture was stirred with NH_3 at room temperature, and then the NH_4Cl and C_5H_6NCl salts removed by filtration. Solvent removal produced a mixture of grass-green $Pu(OPr^i)_4$ and $(Py)Pu(OPr^i)_4$. Recrystallization from isopropanol gives emerald green $Pu(OPr^i)_4(Pr^iOH)$. The base-free, homoleptic $Pu(OPr^i)_4$ compound sublimes at 220°C (0.05 mmHg). A similar reaction employing a large excess of *t*-butanol/benzene gave pale green $Pu(OBu^t)_4$, which sublimes at 112°C (0.05 mmHg). These aliphatic alkoxides were extremely sensitive to moisture, but appeared to be unaffected by dry air. No other characterization data have been reported.

$$(Hpy)_2PuCl_6 + xsPr^iOH \xrightarrow[NH_3/C_6H_6]{} Pu(OPr^i)_4(HOPr^i) + 4(NH_4)Cl + 2HpyCl \tag{7.145}$$

Very little is known about the trivalent isopropoxide, $Pu(OPr^i)_3$, although its use in catalytic reduction of ketones by isopropanol has been reported. Warner and coworkers examined the ability of trivalent and tetravalent lanthanide and actinide isopropoxides to facilitate the Meerwein–Ponndorf–Verley reduction of ketones (Warner *et al.*, 2000). Tetravalent $Pu(OPr^i)_4$ was found to be inactive in ketone reduction, but *in situ* production of $Pu(OPr^i)_3$ by dissolution of $Pu[N(SiMe_3)_2]_3$ in neat isopropanol generated an effective catalyst for the reduction of a range of substituted aryl-alkyl ketones, with yields that were equal or higher than similar reactions employing lanthanides.

(*iv*) *Alkyls*

There is only one example in the literature of an alkyl complex of plutonium, but its characterization data is limited to IR spectroscopy. Zwick and coworkers reported that the reaction of $Pu(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_3$ with three equivalents of $LiCH(SiMe_3)_2$ in hexane solution yields yellow-brown $Pu[CH(SiMe_3)_2]_3$ as an oily solid (Zwick *et al.*, 1992). The IR spectrum was virtually identical to the well-characterized $U[CH(SiMe_3)_2]_3$ analog (Van der Sluys *et al.*, 1989). Other chemical characteristics, such as extreme sensitivity to air, rapid decomposition in solution, and thermal instability are consistent with this formulation. If the formulation is correct, then this complex would be an extremely rare example of a true organometallic complex of plutonium containing metal–carbon sigma bonds.

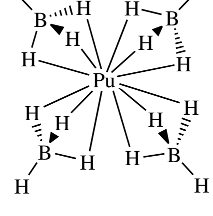
(*v*) *Borohydrides*

The first attempt to prepare plutonium borohydride was made by Schlesinger and Brown at the University of Chicago Metallurgical Laboratory in 1942 (Schlesinger and Brown, 1943). These authors tried to prepare plutonium borohydride in tracer quantities by reaction of uranium tetrafluoride containing trace amounts of plutonium with aluminum borohydride. Excess aluminum borohydride was removed and the reaction products that were volatile at 60°C were condensed at 20, 0, –23, –80, and –190°C. Only a few percent of the plutonium was recovered from the volatile fractions, the bulk of the plutonium remaining in the nonvolatile residue in the reaction vessel. It was therefore concluded that plutonium borohydride was either not formed or was not volatile at 60°C.

The first unequivocal preparation of plutonium(IV) borohydride was accomplished by Banks, Edelstein and coworkers (Banks *et al.*, 1978; Banks, 1979; Banks and Edelstein, 1980) at the Lawrence Berkeley Laboratory. Treatment of anhydrous PuF_4 with $Al(BH_4)_3$ at 0°C for 4 h in a solvent-free sealed tube reaction gives $Pu(BH_4)_4$ according to the reaction below.

$$PuF_4 + 2Al(BH_4)_3 \rightarrow Pu(BH_4)_4 + 2Al(BH_4)F_2 \qquad (7.146)$$

The unreacted $Al(BH_4)_3$ passes through a dry-ice trap and is collected in a liquid nitrogen trap. The $Pu(BH_4)_4$ is not as volatile and can be collected in the dry-ice trap. By intermolecular exchange in the gas phase with D_2, the deuterated compound $Pu(BD_4)_4$ may also be prepared. $Pu(BH_4)_4$ is a pyrophoric bluish-black liquid that melts at approximately 14°C. Infrared spectroscopy indicates that the compound adopts a monomeric pseudo-tetrahedral coordination geometry similar to $Zr(BH_4)_4$ and $Hf(BH_4)_4$ in the gas phase. Low temperature X-ray powder diffraction was consistent with this assessment, and suggests that the monomeric compound consists of a tetrahedral arrangement of four BH_4^- units coordinated by three B–H bridges per borohydride, giving the 12-coordinate structure shown in **27** below.



27

(b) Pi-bonded ligands

(*i*) *Cyclooctatetraene complexes*

The synthesis and characterization of the uranium(IV) sandwich complex, U(η-$C_8H_8)_2$, uranocene, was an important milestone in the history of organometallic chemistry, as it represented the logical extension of the bonding concepts that were developing for organotransition metal complexes (Seyferth, 2004). It was only a few years later when the plutonium analog was reported.

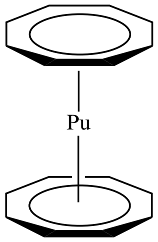
Bis(cyclooctatetraenyl)plutonium, or 'plutonocene' has been prepared by metathesis of $[NEt_4]_2[PuCl_6]$ with two equivalents of $K_2(C_8H_8)$ in THF solution to give a bright red product (Karraker *et al.*, 1970). Alternatively, $Pu(C_8H_8)_2$ may be prepared by reaction of degassed cyclooctatetraene, C_8H_8, with finely divided plutonium metal (prepared through hydride–dehydride cycles) in a sealed glass tube. The reaction mixture was heated at 160°C for 15 min, producing a red sublimate of $Pu(C_8H_8)_2$ (Starks and Streitwieser, 1973). Plutonocene reacts rapidly with air, and is only sparingly soluble in aromatic and chlorinated hydrocarbon solvents.

$$(NEt_4)_2PuCl_6 + 2K_2C_8H_8 \rightarrow Pu(\eta\text{-}C_8H_8)_2 + 2(NEt_4)Cl + 4KCl \qquad (7.147)$$

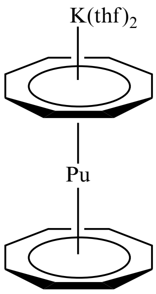
$$Pu + 2C_8H_8 \rightarrow Pu(\eta\text{-}C_8H_8)_2 \qquad (7.148)$$

The hydrocarbon solution solubility of plutonocene is enhanced by adding alkyl groups to the C_8H_8 rings. A number of alkyl substituted derivatives have been prepared, including $Pu(EtC_8H_7)_2$, $Pu(Bu^nC_8H_7)_2$, and $Pu(Bu^tC_8H_7)_2$ using the metathesis route employing $[NEt_4]_2[PuCl_6]$ and the potassium salt of the annulene dianion (Karraker, 1973; Eisenberg *et al.*, 1990). The tetramethyl-substituted complex $Pu(1,3,5,7\text{-}Me_4C_8H_4)_2$ was originally claimed (Solar *et al.*, 1980), but subsequent studies on other alkyl substituted complexes led Streitwieser to conclude that this compound was almost certainly the trivalent complex $[K(THF)_2][Pu(1,3,5,7\text{-}Me_4C_8H_4)_2]$ (Eisenberg *et al.*, 1990).

Single crystal XRD studies on $U(C_8H_8)_2$ shows that this molecule adopts a sandwich-type structure with the uranium center sandwiched between two planar C_8H_8 rings in rigorous D_{8h} symmetry (Zalkin and Raymond, 1969; Avdeef *et al.*, 1972). X-ray powder diffraction, infrared, electronic absorption, solution NMR, and Mössbauer spectroscopy reveal that the neptunium and plutonium analogs maintain the identical D_{8h} structure as shown in **28** (Karraker *et al.*, 1970; Karraker, 1973; Eisenberg *et al.*, 1990). Plutonocene is unique in that it has a $J = 0$ ground state with temperature-independent paramagnetism. Optical spectroscopy shows electronic transitions with intensities approaching 1000 (L mol^{-1} cm^{-1}), which argued against the assignment as 5f–5f transitions, and suggested an unusual 5f–6d orbital mixing with appreciable covalency in the bonding (Karraker *et al.*, 1970; Hayes and Edelstein, 1972).



28



29

A number of trivalent plutonocene complexes of the type $[K(THF)_2][Pu(RC_8H_7)_2]$ have been prepared, where R = an alkyl group or H. These are prepared by reaction of $PuBr_3$ or PuI_3 with $K_2(RC_8H_7)$ in THF solution at –10 to –20°C (Karraker and Stone, 1974). These complexes may also be prepared by the direct reaction of potassium metal with $Pu(RC_8H_7)_2$ in THF solution (Eisenberg *et al.*, 1990).

$$PuX_3 + 2K_2C_8H_8 \underset{\text{THF}}{\longrightarrow} [K(THF)_2][Pu(\eta\text{-}C_8H_8)_2] + 3KX \ (X = Br, I) \quad (7.149)$$

$$Pu(\eta\text{-}C_8H_8)_2 + K \underset{\text{THF}}{\longrightarrow} [K(THF)_2][Pu(\eta\text{-}C_8H_8)_2] \quad (7.150)$$

The trivalent $[K(THF)_2][Pu(C_8H_8)_2]$ complex was described as turquoise-green, and it has been characterized by elemental analysis, X-ray powder diffraction, and magnetic susceptibility measurements (Karraker and Stone, 1974). The lime green $[K(THF)_2][Pu(Bu^tC_8H_7)_2]$ was not isolated, but was produced *in situ* in deuterated THF solvent, and characterized by ^1H NMR (Eisenberg *et al.*, 1990). The change in chemical shifts in the NMR spectrum with temperature was indicative of paramagnetic behavior expected for Pu(III). The solid-state structure of the uranium analog, $[K(diglyme)][U(C_8H_8)_2]$ has been determined by single crystal XRD revealing that the potassium ion is also involved in a multihapto interaction with a C_8H_8 ring. The X-ray powder diffraction data on the plutonium analogs indicate similar structures, as shown in **29** (Karraker and Stone, 1974).

(*ii*) *Cyclopentadienyl complexes*

Cylcopentadienyl ligands (C_5H_5, Cp) have played a central role in the development of the field of organometallic chemistry. The same is true in the field of organoactinide chemistry that was inaugurated with Reynolds and Wilkinson's seminal report on the preparation of $(C_5H_5)_3UCl$ in 1956 (Reynolds and Wilkinson, 1956). The first plutonium compounds containing cyclopentadienyl ligands were reported by Baumgärtner and coworkers in 1965 (Baumgärtner *et al.*, 1965).

The microscale reaction between anhydrous $PuCl_3$ and molten $(C_5H_5)_2Be$ at around 70°C produces tris(cyclopentadienyl)plutonium, $(C_5H_5)_3Pu$, (or Cp_3Pu) (Baumgärtner *et al.*, 1965). Fractional sublimation first removes unreacted $(C_5H_5)_2Be$, and allows the moss green $(C_5H_5)_3Pu$ product to be isolated at a sublimation temperature of approximately 170°C. The transmetallation using $(C_5H_5)_2Be$ has been very useful for preparing transplutonium tris(cyclopentadienyl) complexes, but the nuisance of α-n reactions between the plutonium and beryllium nuclei limit the scale of the reaction. To prepare larger quantities of $(C_5H_5)_3Pu$, Crisler and Eggerman (1974) turned to the reaction between plutonium chloride starting materials with sodium or magnesium metathesis reagents. Both $PuCl_3$ and Cs_2PuCl_6 react with $(C_5H_5)_2Mg$ in THF solution to yield an emerald green product. In THF solution the first product is most likely $(C_5H_5)_3Pu(THF)$, which loses the THF ligand during sublimation to yield $(C_5H_5)_3Pu$ at 140°C under reduced pressure. The reaction is over within minutes when Cs_2PuCl_6 is employed as compared to hours for the reaction with $PuCl_3$. This is most likely because Cs_2PuCl_6 contains discrete $PuCl_6^{2-}$ ions, while $PuCl_3$ displays an extended three-dimensional structure (see Section 7.8.6(b)). Tris(cyclopentadienyl)plutonium can also be prepared from the reaction of $PuCl_3$ with $(C_5H_5)Na$ in THF solution, but the reaction requires 10 days. Zwick and coworkers found that a very convenient way to circumvent this solubility problem is to react $PuI_3(THF)_4$ with three equivalents of $(C_5H_5)Li$ in THF solution (Zwick *et al.*, 1992).

$$2PuCl_3 + 3Be(C_5H_5)_2 \xrightarrow[\text{melt}]{70^\circ} 2(\eta\text{-}C_5H_5)_3Pu + 3BeCl_2 \tag{7.151}$$

$$PuCl_3 + 3Na(C_5H_5) \xrightarrow[\text{THF}]{} (\eta\text{-}C_5H_5)_3Pu(THF) + 3NaCl \tag{7.152}$$

$$2PuCl_3 + 3Mg(C_5H_5)_2 \xrightarrow[\text{THF}]{} 2(\eta\text{-}C_5H_5)_3Pu(THF) + 3MgCl_2 \tag{7.153}$$

$$PuI_3(THF)_4 + 3Li(C_5H_5) \xrightarrow[\text{THF}]{} (\eta\text{-}C_5H_5)_3Pu(THF) + 3LiI \tag{7.154}$$

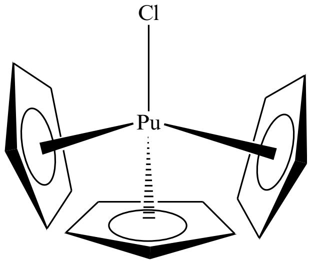
X-ray powder diffraction data suggest that $(C_5H_5)_3Pu$ is isostructural with $(C_5H_5)_3Ln$ compounds. The lanthanide analogs have been shown to contain polymeric zigzag chains of distinct $(C_5H_5)_2Ln(\mu\text{-}\eta^2\text{-}\eta^5\text{-}C_5H_5)$ units (Hinrichs *et al.*, 1983).

Bagnall and coworkers reported that the reaction between $(C_5H_5)Tl$ and Cs_2PuCl_6 in acetonitrile solution does not give an overall reduction to trivalent plutonium as discussed above, but produces tetravalent $(C_5H_5)_3PuCl$ (Bagnall *et al.*, 1982a). The chloride can be replaced with thiocyanate via a simple metathesis reaction with stirring in a THF solution of K(NCS) for 16 h (Bagnall *et al.*, 1982a). Both the chloride and thiocyanate complexes are dark brown and moisture sensitive, and both are soluble in THF and acetonitrile solution. The anionic analog, $(C_5H_5)_3Pu(NCS)_2^-$, is also reported as a tetraphenylarsonium salt, but little characterization data have been reported (Bagnall *et al.*, 1982b).

$$Cs_2PuCl_6 + 3Tl(C_5H_5) \xrightarrow[CH_3CN]{} (\eta\text{-}C_5H_5)_3PuCl + 2CsCl \tag{7.155}$$

$$(\eta\text{-}C_5H_5)_3PuCl + K(NCS) \xrightarrow[THF]{} (\eta\text{-}C_5H_5)_3Pu(NCS) + KCl \tag{7.156}$$

The chloride compound, $(C_5H_5)_3PuCl$, was found to be isostructural with its uranium counterpart (Bagnall *et al.*, 1982a), which contains a pseudo-tetrahedral unit in which the centroids of the Cp rings occupy three vertices, and the chloride takes up the fourth as illustrated in **30**.



30

Bagnall and coworkers have prepared several examples of mono(cyclopentadienyl) plutonium complexes (Bagnall *et al.*, 1985b). Room temperature reaction of $(C_5H_5)Tl$ with $PuCl_4L_2$ or Cs_2PuCl_6 in dry acetonitrile for 48 h gave $(C_5H_5)PuCl_3L_2$ in 50–85% yield depending on the nature of the Lewis base, L. Neutral Lewis base ligands (L) included a number of phosphine oxide (R_3PO) and amide ($RCONR'_2$) derivatives. Similar reactions employing $(C_5H_5)Tl$ and $Pu(NCS)_4L_2$ produced the analogous $(C_5H_5)Pu(NCS)_3L_2$ complexes (Bagnall *et al.*, 1986). All of these materials have been characterized by infrared and Vis-NIR spectroscopy. It is assumed that these complexes adopt a structure similar to their uranium analogs.

7.9.3 Electronic structure and bonding

(a) Ionic and covalent bonding models

The nature of metal–ligand bonding in light actinide compounds and complexes is quite complicated. In general, the actinides are best viewed as being intermediate between the strongly ionic bonding observed in lanthanide elements, and the more covalent bonding observed in d-block transition elements. There are clearly cases that show ionic behavior, and there are just as clearly cases that show considerable covalency.

Many plutonium–ligand bonds are nondirectional, and determined largely by electrostatic attraction to the metal, electrostatic repulsion between ligands, and steric demands around the metal center. These metal–ligand bonds are relatively weak, and kinetically labile in solution. There are also examples of metal–ligand bonds that are incredibly strong, show a stereochemical orientation, and are kinetically inert. The former situation is often taken as evidence for ionic behavior, while the latter is clearly consistent with covalent interactions. The view that plutonium complexes are generally ionic is supported by the premise that the 5f orbitals are core-like in that they are so contracted they cannot interact in bonding with the ligands. This is generally what is observed, especially for the heavier actinide elements. However, the 5f orbitals of the lighter actinides are much less contracted, and there are certain classes of compounds where the 5f orbitals have been shown to play a significant role in covalent metal–ligand bonding. By consideration of the behavior of the 5f orbitals alone, it is difficult to reconcile these stark differences in chemical behavior.

This is an area where electronic structure calculations have taught us a great deal about how to think about the nature of chemical bonding in molecular plutonium complexes. Electronic structure calculations have demonstrated that for metal–ligand bonding in plutonium (and all light actinides) one cannot consider the 5f orbitals alone, but must consider the relative roles of both the virtual 5f and 6d orbitals as well as the 'semicore' 6s and 6p orbitals. The radial distributions of the plutonium 6s and 6p semicore orbitals lie in the valence region, and they must be considered as active in chemical bonding. In addition, the virtual 6d orbitals are relatively low-lying, and have far larger radial extent than the 5f orbitals. This is illustrated in the radial distribution function for a Pu^{3+} ion shown in Fig. 7.120 (Schreckenbach *et al.*, 1999). Most modern quantum chemical calculations find evidence of mixing of the 6p semicore orbital into metal–ligand bonding combinations. Moreover, there is now a general consensus that the dominant metal–ligand bonding takes place through ligand interactions with the 6d orbitals. The 6d orbitals are strongly split by the presence of a ligand field (as in transition element complexes), but the more contracted 5f orbitals show only weak splitting. The ground state electron configurations are therefore generally governed by the occupation of these closely spaced 5f orbitals, which leads to many open shell states. Spin–orbit coupling and electron correlation effects are extremely important, particularly for understanding spectroscopic properties. In addition to Chapter 17, several excellent reviews exist that describe trends and views on the electronic structure of actinide molecular complexes (Bursten and Strittmatter, 1991; Pepper and Bursten, 1991; Denning, 1992; Schreckenbach *et al.*, 1999; Matsika *et al.*, 2001).

(b) Specific examples

There are a number of specific examples in plutonium chemistry where covalency in metal–ligand bonding plays an important role in the observed chemical

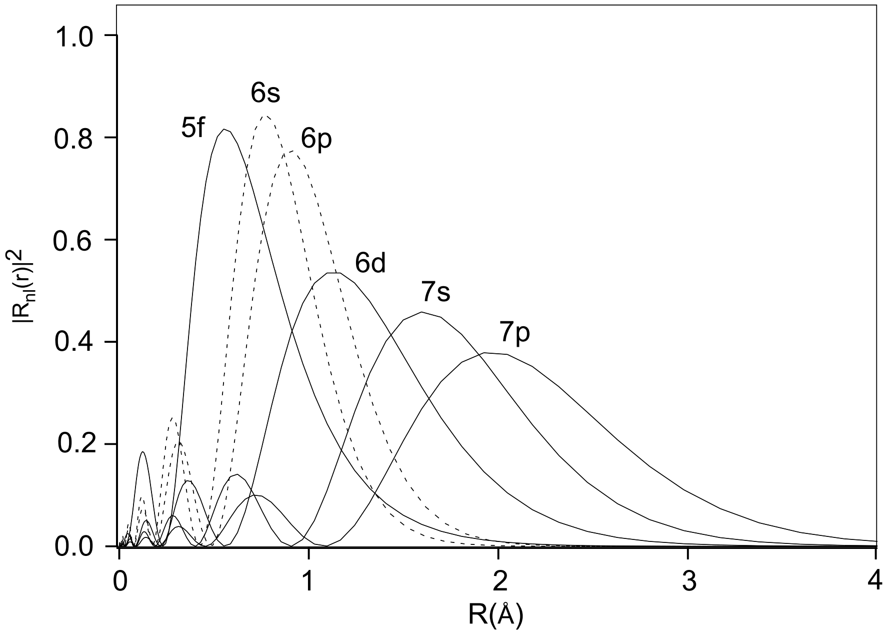


Fig. 7.120 *Radial probability densities of Pu*$^{3+}$ *valence orbitals from relativistic Hartree–Fock orbitals* $\Phi_{nl}(r)$ (*Schreckenbach* et al., 1999). *The authors are grateful to P.J. Hay of Los Alamos for providing the raw data used to prepare this figure.*

behavior. These are plutonium hexafluoride, PuF_6, the linear plutonyl cation, PuO_2^{2+}, and the organoplutonium sandwich compound plutonocene, Pu(η-$C_8H_8)_2$. We provide a qualitative discussion of the bonding in these systems, illustrate the main 6d and 5f orbital interactions, and highlight the 'strong field-weak field' differences in 6d and 5f interactions that make spin–orbit splitting important for understanding spectroscopic properties. Before discussing the examples, we remind the reader that unlike p- or d-orbitals, there is no unique way of representing the angular dependence functions of all seven f-orbitals. In high symmetry cubic point groups, a cubic set of orbitals is used, while in systems containing a high order axis of symmetry, a general set can be used. These two common sets of f-orbital depictions are simply linear combinations of each other, and they are illustrated qualitatively in Fig. 7.121. We will use both the general and cubic orbital sets in describing the bonding in our examples.

(*i*) *PuF*$_6$

As discussed in Section 7.8.6(a), plutonium hexafluoride is a stable molecule in the gas-phase. In view of the electronegativity difference between hexavalent plutonium and the fluoride anion, this observation might seem somewhat surprising in that one might expect Pu–F bonds to show the greatest ionic

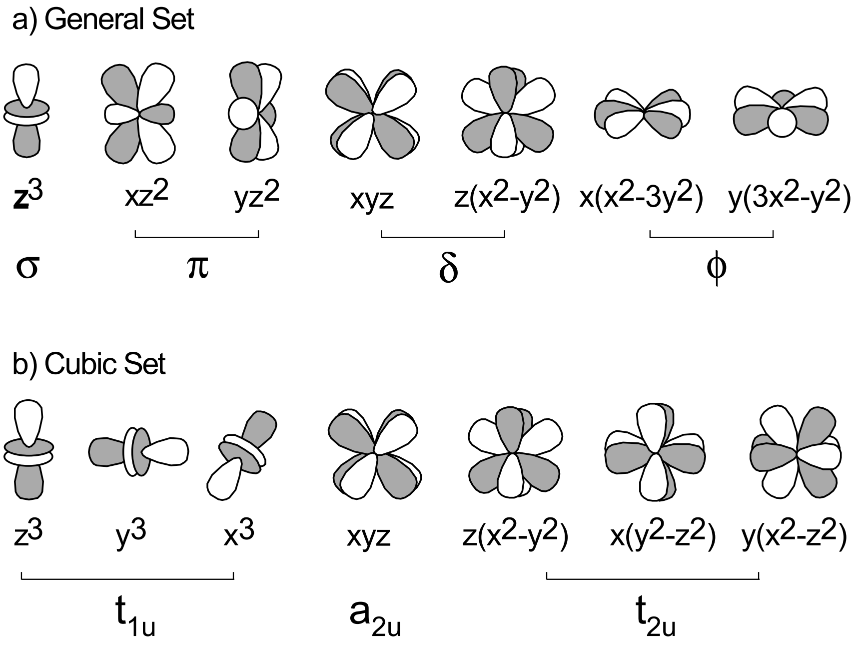

Fig. 7.121 *Qualitative representations of the general* (*a*) *and cubic* (*b*) *sets of valence f orbitals.*

behavior. Spectroscopic properties show that this is clearly not the case. Electronic structure calculations have provided some valuable insights into the nature of Pu–F bonding in this system.

A number of high-level electronic structure calculations have been performed on AnF_6 systems, with the majority of calculations performed on uranium. Calculations on PuF_6 have been reported by Kugel *et al.* (1976), Koelling *et al.* (1976), Boring and Hecht (1978), Wadt (1987), Hay and Martin (1998), Schreckenbach *et al.* (1999), and Onoe (1997). It is clear from all the theoretical calculations that the purely ionic bonding model is an inadequate description of PuF_6. A qualitative molecular orbital diagram for PuF_6 based on an octahedral ligand field that contains the basic features of these calculations is shown in Fig. 7.122. The octahedral point group is relatively straightforward as the 5f and 6d orbitals cannot mix by symmetry. The set of σ lone pairs on the six F atoms transform as $a_{1g} + e_g + t_{1u}$ symmetry under O_h symmetry. The 12 π lone pairs transform as $t_{1u} + t_{1g} + t_{2u} + t_{2g}$ under O_h symmetry. As expected, the set of σ lone pairs interacts most strongly with the Pu atom, resulting in molecular orbitals of a_{1g}, e_g, and t_{1u} symmetry which are lower-lying that the π symmetry orbitals. Of the four triply degenerate sets of F ligand π orbitals, the t_{2g} is of appropriate symmetry to interact with the 6d orbitals of the plutonium atom, the t_{2u} can interact with the 5f orbitals, and the t_{1g} orbital cannot interact with any low-lying metal orbitals, and should remain as an noninteracting set of lone pairs. The t_{1u} orbital can interact with the 5f orbitals of the plutonium atom, but it can also mix with the t_{1u} set of σ orbitals derived from mixing between the semicore 6p and valence 7p orbitals. From simple overlap considerations, one would expect the F lone pair t_{2u} and t_{2g} orbitals to be the most stabilized by donation to the metal, the t_{1g} will be entirely nonbonding, and the t_{1u} will stabilized by π bonding from above, but destabilized by mixing with the σ interaction from below. In all the calculations, appreciable covalency with both 5f and 6d orbitals is present. The covalent interactions are found in Pu–F σ- and π-bonding that takes place through t_{2g} and e_g interactions with Pu 6d orbitals, and σ bonding that takes place through t_{1u} interactions with the 5f and 6p/7p orbitals. These metal–ligand bonding interactions are illustrated qualitatively in the molecular orbital diagram of Fig. 7.122. Wadt employed a Mulliken population analysis to determine the relative amount of plutonium 5f and 6d contribution to bonding (Wadt, 1987). The σ and π components of the t_{1u} interactions are mixed, but the virtual $5t_{1u}$ orbital (the $3t_{1u}$ orbital in Fig. 7.122) was calculated to comprise 71% Pu f, 3% Pu p, and 26% F p character

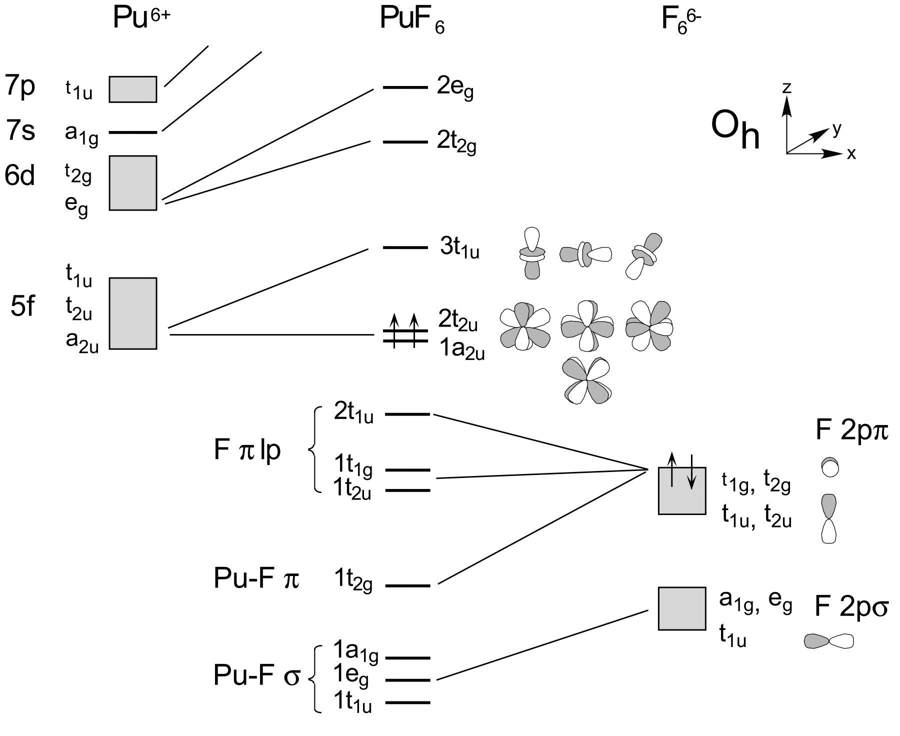

Fig. 7.122 *A qualitative molecular orbital interaction diagram for PuF_6.*

indicating a significant amount of covalency involving Pu 5f orbital interaction with the F ligands. It also shows the importance of mixing 'semicore' 6p character into a f–p σ hybrid orbital that enhances σ bonding. The total population of the Pu 5f orbitals was calculated to be 4.24. Since this system is nominally $5f^2$, the extra 2.24 electrons in 5f orbitals come from σ and π donation from occupied F ligand orbitals into Pu 5f orbitals.

For octahedral PuF_6, a simple filling of this qualitative MO scheme with the 16 valence electrons would give a valence electronic configuration $(1a_{2u})^2$ or $(1a_{2u})^1(2t_{2u})^1$ corresponding to $^1A_{1g}$ or $^3T_{1g}$ ground states, respectively. The 5f ordering in an octahedral ligand field is $a_{2u} < t_{2u} < t_{1u}$, and the calculations indicate that the $1a_{2u}$ and $2t_{2u}$ 5f orbitals are nearly degenerate, suggesting that the $^3T_{1g}$ state would be the likely ground state. This one-electron picture is oversimplistic, because the ligand field splitting of the 5f orbitals is so weak that spin–orbit effects must also be considered. Spin–orbit coupling splits the 5f manifold and gives a $^1\Gamma_{1g}$ (in O_h double group symmetry) ground state. The inclusion of spin–orbit coupling is necessary to understand the stabilization of a singlet ground state, and is in agreement with experiment that shows an absence of temperature-dependent contributions to the magnetic susceptibility, and indicates a nondegenerate ground state. Sophisticated electronic structure calculations are needed to quantify these spin–orbit effects. Wadt employed spin–orbit configuration interaction (CI) calculations that examined all possible arrangements of two electrons in seven 5f levels (Wadt, 1987). Wadt found that the ground $^1\Gamma_{1g}$ state in the octahedral double group representation was comprised of 78% $^3T_{1g}$ and 18% $^1A_{1g}$. More recently, Hay and Martin (1998) performed hybrid DFT calculations on both the $^1A_{1g}$ and $^3T_{1g}$ states and found the $^3T_{1g}$ state to lie lower in energy, consistent with Wadt's study, but did not include the spin–orbit coupling.

(*ii*) PuO_2^{n+}

The linear trans dioxo cations of light actinide elements are among the most well-studied actinide molecular systems. Electronic structure calculations on actinyl ions have revealed a great deal about covalency in metal–oxygen bonds and the relative roles of the valence 5f, 6d, and semicore 6p orbitals. The majority of theoretical studies have been devoted to UO_2^{2+}, but the smaller subset of calculations on PuO_2^{2+} reveals that much of the basic bonding description is essentially the same. The most thorough review on the subject is Denning's 1992 examination of experimental and theoretical work performed up to that time (Denning, 1992). Subsequent reviews build upon that work, and the reader is referred to discussions by Pepper and Bursten (1991), Dyall (1999), Denning *et al.* (2002), and Chapter 17 of this work for additional information.

The trans dioxo cations, AnO_2^{n+}, are invariably linear, regardless of the number of valence 5f electrons. The metal–oxygen bonds are unusually short, strong, and chemically inert. Based on all the experimental and theoretical

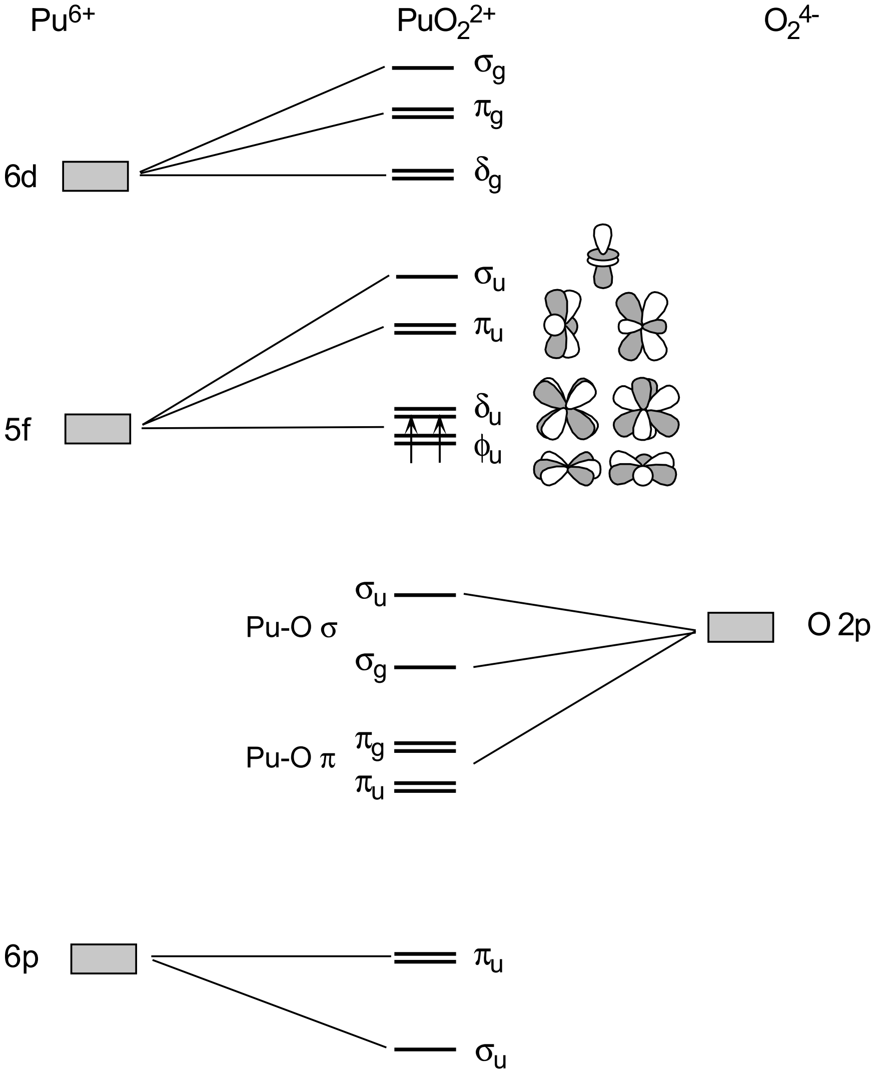

Fig. 7.123 *A qualitative molecular orbital interaction diagram for a linear triatomic PuO_2^{2+} ion.*

studies, there is uniform agreement on the molecular orbital description of bonding in these systems. A qualitative molecular orbital diagram for the linear triatomic PuO_2^{2+} ion that contains the basic features of the calculations is given in Fig. 7.123. In centrosymmetric $D_{\infty h}$ symmetry, the molecular orbitals are conveniently labeled according to their axial symmetry, and the 5f and 6d orbitals cannot mix. The in-phase and out-of-phase combinations of the two O 2p σ orbitals span σ_u and σ_g symmetry, while the corresponding O 2p π orbitals span π_u and π_g symmetry. The metal 6d orbitals span σ_g, π_g, and δ_g symmetry, while the 5f orbitals span σ_u, π_u, δ_u, and φ_u symmetry. Metal–oxygen σ bonds are formed by interaction of the O 2p σ orbitals with metal $6d_{z^2}$ (σ_g) and a hybrid metal orbital formed by mixing $5f_{z^3}$ with the semicore $6p_z$ (σ_u). Metal–oxygen π bonds are formed by interaction of O 2pπ orbitals with metal $6d_\pi$ (π_g) and $5f_\pi$ (π_u) orbitals. The 5f δ_u and φ_u orbitals have no symmetry match with the ligands, and they remain as unperturbed, essentially degenerate, nonbonding 5f orbitals as indicated in Fig. 7.123.

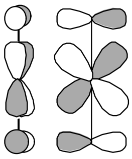
In this qualitative diagram, the 14 valence electrons occupy the molecular orbitals to give a ground state electron configuration of $(\sigma_g^2\pi_g^4\,\sigma_u^2\,\pi_u^4)\,(\delta_u^2)$. Since the δ_u orbital is a nonbonding 5f orbital on the metal, this gives rise to formal Pu–O triple bonds in the linear PuO_2^2+ unit. These four metal–ligand bonding orbitals are shown qualitatively in **31–34** below.

σ_u

31

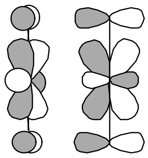
σ_g

32



π_g

33



π_u

34

Much discussion and debate has centered around the ordering of the four occupied metal–oxygen bonding orbitals σ_g, π_g, σ_u, and π_u. It is now generally accepted that a filled–filled interaction takes place between the σ_u Pu–O bonding orbital and the lower-lying (semicore) metal $6p_z$ orbital that also has σ_u symmetry. This repulsive interaction keeps the metal–oxygen bonding σ_u at high energy, and this now classical picture has been verified experimentally by Denning and coworkers using polarized oxygen Kα X-ray absorption and emission spectroscopy on a uranyl sample (Denning *et al.*, 2002). The linear trans dioxo cations were the first systems where theoretical calculations revealed that the closed shell (semicore) 6p orbitals were active in chemical bonding. Several studies have focused on the role of semicore 6p involvement, and have shown that $5f_{z^3}$–$6p_z$ hybridization forms an unusually strong metal–oxygen σ bond, and stabilizes the linear geometry (Dyall, 1999; Kaltsoyannis, 2000).

This basic bonding picture holds for all the trans dioxo cations from uranium through plutonium (Hay *et al.*, 2000) and americium. For the 5f orbitals, the overall ordering of levels is $\delta_u \sim \varphi_u < \pi_u << \sigma_u$ because the π_u and σ_u orbitals are destabilized by bonding interactions at lower energy. This basic orbital ordering scheme makes it easy to understand why the AnO_2^{n+} ions remain linear regardless of the number of 5f electrons. As the 5f electron count increases from UO_2^{2+} (f^0) to AmO_2^{2+} (f^3), each successive 5f electron is added to the nonbonding

5f orbitals of δ_u or φ_u symmetry. This is in contrast to transition element complexes where d^0 dioxo complexes are invariably cis, while d^2 dioxo complexes are invariably trans in order to maximize metal–oxygen π bonding. For the actinyl ions, the trans geometry maximizes σ bonding, and the formal metal–oxygen triple bond is retained regardless of the metal 5f electron count.

From this basic molecular orbital description, it is also easy to understand why most equatorial ligands show only a weak interaction with the highly covalent linear AnO_2^{2+} core. Let us consider the D_{4h} symmetry case of four equatorial ligands that only interact via σ bonding to form $PuO_2L_4^{2+}$. The four lone-pair orbitals of the equatorial ligands span a_{1g}, b_{1g}, and e_u symmetry, and these correspond to the $D_{\infty h}$ σ_g, δ_g, and π_u orbitals of the linear PuO_2^{2+} ion. The σ_g orbital has already been significantly destabilized by formation of the axial PuO_2^{2+} σ bonds, and the π_u orbital has very little overlap with incoming ligands in the equatorial plane. This leaves only one component of the degenerate δ_g orbital $\left(d_{x^2-y^2}, d_{xy}\right)$ that is directed towards the incoming ligands. In D_{4h} symmetry, the δ_g orbital $\left(d_{x^2-y^2}, d_{xy}\right)$ transforms as $b_{1g} + b_{2g}$, and only the b_{1g} orbital has the appropriate symmetry to interact. Overall, this gives only one molecular orbital (b_{1g}) that is bonding to all four equatorial bonds with a formal bond order of one quarter. The $PuO_2L_4^{2+}$ molecule therefore has two strong covalent Pu–O triple bonds in the axial direction, and four weak, relatively ionic bonds in the equatorial plane. This qualitative molecular orbital interaction diagram is illustrated in Fig. 7.124.

As in the PuF_6 example, the weak ligand field splitting of the 5f manifold, particularly the δ_u and φ_u orbitals mandates that electron repulsion and spin–orbit interactions be taken into account in order to understand the complexity of molecular electronic spectra. In the actinyl ions, Matsika and coworkers concluded that after consideration of the axial ligand field, electron repulsion was generally larger than spin–orbit coupling, leading them to the use of a Russell–Saunders-like Λ-S coupling scheme to calculate electronic states and optical transitions (Matsika *et al.*, 2001). For the $5f^2$ PuO_2^{2+} system, the $(\delta_u,\varphi_u)^2$ configuration gives two ${}^3\sum_g^-$ states, ${}^3\Pi_g$, ${}^3H_g$ and several higher energy singlets when only considering electron repulsion. When spin–orbit interaction is taken into account, the ${}^3H_g$ is lowered considerably, giving a ground state of ${}^3H_{4g}$ in agreement with spectroscopic data (Bleaney, 1955; Denning, 1992). Hay *et al.* (2000) obtain the same ${}^3H_{4g}$ ground state using spin–orbit configuration interaction (CI) calculations.

(*iii*) *Pu*$(C_8H_8)_2$

Following the discovery of the transition metal sandwich complex ferrocene, $Fe(\eta\text{-}C_5H_5)_2$, R. D. Fischer predicted the existence of the $U(\eta\text{-}C_8H_8)_2$ sandwich complex based on the recognition that the nodal properties of f-orbitals would require an expanded C_8H_8 ring (Fischer, 1963). Five years later uranocene, $U(\eta\text{-}C_8H_8)_2$, was synthesized and only shortly thereafter the plutonium

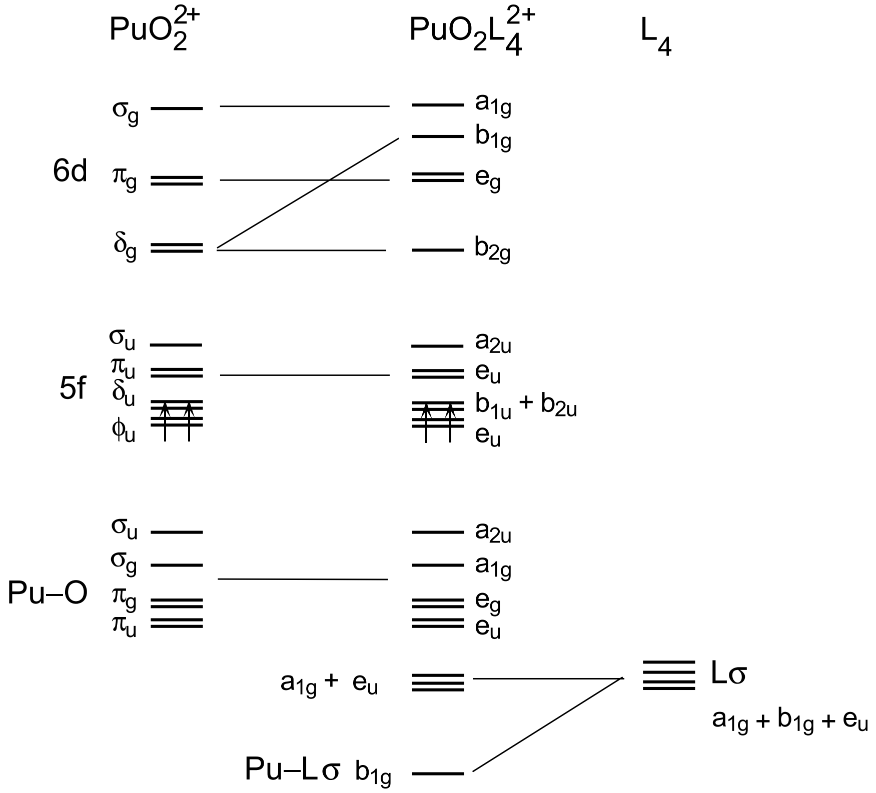


Fig. 7.124 *A qualitative molecular orbital interaction diagram for a linear triatomic* PuO_2^{2+} *ion interacting with four equatorial ligands, L, to form* $PuO_2L_4^{2+}$.

analog was prepared. As one of the first organometallic actinide complexes, the actinocene system has been the topic of much study aimed at understanding the relative roles of 5f and 6d orbitals in bonding (Boerrigter *et al.*, 1988; Brennan *et al.*, 1989; Kaltsoyannis and Bursten, 1997; Li and Bursten, 1998). A qualitative molecular orbital interaction diagram for Pu(η-C_8H_8)$_2$ under D_{8h} symmetry that contains the basic features of the electronic structure calculations is given in Fig. 7.125. The eight carbon $2p_\pi$ orbitals of the planar $C_8H_8^{2-}$ ring transform as a_{2u}, e_{1g}, e_{2u}, e_{3g}, and b_{1u} symmetry in D_{8h}, and these are often referred to as π_0, π_1, π_2, π_3, and π_4. This π_n nomenclature is convenient for visualization because the value of n refers to the number of nodes in the Hückel p_π orbitals of the $C_8H_8^{2-}$ ring. When two $C_8H_8^{2-}$ rings are brought together in D_{8h} symmetry, the in-phase and out-of-phase combinations of these π_n orbitals give rise to 16 orbitals as indicated in Fig. 7.125. These orbitals retain their π_n parentage as π_0 ($a_{1g} + a_{2u}$), π_1 ($e_{1g} + e_{1u}$), π_2 ($e_{2g} + e_{2u}$), π_3 ($e_{3g} + e_{3u}$), and π_4 ($b_{1u} + b_{2g}$). Interaction of these 16 π orbital combinations with Pu 6d atomic

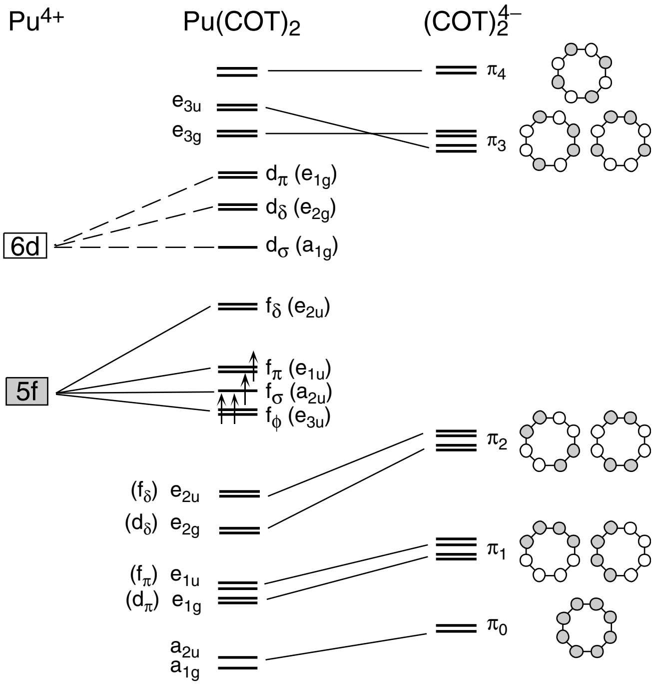

Fig. 7.125 *A qualitative molecular orbital interaction diagram for plutonocene, Pu(η-C_8H_8)$_2$.*

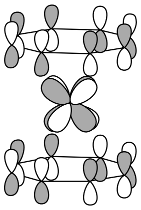
orbitals of d_σ, d_π, and d_δ symmetry gives rise to metal–ligand bonding molecular orbitals of a_{1g}, e_{1g}, and e_{2g} symmetry, respectively. Both the d_π (e_{1g}) and d_δ (e_{2g}) molecular orbitals are significantly destabilized due to strong interactions that occur with ligand orbitals at lower energy. The Pu 5f orbitals are split into the f_σ, f_π, f_δ, and f_φ molecular orbitals of a_{2u}, e_{1u}, e_{2u}, and e_{3u} symmetry, respectively. The lobes of the f_δ orbital are directed towards the $C_8H_8^{2-}$ rings, and interaction with the ligands strongly destabilizes this orbital and moves it significantly higher in energy than the remaining f_σ, f_π, and f_φ orbitals. Ligand interactions with the remaining f_σ, f_π, and f_φ orbitals are significantly weaker, giving rise to an f-orbital splitting pattern where one degenerate set is removed from the 5f manifold, leaving the other five orbitals clustered at lower energy (Boerrigter *et al.*, 1988). These general interactions are illustrated in Fig. 7.125.

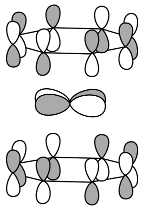
As seen in the other examples, the 6d orbital interactions with the ligands are significantly stronger than the 5f interactions. The δ-type interactions have significant metal–ligand overlap and give rise to appreciable covalency through both 6d and 5f orbital interactions. A Mulliken population analysis for nonrelativistic orbitals showed that the $6d_\delta$ orbital is approximately 88% ligand and

11% 6d in character, while the $5f_\delta$ orbital is 48% ligand and 49% 5f in character (Boerrigter *et al.*, 1988). The latter represents significant 5f covalency. In addition, these calculations reveal that the semicore 6p orbitals also have a considerable amplitude at the position of the rings, and that this permits a strong interaction with deeper lying ring orbitals of the appropriate symmetry (Boerrigter *et al.*, 1988). These $6d_\delta$ (e_{2g}) and $5f_\delta$ (e_{2u}) metal–ligand bonding orbitals are illustrated qualitatively in **35** and **36**.



f_δ

35



d_δ

36

This general bonding scheme has been experimentally confirmed by Brennan and coworkers who performed variable energy photoelectron spectroscopy on $U(\eta\text{-}C_8H_8)_2$ over a photon energy range of 24–125 eV (Brennan *et al.*, 1989). A mapping of the intensity changes in the ionization from the $5f_\delta$ (e_{2u}) orbital

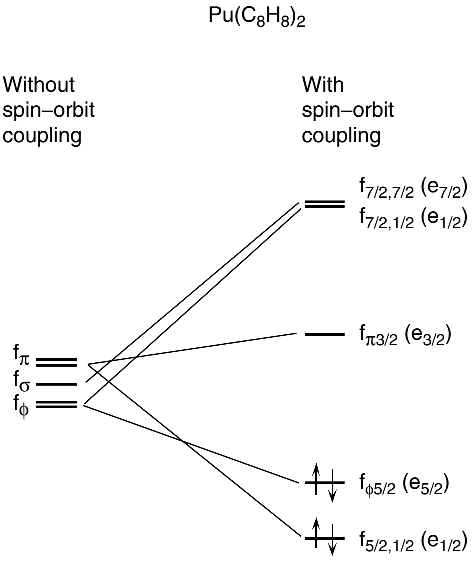


Fig. 7.126 *The effect of spin–orbit coupling on the 5f orbitals of* $Pu(\eta\text{-}C_8H_8)_2$ *adapted from Boerrigter* et al. (1988). *For consistency with Chapter* 17, *the* D_{8h}* *double group notation is given in parentheses.*

provided conclusive spectroscopic evidence for substantial 5f orbital covalency in U(η-C_8H_8)$_2$.

Relativistic calculations employing the HFS LCAO method conclude that the f_σ, f_π, and f_φ orbitals are nearly degenerate, and that they are equally populated with the four valence electrons in Pu(η-C_8H_8)$_2$ (Boerrigter *et al.*, 1988). This is not consistent with the experimental observation of a $M_j = 0$ ground state. As in our other examples, spin–orbit coupling must be taken into account in order to understand spectroscopic data. Boerrigter and coworkers have shown that strong ligand field splitting effectively removes the $5f_\delta$ orbital from the 5f orbital manifold, and this simplifies the discussion of spin–orbit coupling. The spin–orbit interaction on a degenerate set of f_σ, f_π, and f_φ orbitals gives a four-level pattern with two low-lying orbitals, the $f_{5/2,1/2}$ and $f_{\varphi 5/2}$, and three high-lying orbitals, the $f_{\pi 3/2}$, and the degenerate $f_{7/2,7/2}$ and $f_{7/2,1/2}$, as shown in Fig. 7.126. After inclusion of spin–orbit coupling, it is easy to see that Pu(η-C_8H_8)$_2$ is closed shell as both the low-lying $f_{5/2,1/2}$ and $f_{\varphi 5/2}$ are fully occupied leading to a $M_j = 0$ ground state in agreement with the measured magnetic properties.

CHAPTER EIGHT

AMERICIUM

Wolfgang H. Runde and Wallace W. Schulz

8.1 HISTORICAL

Americium, element 95, was discovered in 1944–45 by Seaborg *et al.* (1950) at the Metallurgical Laboratory of the University of Chicago as a product of the irradiation of plutonium with neutrons:

$$^{239}\mathrm{Pu}(n,\gamma)^{240}\mathrm{Pu}(n,\gamma)^{241}\mathrm{Pu}\xrightarrow{-\beta^-}{}^{241}\mathrm{Am}$$

This reaction is still the best method for the production of pure ^{241}Am. In post-World War II work at the University of Chicago, Cunningham isolated Am(OH)$_3$ and measured the first absorption spectrum of the Am^{3+} aquo ion (Cunningham, 1948). By the 1950s, the major center for americium chemistry research in the world was at Los Alamos. Since the 1970s, the majority of publications on americium have come from researchers in the former USSR and West Germany. Extensive reviews of americium chemistry can be found in Freeman and Keller (1985), Gmelin (1979), Penneman and Asprey (1955), and Schulz (1976).

8.2 NUCLEAR PROPERTIES OF ISOTOPES

To date, 13 americium isotopes with mass numbers 232–247 and half-lives ranging from 55 s to 7370 years are known (Table 8.1). While the isotopes with mass numbers 232, 234, and 237–247 have been known for some time, the neutron-deficient isotopes Am-233, Am-235, and Am-236 have only recently

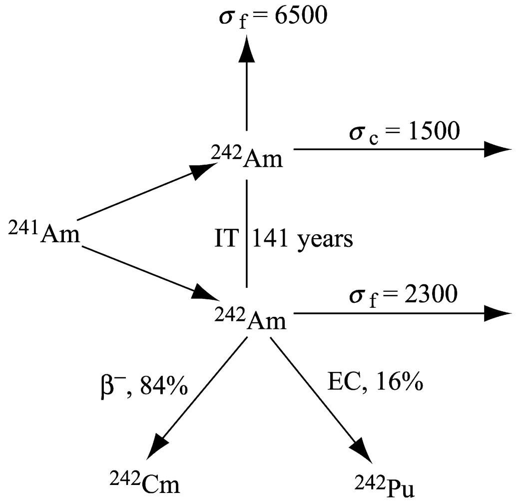
been produced and characterized (Hall, 1989; Tsukada *et al.*, 1998; Weifan *et al.*, 1999; Sakama *et al.*, 2000). The light isotopes up to ^{243}Am mainly decay by electron capture, emission of alpha particles, and spontaneous fission; the isotopes beyond ^{243}Am are short-lived β^--emitters. Data in Table 8.1 are taken primarily from the comprehensive compilation in Gmelin (1973) and others (Hyde *et al.*, 1971; Wapstra and Gove, 1971; Skobelev, 1972; Natowitz, 1973; Schulz, 1976; Lederer and Shirley, 1978; Kuznetsov and Skobelev, 1966). Although not noted in Table 8.1, literature references (e.g. Schulz, 1976) indicate that some of the identified americium isotopes exist in more than one isomeric energy state.

8.3 PRODUCTION OF PRINCIPAL ISOTOPES

The most important isotopes of americium are ^{241}Am and ^{243}Am due to their long half-lives of 433 and 7380 years, respectively. These isotopes have been made in kilogram quantities with high purity. ^{242}Am ($t_{1/2}$ = 141 years) can be produced to the extent of only a few percent in ^{241}Am by neutron capture.

Americium-241 is superior to all competing radionuclides as a low-energy gamma source because of its cost, convenience, spectral purity, and half-life (Crandall, 1971) and its application as a low-energy gamma source may well be the largest of any actinide nuclide (Seaborg, 1970; LeVert and Helminski, 1973). The major use for ^{241}Am is in smoke-detector alarms and in neutron sources to furnish alpha particles for the (α,n) reaction on beryllium. As a source of nearly monoenergetic alpha (5.44 and 5.49 MeV) and gamma (59.6 keV) radiation, ^{241}Am is also widely used in thickness gauging and density and radiographic measurements, and is utilized to produce ^{242}Cm (up to 0.65 g ^{242}Cm per gram of ^{241}Am (Hennelly, 1972)) by thermal neutron capture. The thermal neutron capture sequence involved in producing ^{242}Cm from ^{241}Am is:



The lower specific activity of ^{243}Am compared to ^{241}Am makes it particularly useful in chemical studies. It is also used in the production of ^{244}Cm, ^{249}Bk/Cf, ^{252}Cf, and other transcurium elements in high neutron-flux reactors.

8.3.1 Production of ^{241}Am by irradiation of ^{239}Pu

Neutron irradiation of ^{239}Pu yields ^{241}Pu, which decays by beta emission with a half-life of 14.4 ± 0.3 years to ^{241}Am. In 1977, more than 1.5 kg of ^{241}Am was isolated from reprocessing aged plutonium at the US Department of Energy (DOE) Rocky Flats site. In 1980, a similar amount was isolated at the DOE Los Alamos site.

8.3.2 Production of ^{243}Am by irradiation of ^{242}Pu

Nearly isotopically pure ^{243}Am results from irradiation of ^{242}Pu with thermal neutrons:

$$^{242}\mathrm{Pu}(\mathrm{n},\gamma)^{243}\mathrm{Pu} \xrightarrow[5\mathrm{h}]{\beta^-} {}^{243}\mathrm{Am}$$

8.3.3 Availability of ^{241}Am and ^{243}Am from power reactor fuel

Commercial nuclear power reactors produce kilogram quantities of both ^{241}Am and ^{243}Am with an isotopic composition dependent on reactor burn-up. The US DOE Savannah River site reactors produced about 9 kg of a ^{243}Am–^{244}Cm mixture over a period of 10 years (Baybarz, 1970). About 1 kg of mixed ^{241}Am and ^{243}Am was recovered at the US DOE Hanford site during reprocessing of the Shippingport reactor blanket fuel (Wheelwright *et al.*, 1968). Approximately 30 kg of americium is reported to remain in the US DOE Hanford site waste tanks (Agnew *et al.*, 1997). But, no industrial reprocessor of commercial nuclear reactor fuel anywhere in the world has opted to pursue systematic recovery of americium. However, a potentially large source of americium is the high-level Purex-process liquid waste from plutonium processing; indeed, future waste storage may require separation of americium.

8.3.4 Critical mass

The calculated minimum critical mass of ^{242}Am in aqueous solution is 23 g at a concentration of 5 g L^{-1} (Bierman and Clayton, 1969). Note that mass separation of ^{242}Am from ^{241}Am is required to obtain pure ^{242}Am.

8.4 SEPARATION AND PURIFICATION OF PRINCIPAL ISOTOPES

Most of the standard methods, aqueous and non-aqueous, for separating and purifying americium from all kinds of sources and materials were developed in the 1950s, 1960s, and 1970s; progress made in this time frame was summarized in the second edition of this work. In contrast to the earlier time period, in the 1980s and 1990s research efforts to develop new or improved technology for recovery and/or purification of americium were largely confined to development and testing of new and improved solvent extraction processes. Worldwide, aside from purely academic investigations mainly in Russia and India, scientists and engineers were motivated by one of two main goals:

(1) In the USA, principally, to find new or modified practicable ways of removing minor amounts of neptunium, plutonium, and americium from various stored defense wastes to convert such wastes from so-called TRU (transuranium) wastes to non-TRU wastes, thus requiring less expensive final disposal procedures and facilities.
(2) To develop and demonstrate practicable technology for removal (partitioning) of long-lived actinides as well as certain long-lived and mobile fission products, e.g. ^{99}Tc, ^{129}I from the high-level aqueous waste (HLW) generated in reprocessing of irradiated commercial nuclear power reactor fuel. Partitioning of these species from the HLW, it is believed, would greatly facilitate and simplify the many current technical and legal obstacles to final geologic disposal of the HLW. Recovered, purified, and concentrated actinides and fission products can, it is further believed, be converted (transmuted) to stable or short-lived radioisotopes by suitable neutron irradiation. Because irradiated commercial nuclear reactor fuel is being reprocessed in Japan, France, and China, investigators in these countries have been active in pursuing partitioning technology options. Several references (ANS, 1993; Prunier *et al.*, 1997; Cohen, 2000; NN, 2002) provide much additional detail concerning the incentives for and status of the development of partitioning and transmutation technology. Particular attention is called to an excellent summary article on actinide partitioning technology (Mathur *et al.*, 2001).

Americium separation technology is presented and discussed here in the same order used in the second edition of this monograph. Significant separation technology developments that have occurred since the second edition was published are incorporated and discussed at appropriate places in the text. (The knowledgeable reader will appreciate that when this text was prepared (early 2002) all the americium separations technologies described in the subsequent parts of Section 8.4 was essentially only of academic and/or historic interest. The present authors are not aware of any current significant effort in any country to actually separate and/or purify americium isotopes from any source.)

8.4.1 Pyrochemical processes

A two-stage, countercurrent molten-salt extraction process was used to extract ^{241}Am from many kilograms of aged plutonium, in which ^{241}Am had grown-in by beta decay of ^{241}Pu. The purification scheme removed about 90% of the americium from plutonium metal, typically containing 200–2000 ppm ^{241}Am (Schulz, 1976).

Mullins and Leary (1969) patented a method of separating americium from plutonium that involves bubbling a mixture of oxygen and argon gas into a molten salt containing both elements. Plutonium precipitates as PuO_2, whereas americium remains in solution.

Ferris *et al.* (1972) determined the equilibrium distribution of americium (and other transuranium elements) between liquid bismuth and molten LiCl, LiBr, and several $LiF–BeF_2–ThF_4$ solutions at temperatures of 600–750°C. Some of the americium appeared to be in the divalent state in the $Am/PuCl_3$ system (Mullins and Leary, 1969). The distribution coefficient, $D =$ (g Am per g metal phase)/(g Am per g salt phase), of americium between molten aluminum metal and molten $AlCl_3–KCl$ is 1.96 (Moore and Lyon, 1959). Mills and Reese (1994) demonstrated that ^{241}Am in aged PuF_4 can be cleanly separated from plutonium by low-temperature reaction with O_2F to generate volatile PuF_6. Americium remains in the fluorination residue from which it can be recovered and concentrated by any of the several aqueous methods.

As part of their comprehensive experimental and theoretical studies of the partitioning of actinides from high-level radioactive fuel reprocessing aqueous waste, Japanese scientists, in collaboration with some US investigators, have been developing a pyrometallurgical partition process (Sakamura *et al.*, 1998). The process consists of four main steps: (1) denitration of the HLW; (2) chlorination to convert oxides to chlorides; (3) reductive extraction to reduce actinides in a molten salt by lithium metal and to extract them into liquid cadmium; and (4) electrorefining in LiCl–KCl eutectic to separate actinides from the liquid cadmium anode. Preliminary experimental tests of the entire process show that uranium, plutonium, and neptunium are relatively easily separated from fission product rare earths but that americium is accompanied by some rare earth elements. In related theoretical studies of actinide partitioning technology, Yamana and Moriyama (1996) concluded that it may be feasible to separate americium and curium from lanthanide elements by electrolytic amalgamation techniques.

8.4.2 Precipitation processes

Initially, only precipitation processes were available for recovery and purification of americium. Later, new ion-exchange and solvent extraction processes largely, but not completely, supplanted the early precipitation recovery/purification processes. Because of their insolubility and other special properties precipitation of certain compounds of americium, e.g. AmF_3, $K_8Am_2(SO_4)_7$, $Am_2(C_2O_4)_3$, $K_3AmO_2(CO_3)_3$, is routinely considered for recovery or purification of a batch of americium. The latter two compounds are useful because oxalate ion prevents certain impurities from accompanying americium in the precipitate and, also, because americium oxalate is a convenient starting point for preparation of AmO_2. The insoluble Am(V) carbonate complex is particularly useful for the large-scale separation of americium from curium (Buijs *et al.*, 1973; King *et al.*, 1973).

Hermann (1956) demonstrated that a substantial separation of americium from lanthanum can be obtained by fractional precipitation of americium and lanthanum oxalates. The precipitation is effected in homogeneous solution; the precipitant is generated by slow hydrolysis of dimethyl oxalate. The oxalate precipitate is greatly enriched in americium; about 50% of the lanthanum can be rejected at each stage with only about 4% of the americium.

Stephanou and Penneman (1952) found that Cm(iii) could be separated from americium by oxidizing the latter to Am(vi) with potassium persulfate and precipitating CmF_3; Am(vi) is soluble under these conditions. Proctor and Connor (1970) at the US DOE Rocky Flats site used precipitation of cerium peroxide to separate gram quantities of americium from cerium. Proctor (1976) also separated Am(vi) from large quantities of rare earths by precipitation of their trifluorides.

Bhanushali *et al.* (1999) have recently proposed a new application of oxalate precipitation technology for separation of americium. Based on some experimental data, these workers suggest that traces of americium and plutonium remaining in the aqueous waste generated during plant-scale precipitation of plutonium oxalate can be effectively removed by simple coprecipitation with thorium oxalate. It is not known if such a coprecipitation step has been incorporated into routine processing of plutonium in India.

8.4.3 Solvent extraction processes

Solvent extraction processes and systems using amine and organophosphorus compounds are extensively used for the initial recovery and separation of gram to kilogram amounts of americium. Excellent reviews of the solvent extraction chemistry of trivalent americium have been published by Weaver (1974) and Shoun and McDowell (1980). Myasoedov *et al.* (1974a) discussed solvent extraction systems useful for the analysis of americium.

(a) Organophosphorus extractants (Gureev *et al.*, 1970)

(*i*) *Tri*-n-*butyl phosphate* (*TBP*)

TBP is the extractant in widest use for nuclear fuel processing. Extraction of Am^{3+} from nitrate media by TBP conforms to the reaction (Weaver, 1974):

$$\mathrm{Am^{3+}(aq) + 3\,NO_3^-(aq) + 3\,TBP(org) \rightarrow Am(NO_3)_3 + 3\,TBP(org)}$$

The equilibrium constant, $K_{\mathrm{ex}} = [\mathrm{Am(NO_3)_3 \cdot 3TBP}]/[\mathrm{Am^{3+}}][\mathrm{NO_3^+}]^3[\mathrm{TBP}]^3$, has the value of 0.4 at zero ionic strength (Zemlyanukhin *et al.*, 1962). While

TBP, even undiluted, extracts americium only weakly from strong nitric acid solutions, americium is extracted by TBP quite strongly from neutral (or low-acid), highly salted nitrate solutions.

As part of their intensive effort to develop feasible partitioning–transmutation technologies, Kamashida and his coworkers investigated TBP extraction of Am(VI) from nuclear reactor fuel reprocessing solutions (Kamashida and Fukasawa, 1996; Kamashida *et al.*, 1998) as a means of removal of americium while separating it from associated trivalent rare earths (good separation of americium from rare earth elements is desirable/necessary to make efficient use of neutrons in the transmutation process). In these studies, Am(VI) was produced by oxidation of Am(III) with silver-catalyzed peroxydisulfate, both in the presence and absence of $(NH_4)_{10}P_2W_{17}O_{61}$ added to stabilize americium in the hexavalent oxidation state. By use of neat TBP to extract Am(VI) from 1 M HNO_3, an americium distribution ratio as high as 4 was realized; the separation factor from Nd(III) was 50.

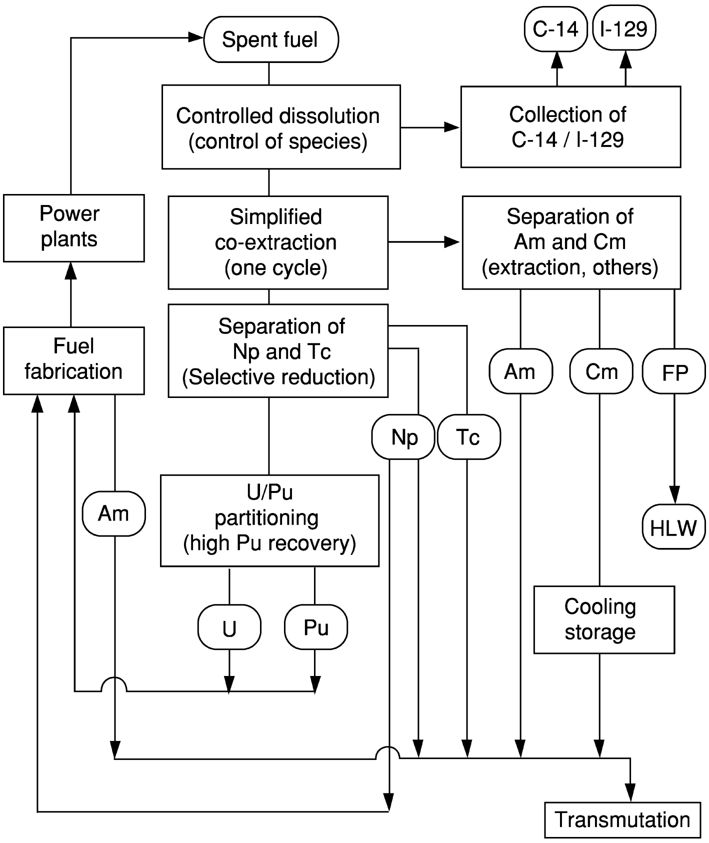


Fig. 8.1 *Schematic of Japanese PARC process* (*Uchiyama* et al., 2000).

In other recent studies, Japanese scientists have developed an advanced Purex process, the PARtitioning Conundrum Key (PARC) process (Uchiyama *et al.*, 2000). Fig. 8.1 shows a schematic diagram of the PARC process concept where americium is not separated in the mainline Purex process, but from HLW generated in the Purex process. The PARC process thus provides for use of certain organic compounds to provide effective Purex process recovery and separation of uranium, neptunium, plutonium, and technetium. Uchiyama *et al.* (2000) conducted tests of parts of the PARC process with aqueous feeds resulting from nitric acid dissolution of highly irradiated (8000 MWD/tU) fuel. Important findings were:

- Np(VI) was reduced to Np(V) by *n*-butyraldehyde selectively in the presence of U(VI), Pu(VI), and Tc(VII);
- high acid scrubbing was effective for separation of technetium;
- isobutyraldehyde reduced Pu(IV) to Pu(III) very effectively;
- *N*-butylamine compounds (carbonate and oxalate) were effective solvent-washing agents.

The French, as stated earlier, are energetically pursuing the partitioning–transmutation alternative for their Purex process HLW. Apparently for proprietary reasons, they have not widely publicized their progress. However, a recent article (NN, 2002) states: "... the Marcoule team have been able to push the current Purex processing technique to enable about 99% of uranium, plutonium, and the minor actinides of most concern, which are neptunium, americium, and curium to be isolated. The separation levels of the main long-lived fission products, which include iodine-129, technetium-99, and cesium-135, are equally impressive. The yields of iodine and technetium extracted are 95 and 90%, respectively. The process for separating cesium is nearing fruition, and technical feasibility is also expected by 2005. These levels of separation provide important benefits as the resulting vitrified waste contains fewer long-lived isotopes. According to the CEA, the radioisotopes of the advanced vitrified product – referred to as 'light glass' – will drop to the level of natural uranium in less than 300 years. This compares to more than 10000 years for the current vitrified HLW and hundreds of thousands for spent fuel." The article in *Nuclear News* does not provide any detail as to the Purex process modifications used to separate americium; it may be, just as in the Japanese PARC process, that the French plan to recover americium from the Purex process HLW by any of several available procedures.

It should be noted that formation constants of complexes formed by Am(III) with aminopolycarboxylic acids are larger than for the comparable complexes of the light lanthanides ($Z = 57$–61). Thus, addition of an aminopolycarboxylic acid to a lithium or aluminum nitrate solution containing Am(III) and rare earth enhances TBP extraction of the lanthanides relative to americium (Koehly and Hoffert, 1967). Americium can be separated from rare earths by TBP extraction from 1 M ammonium thiocyanate solution (Penneman and Keenan, 1960).

The mechanism of Am(III) and Eu(III) extraction from 1 M ammonium thiocyanate media by TBP in both the presence and the absence of a quaternary ammonium thiocyanate compound was investigated by Indian scientists (Khopkar and Narayankutty, 1971).

(*ii*) *Dibutyl butylphosphonate* (*DBBP*)

DBBP, $(C_4H_9O)_2(C_4H_9)PO$, extracts Am(III) from nitrate media more strongly than TBP and was used in a production-scale process at the US DOE Hanford site for several years (Schulz, 1976).

(*iii*) *Trialkylphosphine oxides* (*TRPO*)

It is well known that the basicity of the P–O functionality increases in going from alkyl phosphates (e.g. TBP) to alkyl phosphonates (e.g. DBBP) to alkylphosphine oxides (e.g. TRPO). Corresponding to the increased basicity is increased extractive power for trivalent actinides, e.g. Am(III) and Cm(III) from aqueous 1–2 M HNO_3 solutions. Chinese investigators have made use of the extractive power of TRPOs to develop a process for partitioning actinides, including americium and curium, from acidic Purex process HLW (Zhu and Jiao, 1994). Most of the results of Zhu *et al.* have been published in Chinese language journals, which, apparently, have not been translated into readily available English versions. Zhu and Jiao (1994) presented an admirable English language summary of their work up to 1994. They used a 30 vol% TRPO–kerosene solvent to extract trivalent (Am, Cm, lanthanides), tetravalent (Np, Pu), and hexavalent (U) actinides from both synthetic and actual Purex process HLW adjusted to about 1 M HNO_3. These experimenters used a mixture of C_6–C_8 alkylphosphine oxides available commercially (at least in the early 1990s) from operation of a fertilizer manufacturing plant. Zhu and coworkers found their particular 30% TRPO reagent to be very effective in extracting over 99% of all the actinides and lanthanides from the adjusted HLW. Extracted actinides could be stripped successively with 5.5 M HNO_3, 0.6 M oxalic acid, and 5% Na_2CO_3 solution to yield Am + rare earth, Np + Pu, and U fractions, respectively. Auxiliary experiments showed the TRPO solvent to have excellent actinide extraction kinetics and to be quite resistant to radiolytic degradation. Their highly successful batch and continuous countercurrent extraction–stripping tests led the Chinese to believe (at least in 1994) that their TRPO extractant was eminently suited for use in plant-scale partitioning of actinides from Chinese defense HLW. We, the authors, were not able to establish the present status of development/utilization of the Chinese TRPO extraction process.

Very recently, Murali and Mathur in India revisited use of TRPO for partitioning actinides from Purex process HLW (Murali and Mathur, 2001). They used a 30 vol% solution of a commercially available mixture of alkyl TRPOs (Cyanex-923) in dodecane. Cyanex-923 (Cytec Canada, Inc.) is a mixture of four alkylphosphine oxides, $R_3PO, R'_3PO, R_2R'PO, RR'_2PO$; R = hexyl and R′ = octyl. (Murali and Mathur point out that Cyanex-923 is not the same mixture of alkylphosphine oxides used earlier by the Chinese investigators.) With dodecane as the diluent, the Indian investigators found it necessary to add TBP (5–20 vol%) to the Cyanex-923-dodecane solvent to avoid formation of a third phase even after adjusting the HLW acidity to 1 M HNO_3. Under the latter conditions, Murali and Mathur were able to both successfully extract and strip actinides, including americium, from synthetic Purex process HLW. Despite this successful performance, Murali and Mathur judged, "... the TRUEX solvent (0.2 M CMPO + 1.2 M TBP in dodecane) seems to be a superior extractant for partitioning of minor actinides from HLW solutions as there is no need for any feed adjustment and it tolerates significant amounts of sulfate, fluoride, and oxalate anions." (The TRUEX process is discussed in the later part of Section 8.4.3.)

(*iv*) *Bis*(*2-ethylhexyl*)*phosphoric acid* (*HDEHP*)

HDEHP is an excellent extractant for Am(III) from certain aqueous solutions. This extractant is commercially available in large quantities, can be readily purified, and has been widely used for both analytical purposes and plant-scale recovery and purification of americium (Peppard *et al.*, 1958, 1962; Gureev *et al.*, 1964). A countercurrent HDEHP extraction process was used at the DOE Hanford site in the late 1960s as part of the processing sequence for recovering and purifying 1 kg of americium and 50 g of curium from irradiated Shippingport reactor fuel (Boldt and Ritter, 1969). An HDEHP batch extraction–strip process (Cleanex process) was routinely used in the Transuranium Processing Plant at the DOE Oak Ridge National Laboratory to reclaim americium, curium, and other transuranium elements from rework solution and/or to convert from nitrate to chloride media (Bigelow *et al.*, 1980). The Talspeak HDEHP processes are based upon the results of Weaver and Kappelmann (1964) who were the first to show that HDEHP extracts lanthanides much more strongly than actinides from aqueous carboxylic acid solutions containing an aminopolycarboxylic acid chelating agent. Lactic acid is used to avoid precipitation of solids when the concentration of lanthanides is high. HDEHP solutions have been used to selectively extract Am(VI) from Cm(III) (Musikas *et al.*, 1980a); in such systems rapid reduction of Am(VI) to lower oxidation states is a problem.

Extraction of Am(III) is very sensitive to the nature of compounds used to dilute the HDEHP (Gureev *et al.*, 1964). The kinetics of Am(III) extraction by HDEHP solutions were studied by Choppin and Nash (1977). In 1998, Indian scientists (Mapara *et al.*, 1998) studied solvent extraction of Am(III) from aqueous 0.1–1.0 M HNO_3 solutions using both HDEHP and 2-ethylhexyl phosphonic acid (PC88a in their notation). Before use, 1 M solutions of both extractants in kerosene were partially neutralized (saponified) to varying degrees with NaOH. In agreement with previously well-known chemistry of

HDEHP and PC88a, Am(III) extraction increased as more and more of the acidic extractant was converted to the sodium form.

(*v*) *Diisodecylphosphoric acid* (*DIDPA*)

Morita, Kubota, and other Japanese scientists (Morita and Kubota, 1988; Morita *et al.*, 1993) closely examined properties of solutions of DIDPA for extraction of actinides from acidic Purex process HLW. DIDPA solutions extract hexavalent (U) and tetravalent (Pu,Np) actinides quite efficiently from 1 to 3 M HNO_3 media. (Before extraction of ^{237}Np, however, it must be first reduced to Np(IV) by reduction of Np(V) and Np(VI) with hydrogen peroxide.) But, a disadvantage of the DIDPA extraction technique is that trivalent americium and curium do not extract well at feed acidities much above about 0.5 M HNO_3. Once extracted, Am(III) and Cm(III) can be selectively stripped with a diethylenetriaminepentaacetic acid (DTPA) solution; lanthanides can be easily stripped with 4 M HNO_3; and plutonium and neptunium can be removed from the organic phase by stripping with an aqueous oxalic acid solution. Japanese tests, both batch and countercurrent, of the DIDPA process with simulated Purex process HLW were generally regarded as successful.

(*vi*) *Neutral multifunctional organophosphorus and carbamoylphosphonate reagents*

Monofunctional organophosphorus extractants, e.g. TBP, DBBP, tri-*n*-octylphosphine oxide (TOPO), do not extract Am(III) from strongly acidic (>1 M HNO_3) aqueous solutions. Such behavior is desirable when the goal decades ago was to separate and purify plutonium and uranium from nitric acid solutions of irradiated nuclear fuel, e.g. the Purex process. But, evolving nuclear waste management strategies and policies have driven an urgent need for liquid–liquid extraction agents and processes capable of effective recovery and/or removal of Am(III) and Cm(III) as well as actinides in the +4 and +6 oxidation states from strong nitric acid medium. Thus, in the USA in the 1970s and 1980s there was an economic incentive to convert so-called transuranic acidic waste solutions containing ^{241}Am and various other actinides, chiefly plutonium, to low-level waste, which could be disposed of inexpensively. And, of course, the emergence of the partitioning–transmutation philosophy for advanced nuclear waste management and disposal places a premium on solvent extraction technology for efficient removal of trivalent actinides from acidic HLW solutions.

In the early 1960s, Siddall (1963, 1964) opened the door to the desired practical solvent extraction schemes for extraction of trivalent americium and curium from concentrated nitric acid solutions. Siddall in his papers noted that certain bifunctional organophosphorus reagents, e.g. diphosphonates and carbamoylmethylphosphonates (CMPs), i.e. compounds of the type $(R_1O)_2P(O)$—$(CH_2)_n$—(O)C—N—$(R_2)_2$, were especially effective in extracting trivalent actinides and lanthanides from strong nitric acid solutions.

Siddall's highly significant work lay buried in the literature until resurrected by Schulz and coworkers (Schulz, 1974, 1975; McIsaac and Schulz, 1976; Schulz and Navratil, 1982) in the early and middle 1970s. Both Schulz at the US DOE Hanford site and McIsaac at the US DOE Idaho site were motivated to develop solvent extraction processes for removing Am(III) and Pu(IV) from certain site acid waste solutions to convert the large volumes of these wastes to more easily managed and disposed of low-level wastes.

Based upon Siddall's data, both Schulz and McIsaac elected to use dihexyl-*N*,*N*-diethylcarbamoylmethyl phosphonate (DHDECMP) as the extractant for Am(III) and 4+ and 6+ actinides. Siddall's results indicated that CMPs were better extracting agents for 3+ actinides than diphosphonates. Another candidate, dibutyl-*N*,*N*-diethylcarbamoylmethylphosphonate, was rejected for use because of its high solubility in aqueous phases. Finally, of considerable significance, DHDECMP was available in liter quantities, albeit in a highly impure state (50–70% DHDECMP), from the Wateree Chemical Co. in South Carolina.

Batch tests with the impure DHDECMP solvent at both the Hanford and the Idaho sites quickly confirmed Siddall's results and demonstrated that this particular reagent would indeed permit efficient removal of all actinides from actual candidate acidic wastes. Auxiliary tests soon showed DHDECMP were sufficiently resistant to radiolysis, both alpha and gamma, to have a long useful life in plant-scale continuous countercurrent operations, especially in short residence time contacting equipment. Kinetics of actinide extraction and stripping were sufficiently rapid for satisfactory operation of continuous countercurrent contactors. The propensity of 20–30 vol% DHDECMP–NPH (normal paraffin hydrocarbon) solvents to form a third phase (second organic phase) when contacted with some acidic (HNO_3) waste solutions was overcome by either changing to an aromatic diluent, e.g. tetrachlorobenzene or decalin, or substituting TBP for a large portion of the NPH diluent. All the batch contact experiments culminated in chemical flowsheets (extraction–scrub–strip) that were very successfully demonstrated with both actual Idaho and Hanford sites acid waste solutions.

The only serious discordant note observed in tests with the impure Wateree Chemical Co. DHDECMP arose in attempts to use very dilute, e.g. ~0.01 M HNO_3 solutions to selectively strip 3+ actinides and lanthanides from pregnant organic phases. With as-received DHDECMP extractant D_{Am} instead of decreasing regularly upon successive strip contacts actually increased, resulting in a certain fraction of unstrippable americium. Such behavior is very symptomatic of the presence of an acidic organic compound in an otherwise neutral extractant. To overcome the deleterious effects of the acidic organic impurity, the 20–30 vol% DHDECMP solvent, before use, was subjected to various empirical chemical treatments designed to remove or at least reduce the concentration of the impurity, e.g. washing with ethylene glycol or alternate washing with HCl and NaOH solutions to hydrolyze the organic impurity. These chemical treatments, although cumbersome, removed enough of the offending impurity to allow successful selective stripping of americium in continuous countercurrent flowsheet tests.

Tetravalent actinides and, if not previously removed, trivalent actinides were easily and effectively stripped from the DHDECMP phase with aqueous solutions containing fluoride or oxalate ions. And, as would be expected, dilute NaOH solutions effectively removed all 3+, 4+, and 6+ actinides from the DHDECMP solvent.

Following publication of the Schulz and McIsaac work, many other investigators, both in and outside the USA, conducted comprehensive experimental studies with DHDECMP and various other CMP-type reagents (Martella and Navratil, 1979; Petrzilova *et al.*, 1979; Horwitz *et al.*, 1981; Kalina *et al.*, 1981b; Hugen *et al.*, 1982; McIsaac, 1982; McIsaac and Baker, 1983; Kalina and Horwitz, 1985; Mathur *et al.*, 1991, 1992b). Indeed, as late as 1994, long after the TRUEX process had been proposed (cf. Section 8.4.3a(vi)), Rapko and Lumetta (1994) were still investigating use of a 0.75 M DHDECMP–1.05 M TBP/NPH solvent for extracting U(VI), Pu(IV), and Am(III), as well as competing metal ions, e.g. Fe(III), Zr(IV), from nitric acid solutions. And, in the late 1980s DHDECMP-based flowsheets were still under consideration for removal of all actinides from the DOE Idaho site sodium-bearing waste. Most of the work with CMP-based reagents after the early Schulz and McIsaac studies were done with DHDECMP; some investigators, however, synthesized various other CMP-type compounds to investigate their capability for extracting 3+ as well as 4+ and 6+ actinides from various acid waste solutions.

As discussed in the next section, CMP processes for efficient extraction of Am(III) and other actinides from acidic media have been supplanted and superseded by advanced organophosphorus reagent technology. Even so, the significance of the pioneering work of Schulz and McIsaac cannot be overstated. Through their efforts, scientists and engineers throughout the world became aware of Siddall's papers and the great potential of multifunctional organophosphorus reagents in actinide separation and recovery from many other sources.

Carbamoylphosphine oxide reagents

"CMPO" is a generic acronym for any carbamoylmethylenephosphine oxide. CMPO is also used here and elsewhere in the literature to denote one particular compound, namely, octylphenyl-*N*,*N*-diisobutylmethylenecarbamoylphosphine oxide, $(C_8H_{17})(C_6H_5)P(O){-}CH_2{-}(O)C{-}N{-}N{-}(iC_4H_9)_2$. The actinide separation community is indebted to Dr E. P. Horwitz and his colleagues for their innovative efforts in initially synthesizing this particular CMPO and in evaluating many of its outstanding properties.

Being familiar with the Schulz and McIsaac results with DHDECMP (Section 8.4.3a(vi)), and having worked with this carbamoylphosphonate, Horwitz was motivated to find an improved trivalent actinide extractant with the following highly desirable attributes:

- Greatly increased capability for extracting 3+ actinides.
- Ease of synthesis of high-purity reagent.
- Increased solubility/compatibility with straight-chain hydrocarbon diluents.
- Excellent chemical and radiolytic stability.
- Suitability of extractant-diluent(s) solution for use in centrifugal contactors.
- Satisfactory selectivity for actinide and lanthanide extraction from aqueous media.

Horwitz's aspirations were essentially realized with the synthesis of the octylphenyl CMPO compound and the many successful tests of this reagent.

Gatrone and coworkers (Gatrone and Rickert, 1987; Gatrone *et al.*, 1987, 1989) published complete details of the synthesis of CMPO via a Grignard reaction. The crude CMPO product from the Grignard synthesis contains one or more acidic organophosphorus impurities that seriously interfere with the use of dilute nitric acid solutions to strip trivalent actinides and lanthanides. After testing various purification schemes, Gatrone and coworkers concluded that the most effective way to remove the offending acidic compounds was to first contact a heptane solution of the CMPO with 50 g L^{-1} of a macroporous cation-exchange resin at 50°C and then, without removing the cation resin, contact the heptane–CMPO solution with 50 g L^{-1} of a macroporous anion-exchange resin. This procedure, which Gatrone and his collaborators believe is generic and applicable to removal of acidic compounds from anyneutral organophosphorus extractant, yields solvent extraction-grade CMPO, i.e. $D_{\mathrm{Am}} = <0.02$ in 0.01 M HNO_3/CMPO.

Many different diluents have been used in bench-scale studies of the extraction properties of solvent extraction-grade CMPO. Candidate diluents used at one time or another include aromatic (decalin), chlorinated (tetrachloroethylene), and aliphatic (dodecane) commercially available mixtures of C_{10}–C_{12} NPHs. For plant-scale application of CMPO a mixture of NPHs is the preferred diluent. However, HNO_3 and metal nitrates, e.g. lanthanide nitrates, have only a very limited solubility in CMPO/NPH solutions; once the solubility limit is exceeded, the organic phase splits into two phases (familiar third-phase formation phenomenon). Horwitz *et al.* (1985b) found that a simple and highly effective way to avoid the complications of a third-phase formation is to dilute the CMPO extractant with Purex process solvent to yield, for example, a 0.2 M CMPO/1.2 M TBP/dodecane solution. This solvent composition allows the CMPO fraction to be loaded to near theoretical capacity with trivalent lanthanides without causing a second organic phase to form. And, of course, an added advantage of the latter solvent composition is that its physical properties are little changed from those of familiar Purex process solvent and, therefore, no mechanical difficulties are encountered in operating centrifugal (or other) contactors with the CMPO/TBP/dodecane (or NPH) solvent. Horwitz and coworkers (Kalina *et al.*, 1981a; Horwitz *et al.*, 1982, 1985b, 1986; Horwitz and Kalina, 1984; Kolarik and Horwitz, 1988), as well as many other investigators (Liansheng *et al.*, 1991; Mathur *et al.*, 1992a; Rapko, 1995), conducted comprehensive bench-scale studies to establish the extractive properties of CMPO/TBP/diluent solvents for many different metal ions over a wide range of conditions. Most of these studies were concerned with the extraction of actinides and other metal ions from nitrate-based aqueous media with CMPO/TBP/dodecane (or NPH) solvent, but some work has been done with aqueous HCl solutions (Horwitz *et al.*, 1987). All these bench-scale studies confirmed that the CMPO/TBP/diluent mixture would efficiently extract trivalent actinides and lanthanides as well as 4+ and 6+ actinides from almost any strong, i.e. ca. 1 M, nitric acid solution. Indeed, the more or less constant distribution ratio values for Am(III), Pu(IV), and U(VI) between 1 and 6 M HNO_3 is a very valuable and unique aspect of the CMPO/TBP system.

While the lanthanides and actinides are extracted almost quantitatively by CMPO/TBP/diluent solutions, with only a few exceptions most common metal ions in nuclear waste solutions are not extracted by the CMPO reagent (Horwitz *et al.*, 1985b). Not unexpectedly, Zr(IV) is significantly extracted ($D_{Zr} = \sim 1–3$) by CMPO/TBP/diluent solution from aqueous 1 M HNO_3. Zirconium is one of the major constituents of the DOE Idaho site waste; this particular waste also contains large concentrations of fluoride ion, which, fortunately, greatly inhibits CMPO extraction of inert zirconium (McIsaac and Baker, 1983). Paralleling known Purex process experience, ^{99}Tc, if present, is also well extracted (D_{Tc} = 1–3) from nitric acid feed solutions as the $HTcO_4$ species. (Technetium largely remains in the CMPO phase during actinide scrubbing and stripping stages and is removed when the CMPO phase is washed with alkaline carbonate solutions to remove degradation and other species.) Other metallic contaminants of some interest (D_M = 0.1–0.6) include Mo, Ru, Pd, Ag, and Fe; these constituents are present in nearly all nuclear waste solutions that contain Am and other actinides. Adequate separation of actinides from the latter metal ions in CMPO extraction systems can be controlled by adding oxalic acid to the feed solution and/or by scrubbing the CMPO extract with a dilute oxalic solution before stripping of actinides.

To strip actinides from the CMPO/diluent or, more commonly, CMPO/TBP/NPH phase, conventional practice is to selectively strip, in order, 3+ actinides and lanthanides, 4+, and, if present, 6+ actinides. For this order of actinide stripping, preferred reagents (Mathur *et al.*, 2001) are, respectively, dilute nitric acid, e.g. <0.05 M HNO_3; a dilute oxalic acid, dilute ammonium oxalate, or a mixture of HF and HNO_3, e.g. 0.05 M HNO_3/0.05 M HF; and dilute sodium carbonate, e.g. 0.25 M Na_2CO_3. Sodium carbonate solutions do double duty and also act as a solvent cleanup reagent to remove solvent degradation products. But, in the case where it is desired to strip all the 3+, 4+, and 6+ actinides and lanthanides into a single aqueous phase, Horwitz and Schulz (1990) recommended use of a solution of either vinylidene-1,1-diphosphonic acid (VDPA) or 1-hydroxyethylene-1,1-diphosphonic acid (HEDPA). Also, in a novel approach, Rizvi and Mathur (1997) utilized the ferrocyanide ion to co-strip actinides and lanthanides from CMPO phases. Other stripping agent studies of interest are those of Chitnis *et al.* (1998, 1999) who used a mixture of formic acid, hydrazine hydrate, and citric acid to remove Am(III) and Pu(IV) from CMPO solutions. Finally, Ozawa *et al.* (1998) reported that a mixture of hydrazine oxalate, hydrazine carbonate, and tetramethylammonium hydroxide will selectively strip 3+, 4+, and 6+ actinides from CMPO extractants.

A matter of concern for any liquid–liquid extraction process, especially one dealing with radionuclides, is the resistance of the extractant and its diluents to chemical and radiolytic degradation. Five separate studies (Chiarizia and Horwitz, 1986, 1990; Nash *et al.*, 1988, 1989; Mathur *et al.*, 1998) addressed this concern for CMPO extraction systems. Three of these investigations were concerned only with CMPO/TBP/dodecane solvents while two (Chiarizia and Horwitz, 1986; Nash *et al.*, 1988) also addressed radiolysis of CMPO diluted with decalin or tetrachloroethylene. Test solvents were irradiated both neat and while in contact with aqueous nitric acid solutions. Although results varied to some degree with the reagent used to dilute the CMPO and TBP, the general degradation behavior of CMPO/TBP/diluent solvent was independent of the nature of the diluent. Thus, the general degradation behavior is that chemical hydrolysis produces only acidic degradation products while radiolysis generates both neutral and acidic organophosphorus compounds.

The neutral organophosphorus degradation products of CMPO serve only as diluents for CMPO and TBP. But the acidic radiolytic degradation products are highly troublesome because they seriously interfere with stripping of Am(III) by dilute (<0.05 M HNO_3) solutions. Mathur *et al.* (2001) have published an excellent table, based on data obtained by Mathur *et al.* (1998) that illustrates very markedly the increase in the distribution ratio for Am(III) at 0.04 M nitric acid upon irradiation of a 0.2 M CMPO/1.2 M TBP/dodecane solvent to a total absorbed dose of 26–28 Mrad. According to these data, up to a dose of about 20 Mrad the distribution ratio of Am(III) at 0.04 M nitric acid is less than 1 and, hence, stripping with 0.04 M nitric acid should still be possible. Also, up to a dose of about 20 Mrad washing the spent solvent with a dilute sodium carbonate solution will remove most of the acidic degradation products. But, at higher absorbed radiation doses, in addition to sodium carbonate washing, it is necessary to provide a secondary solvent cleanup step, i.e. treatment with macroporous anion and cation-exchange resins or treatment with basic alumina.

In 1985, Horwitz and his collaborators (Horwitz and Schulz, 1985, 1986, 1990, 1999; Horwitz *et al.*, 1985a,b; Schulz and Horwitz, 1988) proposed a generic actinide solvent extraction process, the TRUEX process (Table 8.2) based on the superior properties of CMPO to remove all 3+, 4+, and 6+ actinides from any nitrate-based aqueous nuclear waste solution. The generic

TRUEX process, which utilizes a nominal 0.2 M CMPO/1.05 M TBP/dodecane (or other NPH-type diluent) solvent, is intended for use in short residence time centrifugal contactors. It typically comprises four separate operations: extraction, scrubbing of the organic phase, one or more stripping steps, and solvent cleanup. The users of the TRUEX process are free to specify whatever the number of extraction stages and organic-to-aqueous phase flow ratios are required to provide the required degree of removal of Am(III) and other actinides. Similarly, the TRUEX process operator is responsible for choosing the number of scrub stages (if any) and the composition of scrub solution(s) needed to adequately remove any co-extracted impurities, e.g. Zr(IV). The generic TRUEX process allows, by choosing particular aqueous phase strip compositions, either selective stripping of 3+, 4+, and 6+ actinides or stripping of combinations of actinides, e.g. 3+ and 4+ or 4+ and 6+. One or two contactor stages for washing the stripped TRUEX process solvent with a dilute sodium carbonate solution are typically included to remove solvent degradation products and any traces of metal ions. Investigators in several countries have conducted continuous countercurrent demonstrations of variations of the TRUEX process with actual radioactive waste solutions of interest to them: references cited in the following list should be consulted for further details:

For various reasons, including the prolonged Cold War syndrome, Russian scientists, largely independent of Western world progress, conducted extensive studies of the actinide extraction properties of multifunctional organophosphorus reagents (Myasoedov *et al.*, 1980, 1986; Chmutova *et al.*, 1983, 1989; Myasoedov and Lebedev, 1991). A recent review paper by Myasoedov (1994) is of special interest. The Russian version of the American TRUEX process utilizes diphenyl-*N*,*N*-dibutylcarbamoylmethylenephosphine oxide dissolved in a commercially available (at least in Russia) fluoroether diluent (Fluoropol 732). According to Russian investigators, use of the fluoroether diluent eliminates any need to dilute the diphenyl CMPO with TBP to avoid third-phase formation; but others (Horwitz and Schulz, 1999) have expressed concern that diluent degradation under plant-scale conditions could lead to undue formation of corrosive HF. The Russian transuranium element extraction process behaves very similarly (Myasoedov, 1994) to the TRUEX process in its efficiency for extracting trivalent americium; in continuous countercurrent tests of the process in centrifugal extractors greater than 99.5% of the actinide elements in the aqueous feed were removed. In addition to the possibility of excessive generation of HF, other possible limitations to the Russian process include difficult americium stripping because of the need to use a very low concentration of nitric acid in the aqueous strip solution and complex solvent cleanup before reuse of the solvent (Horwitz and Schulz, 1999). In addition to the americium extraction results discussed earlier in Section 8.4.3a, certain other, more academically oriented studies of the extraction characteristics of novel phosphate-based reagents are of interest. For example, Paine and his research group (Bond *et al.*, 1997, 1998) investigated the extraction of Am(III) by 1,6-bis(diphenylphosphino)methyl-pyridine-*N*,*P*,*P*′-trioxide solutions from both hydrochloric and nitric acid media. And, Mishra *et al.* (1996) investigated the synergistic extraction of Am(III) by a mixture of Aliquat 336 and TOPO from acidic nitrate medium.

Rais and Tachimori (1994) studied the synergism in extraction and separation of Am(III) and Eu(III) in two systems: (1) dicarbollide anion and dibutyldiethylcarbamoylmethylenephosphonate (DBDECMP) and (2) dicarbollide anion and CMPO. Synergism was observed in both systems at low aqueous phase acidities but the effect was lower with CMPO than with DBDECMP.

Mohapatra and Manchanda (1995, 1999) reported on the unusual extraction behavior of Am(III) and UO_2^{2+} from aqueous picric acid solutions by TBP and TOPO extractants. Surprisingly, under these conditions, the organophosphorus compounds extract Am(III) better than the uranyl ion. Of course, from aqueous nitrate media, TBP and TOPO both extract U(VI) much better than Am(III). Mohapatra and Manchanda attribute the different extraction order from picric acid media to the formation of outer sphere rather than inner-sphere coordination complexes.

(b) Amine extractants

Nitrogen-based extractants, especially tertiary amines and quaternary ammonium compounds, are particularly effective in separating and recovering americium and other actinide elements from aqueous media.

(*i*) *Tertiary amine salts*

Tertiary amine salts extract Am^{3+} poorly from concentrated nitric or hydrochloric acids but extract it very strongly from concentrated nitrate or chloride solutions of low acidity (Myasoedov *et al.*, 1974a). Marcus *et al.* (1963) and Horwitz *et al.* (1966) found that Am^{3+} is extracted from nitrate media as complex $(R_3NH)_2Am(NO_3)_5$. A much more detailed account of the application of tertiary amine salts to extract americium is provided in Schulz (1976); indeed, essentially all the reported results obtained with tertiary amine salts in extraction of americium have been summarized in Schulz (1976).

(*ii*) *Quaternary ammonium salts*

Quaternary alkylammonium nitrate salts were shown by Horwitz *et al.* (1966) to extract Am^{3+} considerably more efficiently from low-acid, highly salted aqueous nitrate solutions than do tertiary alkylamines. The extraction sequence for trivalent actinides into either Aliquat 336 (a mixture of trioctylmethylammonium and tridecylmethylammonium salts made by General Mills, Inc.) nitrate or trilaurylmethylammonium nitrate is Cm<Cf<Am<Es. Horwitz *et al.* (1969) included an extraction step with Aliquat 336 in the preparation of 20–30 Ci of high-purity ^{242}Cm. Koch and Schoen (Koch and Schoen, 1968; Koch, 1969) devised and tested on a laboratory scale a quaternary ammonium extraction process for the isolation of ^{241}Am from aged plutonium scrap. Advantages of a quaternary ammonium nitrate extraction process over other schemes, e.g. Tramex process, for isolating trivalent lanthanides and actinides were discussed by Moore (1966a). Finally, Moore (1964, 1966b) and later Gerontopulos *et al.* (1965) found that the thiocyanate salt of Aliquat 336 preferentially extracts actinides over lanthanides in moderately concentrated NH_4SCN solutions.

(c) Amide extraction reagents

Diamide extractants are generally organic compounds with the generic formula $(R_1,R_2)N–C(O)–CR_3H–C(O)–N(R_1,R_2)$ where R_1, R_2, and R_3 are (typically) alkyl substituents. For various reasons, including doubtlessly their well-recognized nationalistic pride, French investigators have chosen to focus on diamides for possible application in partitioning of americium and other actinides from aqueous Purex process HLW vis-à-vis one of the more well-known and tested carbamoylphosphonates or phosphine oxides. Interestingly, various researchers including the French repeatedly extol the virtues of the carbon, hydrogen, oxygen, nitrogen (CHON) principle, i.e. design and use of liquid–liquid extraction reagents that contain neither sulfur nor phosphorus. Supposedly, degraded CHON-type extractants would be easier to dispose of, e.g. incinerate, than spent extractants that contain phosphorus or sulfur; there are no economic or technical data and/or experience to support the latter claim.

Between 1987 and 2002, numerous diamide compounds have been synthesized and examined for their ability to extract actinides in various oxidation states from aqueous nitric acid solutions. Details and results of these studies were reported (Musikas and Hubert, 1983; Musikas, 1987, 1995; Charbonnel and Musikas, 1988; Cuillerdier *et al.*, 1991a,b, 1993; Musikas *et al.*, 1991; Baudin *et al.*, 1993; Madic *et al.*, 1994; Nigond *et al.*, 1994; Shen *et al.*, 1996; Tan *et al.*, 1999).

Currently, one diamide, namely, *N*,*N*′-dimethyl-*N*,*N*′-dibutyl-2-tetradecylmalonamide (DMDBTDMA) appears particularly suitable for use in plant-scale removal of actinides from Purex process HLW. In France DMDBTDMA has been chosen as the extractant in their DIAMEX process for partitioning of actinides from Purex process HLW. Experiments show that DMDBTDMA is soluble in dodecane and does not produce a third phase when dodecane solutions are contacted with 3–4 M HNO_3. Indian scientists (Mahajan *et al.*, 1998) have also studied DMDBTDMA extraction of Am(III), U(VI), Np(IV), Fe(III), Sr(II), and Cs(I) from various nitric acid solutions and also from a simulated HLW, which would result from reprocessing of commercial pressurized water reactor fuel. These latter experiments confirm that DMDBTDMA is very promising for extraction of Am(III) and other actinides from 3 to 4 M HNO_3, particularly under high solvent loadings of neodymium or neodymium plus uranium.

Even after two decades, diamide extraction of actinides from nitric acid media is a continuing fertile research area. For example, Spjuth *et al.* (2000) have recently prepared seven new malonamide extractants by placing phenyl substituents on the nitrogen atoms in the malonamide or an ether oxygen into the bridging chain. The basicity of such compounds is reported to be less than that of DMDBTDMA, which makes them slightly better extractants for Am(III).

Sasaki and Tachimori (2002) have recently synthesized diamide extractants that they term 'structurally tailored diamides.' The diamides investigated include $(CH_2)_n$–$(CONR_1R_2)_2$ ($n = 0$, 1, 2, and 3); O–$((CH_2)_{n'}$–$CONR_1R_2)_2$; S–$((CH_2)_{n''}$–$CONR_1R_2)_2$; and SS–$((CH_2)_{n'''}$–$CONR_1R_2)_2$, (n', n'', $n''' = 1, 2$). The diglycolamide introducing an ether oxygen into the main structure, O–$(CH_2$–$CONR_1R_2)_2$, exhibits the highest extractability for An(III), An(IV), and An(VI) compared with the other bidentate diamides. The results of Sasaki and Tachimori also demonstrated that the thiaglycolamide, which substitutes an ether sulfur atom or oxygen in the molecule also enhances the extraction of actinides.

(d) Separation of americium from lanthanides

The challenge of separating Am(III) from trivalent lanthanides was first addressed and resolved by Weaver and Kappelmann (1964) as early as 1964. These investigators devised the Talspeak process that is based upon the fact that HDEHP solutions extract trivalent lanthanides much more strongly than trivalent actinides from aqueous carboxylic acid solutions containing an aminopolycarboxylic acid chelating agent.

A reverse Talspeak process involves, naturally, using an aqueous solution of an aminopolycarboxylic acid (e.g. DTPA) to preferentially strip Am(III) (and Cm(III) also if present) from an organic phase containing both trivalent actinides and lanthanides. In the DIDPA extraction process (Section 8.4.3a(v)) an aqueous lactic acid solution containing DTPA is used to strip trivalent americium and curium (Persson *et al.*, 1984); lanthanides remaining in the DIDPA phase are subsequently stripped with 4 M HNO_3.

In yet another application of the Talspeak process technology, the Japanese SETFICS (Solvent Extraction for Trivalent f elements Intragroup separation in CMPO-complexant System), a typical TRUEX process extraction stage, utilizes an aqueous 0.4 M $NaNO_3$ solution containing DTPA (Koma *et al.*, 1998). In a countercurrent test of the SETFICS process with radioactive feed, the reported ^{144}Ce/^{241}Am decontamination factor was 72.

The renewed focus on partitioning–transmutation technology that began in the 1980s (and continues unabated to this day) prompted many new studies of technology for separation of trivalent actinides from trivalent lanthanides. (See the review of the subject of lanthanide/actinide separations (Nash, 1994).) The breakthrough to more efficient lanthanide/actinide separation technology originated with Musikas in France who pointed out that soft-donor extractant molecules containing nitrogen or sulfur functionalities offered great potential to achieve the desired separation (Musikas *et al.*, 1980b; Musikas, 1984). In work published in the late 1970s and mid-1980s, Musikas reported that an extractant consisting of tripyridyltriazene (TPTZ) and dinonylnapthalene sulfonic acid (HDNNS) in carbon tetrachloride preferentially extracted Am(III) from a dilute nitric acid solution containing Am(III) and trivalent lanthanides. In 1985, Musikas in his paper noted that the HDNNS could be replaced by bromocapric acid in an aliphatic hydrocarbon diluent.

Musikas' seminal work in the mid-1980s has triggered a cascade of studies of the ability of other nitrogen (and also sulfur)-containing extractants to provide separation of trivalent actinides from trivalent lanthanides. Noteworthy examples of such research efforts, not in chronological order, include work by Ensor and coworkers (Ensor *et al.*, 1988; Smith *et al.*, 1989), who used the synergistic combination of 4-benzoyl-2,3-dihydro-5-methyl-2-phenyl-3H-pyrazol-3-thione and 4,7-diphenyl-1,10-phenanthroline as an extractant to separate trivalent americium and europium, in the USA; Ensor *et al.* reported Am/Eu separation factors of greater than 10 with this synergistic combination of reagents. In Germany, Kolarik *et al.* (1999) investigated an extraction system based on polyaza ligands, e.g. 2,6-di-(5,6-dipropyl-1,2,4-triazin-3-yl) pyridenes for selective extraction of trivalent actinides from 1.9 M NH_4NO_3/HNO_3 solutions. Kolarik *et al.* reported Am/Eu separation factors in the range 100–120. And, of course Madic and Hudson (1998) as late as 1998 were still investigating TPTZ extraction systems for separating trivalent actinides from associated lanthanides in France. Madic's latest efforts center around attempts to suppress the solubility of TPTZ in aqueous phases by placing alkyl substituents at the 2-pyridyl rings and in replacing bromocapric acid by other anion sources.

An effective nitrogen-based soft-donor extractant for separation of trivalent actinides and lanthanides clearly would adhere to the CHON principle. But, unfortunately, to date at least, research efforts from 1987 to 2002 do not appear to have yielded a nitrogen-based 3+ actinide extractant suitably effective and stable for use on a plant scale with radioactive aqueous nitrate media. Conversely, because of recent breakthrough research results obtained by Zhu and his coworkers, prospects for developing a sulfur-based soft-donor extractant (non-CHON-type) suitable for plant-scale application appear to be reasonably good. In 1996, Zhu and coworkers reported that the compound bis(2,3,4-trimethylpentyl)-dithiophosphinic acid dissolved in a suitable diluent, e.g. heptane, preferentially extracted Am(III) from Eu(III) in aqueous nitrate media (Zhu, 1995; Zhu *et al.*, 1996b, 1998); Zhu and his collaborators found a separation factor as high as 5900 in favor of Am(III). Of particular interest and advantage, bis(2,3,4-trimethylpentyl)-dithiophosphinic acid is marketed commercially by Cyanamide Canada, Inc. under the trade name Cyanex 301; Cyanex 301 contains 77.2% of the dithiophosphinic acid compound. The primary impurities in Cyanex 301 are 14.6% R_3PS, 3.5% R_2POOH, and 0.8% R_2PSOH (Zhu *et al.*, 1996b). Chen *et al.* (1996) developed a scheme for upgrading commercially supplied Cyanex 301 to >99% bis(2,3,4-trimethylpentyl)-dithiophosphinic acid.

The excellent results obtained by Zhu and his coworkers with as-received Cyanex 301 were quickly confirmed in work at Florida State University by Zhu *et al.* (1996a). Data in Fig. 8.2 clearly illustrate the propensity of Cyanex 301 solutions to provide clean separation of Am(III) from trivalent lanthanides in

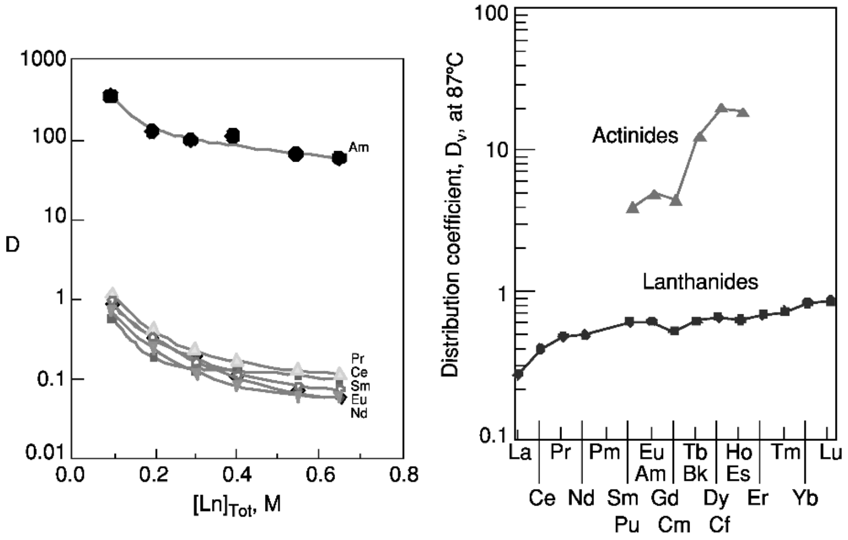

Fig. 8.2 *Distribution ratios of Am*(III) *and Ln*(III) *in* 1.0 M *Cyanex* 301-*heptane* (16 mol% *of Cyanex* 301 *neutralized before extraction contacts*) (*left*) (*Zhu* et al., 1996a). *Distribution coefficients of actinides and lanthanides into Dowex* 1 × 8 *resin from* 10 M *LiCl* (*right*) (*Hulet* et al., 1961).

pH 3 aqueous media. In later work, Modolo and Odoj (1998) also confirmed the initial results of Zhu and his collaborators with Cyanex 301. One very successful continuous countercurrent test of a Cyanex 301-based trivalent actinide/lanthanide separation flowsheet was made; using three extraction and two scrub stages >99.9% of Am(III) was separated from a trace amount of Eu with <0.1% extraction of Eu (Modolo and Odoj, 1998).

An immediate and continuing concern about plant-scale use of Cyanex 301 (or for that matter, any sulfur-based extractant) in a rather hostile environment, e.g. high nitrate concentration–high radiation zone, is its chemical and radiolytic stability. With respect to chemical stability, Sole *et al.* (1993) found that Cyanex 301 exhibits satisfactory resistance to chemical degradation when in contact with aqueous sulfuric acid, hydrochloric acid, and nitric acid solutions provided that the nitric acid concentration is maintained at (or less) than 2 M. With respect to radiolytic stability, one study found that irradiation of Cyanex 301 produces dialkylmonothiophosphonic acid, dialkylphosphinic acid, and other phosphorus compounds (Chen *et al.*, 1996). Purified Cyanex 301 separates tracer amounts of Am(III) from tracer amounts of Eu(III) even after irradiation to a cumulative dose of 10^5 gray; commercially available Cyanex 301 only performs satisfactorily at radiation doses up to 10^4 gray. The practical plant-scale consequences of the relatively poor resistance of Cyanex 301, even purified, to radiolysis would be reflected in the need to conduct countercurrent extraction operations in short residence time equipment, e.g. centrifugal contactors, and, likely, frequent extractant inventory change-outs.

In addition to its relatively poor resistance to radiolytic degradation, Modolo and Odoj (1999) note another serious disadvantage to the use of Cyanex 301 to separate trivalent lanthanides and actinides, namely, the need to conduct extraction operations at an aqueous feed pH of 3 or higher. This latter need derives directly from the mechanism whereby Cyanex 301 humic acid (HA) extracts Am(III) and Eu(III):

$$\mathrm{M}^{3+}_{\mathrm{aq}} + 2(\mathrm{HA})_{2\ \mathrm{org}} \rightarrow \mathrm{MA}_3(\mathrm{HA})_{\mathrm{org}} + 3\mathrm{H}^{+}_{\mathrm{aq}} \text{ where } \mathrm{M} = \mathrm{Am}, \mathrm{Eu}$$

Three protons are released during the extraction operation; thus, Cyanex 301 only becomes an effective extractant at aqueous phase pH of 3 or more.

Modolo and Odoj (1999) recently synthesized and tested a new class of aromatic dithiophosphinic acids as separating agents for trivalent actinides and lanthanides. These compounds are conveniently represented as R_2PSSH with $R = C_6H_5$, ClC_6H_4, FC_6H_4, and $CH_3C_6H_4$. Modolo and Odoj achieved high separation factors (>20) with $D_{\mathrm{Am}} > 1$ in the range 0.1–1.0 M HNO_3 by means of synergistic mixtures of $(C_6H_4Cl)_2PSSH$ with either TBP, TOPO, or tributylphosphine oxide. (Interestingly, none of the R_2PSSH compounds by itself has any capacity to extract trivalent actinides.) Not only do the aromatic dithiophosphinic acids achieve satisfactory separation of trivalent actinides from trivalent lanthanides from low pH (0.1–1.0 M HNO_3) aqueous solutions but they are also reported to be considerably more resistant to radiation degradation than is Cyanex 301. Thus, Modolo and Odoj demonstrated that the selectivity and capacity of all the R_2PSSH–synergist combinations remained intact even at an absorbed dose as high as 10^6 gray. The capability of aromatic compounds to act as radiation 'sinks' is, of course, well known. Finally, it should be noted that none of the R_2PSSH compounds synthesized and studied by Modolo and Odoj are commercially available in large amounts.

Hence, when and if any country commits to plant-scale execution of a partitioning–transmutation approach to nuclear waste management and disposal, it seems quite likely that past and ongoing research and development efforts by many investigators will have culminated in a new solvent extraction process for separation of Am(III) and Cm(III) from lanthanides that operates satisfactorily under plant-scale conditions. The usable fallback technology, even though it may be considered cumbersome, is the Talspeak process.

8.4.4 Ion-exchange processes

The combination of chromatographic elution techniques with cation-exchange resins provides a powerful and sophisticated tool to purify americium from lanthanides and other trivalent actinides. Elution chromatography involves the use of organic chelating agents to produce the largest possible difference in the distribution coefficients of the metal ions to be separated. Both elution-development and displacement-development (also known as barrier-ion or retaining-ion) chromatography have been used in cation-exchange separation and purification of americium. Ryan (1974) points out that displacement-development chromatography is capable of separating macroquantities only, whereas, unless very large columns are used, elution-development chromatography is applicable only to the separation of tracer amounts. Jenkins and Wain (1972) listed publications covering the use of ion exchange to recover and purify ^{241}Am and ^{243}Am.

(a) Cation-exchange resin systems

Cation-exchange resins sorb Am^{3+} very strongly from dilute nitric acid solutions. An important application is to concentrate Am^{3+} and other trivalent and tetravalent ions from dilute acid solutions to separate them, at least partially, from many impurities (Hale and Lowe, 1969; Gmelin, 1979). Before production operations ceased at the US DOE Rocky Flats site, a cation–anion exchange process had replaced the hydroxide precipitation and thiocyanate ion-exchange system formerly used for recovering ^{241}Am from solutions of spent NaCl–KCl–$MgCl_2$ salt residues generated at the site (Proctor, 1975).

(*i*) *Distribution coefficients: separation factors*

Data for the distribution of Am^{3+} between cation-exchange resins and many aqueous solutions were analyzed in a comprehensive review by Ryan (1974). Solutions of α-hydroxycarboxylic acid and aminopolycarboxylic acids are commonly used to elute americium from cation-exchange resins. When these reagents are used in a displacement elution system, they provide excellent separation of americium from trivalent lanthanides and other trivalent actinides. For example, the separation factor for americium from curium ranges from 1.2 to 1.4 for α-hydroxycarboxylic acids and from 1.2 to 2 for aminopolycarboxylic acids (Schulz, 1976).

(*ii*) *Chromatographic elution schemes*

Although citric acid has found use, both lactic and α-hydroxyisobutyric acids provide better separation of americium from curium. Using chromatographic elution from Dowex 50-X12 resin with α-hydroxyisobutyric acid, Campbell (1970) demonstrated the effective use of high-pressure ion-exchange methods for the rapid separation of americium from curium. Highly efficient displacement chromatographic separation schemes that use nitrilotriacetic acid (NTA) and/or DTPA as eluents have been applied at the US DOE Hanford and at Savannah River sites to purify kilogram amounts of americium from curium and lanthanides (Wheelwright *et al.*, 1968; Harbour *et al.*, 1972). Wheelwright *et al.* (1968) successfully used a two-cycle cation-exchange process to separate and purify 1 kg of ^{241}Am and ^{243}Am, about 60 g of ^{244}Cm, and 140 g of ^{147}Pm extracted from 13.5 tons of blanket fuel elements from the Shippingport nuclear reactor. Highly purified americium and curium fractions were obtained by americium–curium displacement elution at 60°C through a series of four Zn^{2+}-form Dowex 50 resins beds with a 0.105 M NTA solution buffered to pH 6.5 with NH_4OH. Harbour *et al.* (1972) adapted the displacement elution scheme to pressurized columns at the Savannah River site.

Nearly 20 years after Wheelwright's work, Chuveleva and some of his colleagues at the Institute of Physical Chemistry in Moscow revisited, as recently as 1999, displacement chromatography for separation of traces of americium and curium (Chuveleva *et al.*, 1999) (interestingly, in these papers Chuveleva *et al.* did not make any reference to Wheelwright's earlier work). The basic system used by the Russian scientists in 1999 utilized their KU-2 cation-exchange resin previously converted to the Ni- (or Zn) form; a NTA solution for elution, and Cd^{2+} as the separating ion. Performance of the Russian system was quite satisfactory; indeed, their results appeared to be in full accord with expectations from Wheelwright's earlier studies.

(b) Anion-exchange resin systems

For routine, large-scale purification of americium, application of anion-exchange resins is limited to sorption from thiocyanate, chloride, and, to a limited extent, nitrate solutions (Hermann, 1956).

(*i*) *Thiocyanate solutions*

Am(III) forms relatively strong complexes, e.g. $AmSCN^{2+}$, $Am(SCN)_2^+$, and Am $(SCN)_3$ in concentrated aqueous thiocyanate solutions, and its thiocyanate species are sorbed on anion-exchange resins considerably more strongly than are the corresponding lanthanide thiocyanate complexes (Coleman *et al.*, 1955, 1957; Surls and Choppin, 1957). Thiocyanate anion-exchange systems have been used to purify americium from rare earths. For example, a plant-scale thiocyanate ion-exchange process has long been used (1960–75) at the US DOE Rocky Flats plant for routine purification of ^{241}Am recovered from aged plutonium metal (Schulz, 1976).

(*ii*) *Chloride solutions*

Am(III) is sorbed much more strongly onto anion-exchange resins from concentrated lithium chloride solutions than are the lanthanides (Hulet *et al.*, 1961). Americium distribution ratios increase with increased lithium chloride concentration whereas increased temperature enhances the separation of americium from rare earths. A lithium chloride-based anion-exchange process for separating milligram amounts of americium and curium from lanthanide fission products and to isolate an Am–Cm fraction free of heavier actinides was routinely operated at the US DOE Oak Ridge facility (Baybarz, 1970).

(c) Inorganic exchangers

Most studies concerned with sorption of Am^{3+} from aqueous solutions have used zirconium phosphate. The order of the distribution coefficients of trivalent actinides and lanthanides on zirconium phosphate is the reverse of the order observed with a typical strong-base cation-exchange resin (Horwitz, 1966). Both American (Moore, 1973) and Russian (Shafiev *et al.*, 1971) scientists utilized the fact that the singly charged AmO_2^+ is not sorbed by zirconium phosphate from dilute acid media to separate americium from curium and other metal ions.

Inorganic exchangers formed by hydrolysis of the alkoxides of titanium, niobium, or zirconium were developed for actinide/lanthanide separation (Lynch *et al.*, 1975) and possible disposal. Schulz *et al.* (1980) investigated the use of sodium titanate [$Na(Ti_2O_5H)$] and bone char (a form of calcium hydroxyapatite) to decontaminate alkaline nuclear waste streams containing minor amounts of americium and other actinides and to separate trivalent curium from trivalent americium.

More recently, as part of the overall Japanese partitioning–transmutation program, Yamagishi *et al.* (1996) reported results of experiments to use the inorganic cation exchanger titanium antimonate 'TiSb' to separate Am(III) from trivalent lanthanides. Before Yamagishi *et al.*'s work the TiSb exchanger had been reported (Kaneko *et al.*, 1992, 1993) to have a high selectivity for Pu^{4+} and trivalent americium and a low selectivity for trivalent lanthanides from concentrated HNO_3 solutions. Yamagishi *et al.* prepared TiSb according to conditions reported by Abe and coworkers (Abe and Tsujii, 1983; Abe *et al.*, 1985) and found that the TiSb exchanger exhibited superior selectivity toward trivalent americium over trivalent europium and other rare earths. The Japanese investigators concluded that TiSb is a promising material particularly for preconcentration of Am^{3+} from HNO_3 solutions containing Am^{3+} and large amounts of La^{3+} without the need for complexing or oxidizing agents.

Ritter (Ebner *et al.*, 1999) and his coworkers synthesized a new magnetic adsorbent material that combines the properties of both organic resin and inorganic material for use in actinide removal from nuclear waste solutions. This new material is called magnetic polyamine–epichlorohydrin (MPE) resin. MPE resin consists of spherical beads of polyamine–epichlorohydrin that have activated iron ferrite (magnetite) particles attached to their outer surfaces. Ferrites have been shown in previous work (Boyd *et al.*, 1986; Kochen, 1987; Kochen and Navratil, 1987; Boyd and Kochen, 1993) to be excellent adsorbents for actinide elements (including Am^{3+}) in wastewaters at relatively low alkaline conditions ($pH > 9$) and independent of a magnetic field. Results obtained by Ritter and his colleagues demonstrated that MPE resin has a significantly enhanced capacity for actinides over conventional-based ferrite surface complexation adsorption processes (where no field is applied) and over traditional high-gradient magnetic separation processes that remove suspended particles.

8.4.5 Extraction chromatographic processes

Extraction chromatography combines the best features of liquid–liquid solvent extraction and chromatographic separation techniques. Extraction chromatographic systems consist of a mobile liquid phase and a stationary liquid phase on an inert support. Separations are achieved by taking advantage of the difference in the distribution of ions between the two liquid phases.

Many systems using either HDEHP or Aliquat 336 as the stationary phase have been studied for extraction chromatographic separation of americium at tracer-level concentrations. An Aliquat 336 (nitrate-form)–kieselguhr system was used both in the USA and in Europe to separate milligram to gram amounts of americium from curium (Horwitz *et al.*, 1967; Müller, 1971).

In the two decades since the publication of the second edition of this monograph extraction chromatographic techniques for separating Am(III) and small amounts of other actinides from various aqueous media have been pursued for routine analytical purposes and for specialized process purposes. Thus far, the analytical applications have met with much greater acceptance and success than the proposed process applications.

Horwitz and his colleagues at the U.S. Argonne National Laboratory have been the prime movers in developing practical extraction chromatographic materials and procedures for analytical-scale separations and determination of Am(III) and other actinides. (Materials developed by Horwitz *et al.* are commercially manufactured and marketed by Eichrom Industries, Darien, Illinois.) Horwitz *et al.* (1990, 1993) initially developed an extraction chromatographic material, which was marketed under the name TRU$^{\mathrm{TM}}$ resin; the TRU$^{\mathrm{TM}}$ resin, which consisted of a solution of CMPO adsorbed on Amberchrom-CG 71 (Rohm & Haas Co.), had a number of attractive features including offering the possibility of sequential elution of individual sorbed actinide elements. However, a major weakness of the TRU$^{\mathrm{TM}}$ resin was that it would not effectively sorb actinides from solutions containing significant concentrations of complexing anions such as fluoride, oxalate, or phosphate. Extraction chromatographic analytical applications of the TRU$^{\mathrm{TM}}$ resin for the separation and determination of Th, U, Pu, Am, and Cm have been described in a series of papers (PilvVo and Bichel, 1998, 2000; PilvVo *et al.*, 1999).

In follow-on development work by Horwitz *et al.* the Diphonix$^{\mathrm{TM}}$ resin, containing geminally substituted diphosphonic acid groups chemically bonded to a styrene-based polymer matrix, was shown to exhibit extraordinarily strong affinity for the actinides particularly the 4+ and 6+ ions. Because of its strong retention of actinides, the Diphonix$^{\mathrm{TM}}$ resin found application in the characterization of mixed and transuranic waste (Chiarizia *et al.*, 1997) and in analytical pre-concentration of actinides from a variety of biological and environmental samples (Smith *et al.*, 1995). Further tests revealed two important weaknesses of the Diphonix^{TM} resin in extraction chromatographic applications, namely (i) insufficient uptake and retention of trivalent actinides and (ii) difficult stripping/recovery of actinides from the loaded resin.

The final important contribution to actinide element extraction chromatography of the Horwitz group at the Argonne National Laboratory was the development and introduction of the DIPEX^{TM} resin (Horwitz *et al.*, 1997). The DIPEX^{TM} resin consists of a new compound, bis(2-ethylhexyl)methanediphosphonic acid (H_2DEH[MDP]) supported on an inert polymeric substrate. Horwitz and his coworkers state that this compound contains the same diphosphonic acid functional group as the Diphonix^{TM} resin but two of the four ionizable hydrogen atoms have been replaced by a C_8 alkyl group to make the molecule more lipophilic. According to the experimental evidence of Horwitz and colleagues, the DIPEX^{TM} resin exhibits stronger affinity for 3+, 4+, and 6+ actinides from acidic chloride media and superior selectivity for Am(III) over Al(III) and Fe(III) than the Diphonix^{TM} resin. Indeed, so strongly does the DIPEX material sorb actinides that the only convenient way to strip sorbed actinides appears to be to wash the resin with isopropanol to completely solubilize the H_2DEH[MDP] for subsequent wet oxidation to liberate the actinides for further treatment and analysis. Despite what appears to be a cumbersome procedure for stripping sorbed actinides, the DIPEX^{TM} resin is considered to be eminently suited for separation and pre-concentration of actinides from complex soil and bioassay matrices.

Nowadays, extraction chromatographic materials and techniques are generally considered to be most suited for analytical aims. But, some process-scale applications of such materials and techniques continue to be proposed from time to time. For example, Akatsu and Kimura (1990) reported on the use of extraction chromatography in the DHDECMP–(XAD-4) HNO_3 system. Also, several investigators (Barney and Cowan, 1992; Lumetta *et al.*, 1993) studied the feasibility of using TRU^{TM} resin and other types of extraction chromatographic supports impregnated with CMPO to separate actinide elements from stored US DOE Hanford site tank wastes including actual neutralized decladding waste and also other acidic waste solutions. Scientists in India (Gopalakrishnan *et al.*, 1995; Mathur *et al.*, 1995) have reported good success in applying an extraction chromatographic material consisting of CMPO adsorbed on Chromosorb-102 to selectively take up U(VI), Pu(IV), and Am(III) from neat nitric acid media, from synthetic sulfate-bearing high-level waste (SBHLW) and actual Purex process oxalate supernatant liquors.

Two other extraction chromatographic process-scale applications for separation of americium and other actinides are noteworthy. Mohapatra *et al.* (2000) found that the diamide DMDBTDMA adsorbed on an inert support was very efficient in taking up tracer concentrations of Am(III) and other actinide ions from 3 to 5 M HNO_3 solutions. Wei and his coworkers (Wei, 2000a,b) prepared and investigated the actinide sorption properties of several novel silica-based extraction chromatographic resins by impregnating organic extractants such as CMPO, HDEHP, and Cyanex 301 into a styrene–divinylbenzene copolymer, which is immobilized in porous silica particles. Recently, these scientists have synthesized 2,6-bis-((5,6-dialkyl)-1,2–4-triazene-3-yl)-pyridine and impregnated such compounds into styrene–divinylbenzene copolymers immobilized in porous silica particles (Wei *et al.*, 2000a,b). The resulting extraction chromatographic material preferentially sorbed Am(iii) over trivalent lanthanides.

A most unusual and intriguing type of extraction chromatographic separation scheme for Am(iii) and other actinides was prepared by Nunez *et al.* (1996). These researchers adsorbed a layer of CMPO/TBP onto polymeric-coated ferromagnetic particles. The CMPO/TBP was very efficient in taking up actinides from 0.01 to 6 m HNO_3 nuclear waste solutions as expected from the results with the TRUEX process (see Section 8.4.3a(vi)). Once loaded with actinides, the ferromagnetic particles could be readily recovered from the waste solutions with a magnet.

8.5 ATOMIC PROPERTIES

8.5.1 Electron configuration

Americium is the sixth member of the actinide series, with electron configurations in its ground and ionized states analogous to those of its lanthanide homolog, europium. Note, however, that the solution chemistries of these two elements show substantial differences, with the major ones being the difficulties in preparing Am(ii) and the absence of Eu(iv), Eu(v), and Eu(vi). Electronic configurations of gaseous americium species as determined from spectroscopic and atomic-beam experiments showed a $5f^77s^2$ ground state for Am(g) and $(5f^7)^{2+}$ state for Am^{2+} (Tomkins and Fred, 1949).

8.5.2 Atomic and ionic radii

Metallic, covalent, and ionic radii of americium in various oxidation states were first calculated by Zachariasen (1948a, 1954). The radius of americium metal with a coordination number (CN) of 12 was reported to be 1.73 Å (McWhan *et al.*, 1960). On the basis of a refined single-crystal structure for $AmCl_3$, Burns and Peterson (1970, 1971) calculated the ionic radius of Am^{3+} (CN 6) in $AmCl_3$ to be 0.984 ± 0.003 Å. Zachariasen (1978) has also deduced some highly useful bond length–bond strength relationships that provide, as a function of americium valence and coordination number, a condensation of many americium–oxygen and americium–halogen distances derived from the best-known structures. For the Am^{3+} and Am^{4+} ions, Zachariasen (1948a) reported crystal radii of 1.00 and 0.85 Å, respectively. Shannon (1976) provided a list of revised effective ionic radii and reported 1.21 Å (CN 6) and 1.26 Å (CN 8) for Am^{2+}, 0.975 Å (CN 6) and 1.09 Å (CN 8) for Am^{3+}, 0.85 Å (CN 6) and 0.95 Å (CN 8) for Am^{4+}. No data are available on Am(V) and Am(VI). David (1986) reported an ionic radius for Am^{3+} of 0.980 Å (CN 6) and 1.106 Å (CN 8).

8.5.3 Ionization potentials

Trautmann and colleagues (Trautmann, 1994; Deissenberger *et al.*, 1995) experimentally determined the first ionization potential of americium to be 5.9738 (2) eV. This determination was made with only 10^{12} atoms of americium using a newly developed method based on resonance ionization mass spectroscopy in the presence of an external electric field. Before the work of Trautmann and colleagues, Carlson *et al.* (1970) calculated the ionization potential values for Am^0 (5.66 eV), Am^+ (12.15 eV), and Am^{2+} (18.8 eV). Penneman and Mann (1976) also estimated the same potentials based on *jj* coupling; these investigators underestimated the first ionization potential but were in good agreement on the potentials for higher ionizations.

8.5.4 Emission spectra

Studies of the arc and spark spectra of americium have been summarized by Carnall (1973a) in *Gmelin's Handbook of Inorganic Chemistry*. Corresponding to the absolute term value (48 767 cm^{-1}) of the ground state, the ionization potential of Am(I) is 6.0 eV (Carlson *et al.*, 1970). As noted above Deissenberger *et al.* (1995) refined the ionization potential to 5.9738(2) eV.

8.5.5 X-ray spectrum

Atomic energy levels (binding energies) of americium have been calculated from experimental measurements of X-ray emission wavelengths; for example, the value for $K–M_{III}$ is 120.319 and 102.041 keV for the $K–L_{II}$ transition (Carnall, 1973b). All K X-ray energies of americium correspond to electric dipole transitions. A critical literature evaluation and a listing of atomic energy levels of americium are given in Bearden (1967).

8.5.6 Photoelectron spectrum

In a highly important experimental measurement, Naegele and coworkers (Naegele *et al.*, 1984) at the European Institute for Transuranium Elements were able in 1984 to directly conduct X-ray and high-resolution ultraviolet photoemission spectroscopy of the conduction band of americium metal. These measurements, parallel to those successfully performed earlier with uranium metal, directly revealed that the 5f electrons in americium metal are localized. Naegele *et al.* state that the final-state multiplet structure arises from a trivalent $5f^6$ Am ground state. In later work, Naegele *et al.* (Martensson *et al.*, 1987) attempted an interpretation of the valence band photoelectron spectrum for americium metal.

8.5.7 Mössbauer spectrum

Beta decay of ^{243}Pu ($t_{1/2} = 4.98$ h) to the 83.9 keV level of ^{243}Am produces an excited nuclear state ($t_{1/2} = 2.34$ ns) of ^{243}Am that is suitable for Mössbauer spectroscopy (Kalvius *et al.*, 1969; Bode *et al.*, 1976). Data obtained with a $^{243}PuO_2$ source at 4.2 K showed the shift of the $^{243}AmF_3$ resonance line relative to $^{243}AmO_2$ to have an unusually large value of 55 mm s^{-1} (Kalvius *et al.*, 1969; Bode *et al.*, 1976).

8.6 METAL AND ALLOYS

8.6.1 Metal preparation

Americium metal has been prepared by the following methods: (1) reduction of AmF_3 with barium (or lithium) metal; (2) reduction of AmO_2 with lanthanum metal; (3) bomb reduction of AmF_4 with calcium metal; and (4) thermal decomposition of Pt_5Am. Lanthanum metal (or thorium metal) reduction of AmO_2 in tantalum equipment and subsequent distillation of the americium metal from the reaction mixture yields americium of very high (>99.9%) purity. Americium is about a factor of 10^4 more volatile than lanthanum. Extensive applications of this technique by the Euratom group led to important new measurements of the physical and thermodynamic properties of americium metal (Oetting *et al.*, 1976). Workers at the U.S. DOE Rocky Flats site also reported similar success with vacuum distillation techniques (Berry *et al.*, 1982).

Preparation of americium metal by thermal decomposition of the intermetallic compound Pt_5Am is a more recent development. Müller *et al.* (1972) produced high-purity americium metal by thermal decomposition of the intermetallic compound at 1550°C and 10^{-6} Torr, followed by further distillation.

8.6.2 Properties

Americium metal is silvery, ductile, non-magnetic, and very malleable. Selected physical properties are listed in Table 8.3. There are two well-established crystalline forms of americium metal, a double hexagonal close-packed (dhcp, *P*6$_3$/*mmc*) phase, stable at room temperature, and a face-centered cubic (fcc, *Fm*3*m*) phase (McWhan *et al.*, 1960; Stephens *et al.*, 1968; Oetting *et al.*, 1976). Differential thermal analysis and dilatometric experiments on americium metal have presented (Rose *et al.*, 1979) evidence for at least three phases existing between room temperature and the melting point (1170°C): an alpha phase

Table 8.3 *Selected properties of americium metal* (*adopted from Schulz* (1976) *and Oetting* et al. (1976); *see also Chapter* 19).

Property	*Values*[a]
Crystallographic data	
symmetry	<658°C, dhcp (α) 793–1004°C, fcc (β) ~1050–1173°C, bcc (?)
space group	$P6_3/mmc$ and $Fm3m$
lattice parameters	dhcp: $a = 3.4681$ Å, $c = 11.241$ Å fcc: $a = 4.894$ Å
density	13.671 g cm^{-3} (calc.); 13.671 g cm^{-3} (obs.)[b]
high-pressure structures[c]	0–5 GPa Am (I): dhcp; 5 to 8–10 GPa Am(II): fcc; 8 to 15–23 GPa Am(III): double body-centered monoclinic, or trigonal distortion of fcc, or monoclinic α-Pu; >15–23 GPa Am(IV): orthorhombic α-U or monoclinic (α-U alloys)
metallic radius (CN 12)	1.73 Å
melting point	(1149 ± 5) K
boiling point	2067°C (calc.)
coefficient of thermal expansion	$\alpha_a = 7.5 \pm 0.2 \times 10^{-6}\ \mathrm{K}^{-1}$ and $\alpha_c = 6.2 \pm 0.2 \times 10^{-6}\ \mathrm{K}^{-1}$
compressibility at 1 atm	0.00277 kbar^{-1} at 23°C
vapor pressure[d]	$\log(p/\mathrm{atm}) = (6.578 \pm 0.046) - (14315 \pm 55)/T$ at 990–1358 K
magnetic susceptibility	$\chi_{20°\mathrm{C}} = (881 \pm 46) \times 10^{-6}\ \mathrm{cm}^3\ \mathrm{mol}^{-1}$
magnetic moment	~0
microhardness (Vickers) at 25°C	800 MN m^{-2}
electrical resistivity	68 μΩ cm (300 K), 71 μΩ cm (298 K)
crystal entropy, $S°298$	55 J K^{-1} mol^{-1}
heat capacity, $(C_P)_{298}$	25.5 J K^{-1} mol^{-1}
heat of vaporization at boiling point	230.2 kJ mol^{-1} (calc.)
entropy of vaporization at boiling point	100.8 J K^{-1} mol^{-1} (calc.)
heat of transformation	5.9 kJ mol^{-1}
heat of fusion	14.4 kJ mol^{-1}
heat of dissolution in aqueous HCl	1 M HCl: −616.3 kJ mol^{-1} 1.5 M HCl: −615.5 kJ mol^{-1} 6 M HCl: −618.0 kJ mol^{-1}

[c] Refer to Section 8.6.2.

[d] Ward *et al.* (1975) give the following equation for americium above its melting point: $\log(p/\mathrm{atm}) = 5.185 - 13191/T$.

existing up to 658°C; a beta phase existing between 793 and 1004°C; and a gamma phase which forms at 1050°C. In studies with high-purity americium metal, Sari *et al.* (1972/73) concluded that there is no phase transition between 600 and 700°C. But, Russian scientists (Seleznev *et al.*, 1979) put forth evidence that the transition from the dhcp structure to the fcc structure occurs at 771 ± 15°C; their observation is in agreement with the conclusions reached from dilatometric and differential thermal analysis measurements.

Smith and Haire (1978) found that americium metal with the dhcp structure became superconducting between 0.55 and 0.75 K; observation of the onset of superconductivity in americium metal confirmed an earlier prediction made from theoretical considerations. In later work, Link *et al.* (1994) found that the superconductivity transition temperature of dhcp americium increases considerably with pressure, reaching a maximum value of 2.3 K at 6.6 GPa. Müller *et al.* (1978), at several laboratories in Europe and in USA, recently measured the electrical resistivity and specific heat of americium metal. These latter investigators observed binding in americium metal to be reduced compared to that in lighter actinide metals and attributed this result to the importance of 5f electrons in electrical conduction. In a later paper, Hall *et al.* (1980) used their data to generate 'best values' for the heat capacity, crystal entropy, and electrical resistivity of americium metal; these 'best values' are shown in Table 8.3.

Owing to its unique position and properties in the actinide series of elements, americium metal has proven to be, over the last quarter of a century, a material of great interest to both theoreticians and experimentalists. In the light actinide metals (Ac–Pu) the 5f electrons are known to be itinerant and not localized. But, there is much evidence, e.g. cohesive properties, magnetic properties, atomic volume, etc. to indicate that the 5f electrons in americium metal at atmospheric pressure are localized and chemically inert. (Indeed, results of recent photoemission spectral studies cited in Section 8.4 essentially prove that 5f electrons in americium metal are localized.) Once the 5f electron localization behavior was noted for americium metal, Johannson (1978) also posited that americium metal under compression will transform to a dense phase where the 5f electrons are itinerant and not localized.

The first experimental study of the behavior and some properties of americium metal above atmospheric pressure was conducted by Stephens *et al.* (1968). These investigators determined the compressibility and electrical resistance of americium metal at room temperature over the range 3.5–12 GPa. They also made an attempt to determine the phase diagram of americium metal over this range of pressures.

Following Johannson's 1978 paper several groups of scientists in the early 1980s determined structural properties from X-ray diffraction data for americium metal at various pressures. The overall goal of these studies was to determine the number and type of different crystalline structures formed as a function of applied pressure and, thereby, obtain experimental evidence for delocalization of the 5f electrons. Thus, Akella and coworkers (Akella *et al.*, 1980;

Roof *et al.*, 1980; Smith *et al.*, 1981; Roof, 1982) established four different crystalline structures in americium metal over the pressure range from 100 kPa (1 atm) to 18 GPa: Am(I)-dhcp; Am(II)-fcc (at 5 ± 1 GPa); Am(III)-not indexed (10 ± 1 GPa); and Am(IV)-not indexed (15 ± 1 GPa). Later Roof (1982) repeated and extended the pressure experiments of Akella and coworkers up to 20 GPa. Roof and his collaborators noted the same four crystalline phases as observed by Akella and coworkers. But, Roof and his collaborators indexed the Am(III) phase (10–15 GPa) as a double-body centered monoclinic structure and the Am(IV) phase (10–20 GPa) as an orthorhombic structure similar to that of alpha uranium metal.

The latest experimental studies of delocalization of 5f electrons in americium metal under pressure were performed by Benedict and colleagues (Benedict *et al.*, 1985, 1986). Benedict *et al.* conducted their experiments over the pressure range 3 to 52 GPa, and, under these conditions, also noted the Am(I)–Am(II)–Am(III)–Am(IV) phase transformation sequence. Benedict *et al.* however, state that the transitions between phases occur at higher pressures than noted by previous workers; in particular, Benedict and his fellow authors state that the Am(III) to Am(IV) transition occurs at 23 GPa, not at 15 GPa. Benedict *et al.* claim that the Am(III) phase is not a monoclinic structure, as previously indexed, but is really a trigonal distortion of the Am(II) fcc structure. Finally Benedict *et al.* state that according to their results, 5f electron delocalization occurs only at a pressure of 23 GPa or above. Lindbaum *et al.* (2001) observed the transition of the normal-pressure double hexagonal close packed ($P6_3/mmc$) structure transforms at 6.1 GPa to the face centered cubic (*Fm3m*) form, which converts at 10.0 GPa to a face centered orthorhombic (*Fddd*) structure. This orthorhombic form converts at 16 GPa to a primitive orthorhombic (*Pnma*) form, which is stable up to at least 100 GPa. Based on the data of americium's pressure behavior the authors concluded that Am f-electrons are involved in the metallic bonding of the AmIII and IV phases.

Coincident with experiments conducted to ascertain the response of americium metal to increasing pressure, theoreticians in several countries have mounted a sustained effort to apply first-principles calculations to deduce the state of 5f electrons both in the presence and absence of applied pressure (Skriver *et al.*, 1980; Johannson, 1984; Nikolaev and Ionova, 1991; Eriksson and Wills, 1992; Eriksson *et al.*, 1993, 1995, 2000; Soderland *et al.*, 2000). The present state of the theoretical calculations is best discussed in a recent paper by Soderland *et al.* (2000). The latter investigators used density functional electronic calculations to study the high-pressure behavior of americium metal. At about 8 GPa, such calculations revealed a phase transition from the fcc structure Am(II) to a dense phase of lower symmetry that Johannson *et al.* were convinced is a monoclinic form similar to the structure of α-plutonium (Fig. 8.3); they state emphatically that it does not have the orthorhombic structure called out by Roof and Benedict *et al.* According to Johannson and collaborators, their calculation results are consistent with a Mott transition;

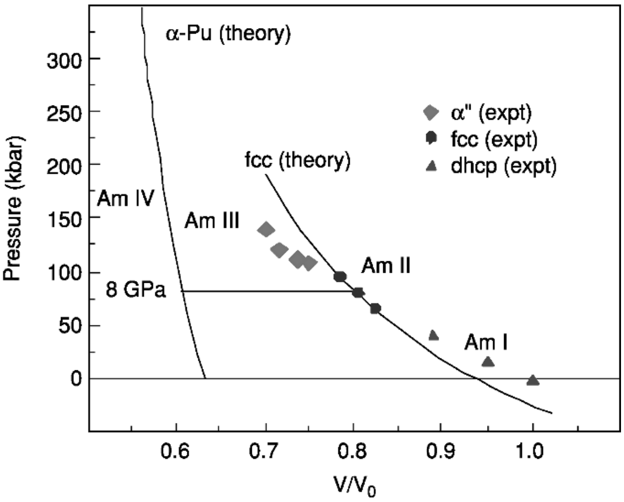

Fig. 8.3 *Calculated equations of state for americium metal from fits to total energies* (*Soderland* et al., 2000)*; equations indicate a volume decrease of* 25% *at* 8 GPa.

the 5f electrons are delocalized and bonding on the high-density side of the transition and chemically inert and non-bonding (localized) on the low-density (fcc phase) side of the transition.

Even at this advanced time in the chemistry of americium, there are still some serious disagreements between experimentally determined and calculated (from theoretical considerations) effects of compression of americium metal. To be sure, both approaches offer strong support for the contention that upon compression the 5f electrons in americium delocalize. Both the experimentalists and the theoreticians concur that at moderate applied pressure, the dhcp structure converts to the fcc phase. And, both groups concur that at some threshold applied pressure the fcc structure transforms to a more dense phase, i.e. Am(III) and, possibly, Am(IV), in which the 5f electrons are delocalized. But, certainly the parties involved do not agree on exactly how many different dense phases (one or two) eventually form on further application of pressure or on the exact pressure of phase transformations and certainly not on the crystal structure of the new dense phase(s). (The data shown in Table 8.3 are listed so as to capture much of the present uncertainty concerning transition pressures and crystalline structures.) Another important point of disagreement and uncertainty, long known and troublesome to theoreticians, is that the experimentally observed volume decreases when the 5f electrons in americium metal are delocalized only to about 6% compared to the 30–35% decrease predicted from theory. The present disagreement between experimental and calculated results point to flaws and deficiencies in both approaches, e.g. difficulties in obtaining and accurately deciphering X-ray diffraction data from a pressurized radioactive system and inadequacies of present calculational tools. It is hoped that future research will resolve the discrepancies between calculation and experiment.

8.6.3 Alloys and intermetallic compounds

Presently, alloy systems involving interaction of americium metal with some 23 different elements have been investigated. One or more intermetallic compounds of definite composition are known to exist in 16 of these systems; Table 8.4 summarizes the significant stoichiometry, structure, and synthesis information for these 16 systems and also provides relevant literature references.

No definite compounds have been observed in the Am–Ce, Am–Hg, Am–La, Am–Np, Am–Pu, Am–Th, or Am–U systems. Phase diagrams for the Am–Np, Am–Pu, and Am–U systems have recently been summarized and published by Okamoto (1998). Okamoto took careful note of the phase diagram for the Am–Pu system constructed earlier by Ellinger *et al.* (1966). Gibson and Haire (1992a) have reported phase relations in the Am–Np system while Adair (1970) prepared alloys of thorium with 0.54–5.0 wt% americium by both levitation and arc melting of prepared mixtures of americium and thorium metal.

Interaction of americium metal with two rare earth metals, lanthanum and cerium, has been investigated, respectively, by Hill and coworkers (Hill and Ellinger, 1971; Hill *et al.*, 1971) and by Connor (1982). Lanthanum–americium alloys containing 0.92–2.37 at% americium dissolved in fcc-beta lanthanum were produced by arc melting the constituent elements. Connor used both co-melting (arc) and co-reduction techniques in his studies of the Am–Ce system. Co-reduction alloy preparation involved calcium metal reduction of an appropriate mixture of AmF_4 and CeF_3 in a sealed vessel.

The Am–Hg system has been studied by Bouissières and Legoux (1965), David and Bouissières (1968), Maly (1969), and Tikhonov *et al.* (1988). A dilute americium amalgam may be prepared either by reduction of Am(III) ions with a sodium amalgam or by electroreduction of Am(III) ions on a mercury electrode. Tikhonov *et al.* also investigated some properties of a concentrated americium amalgam that was prepared electrolytically; their results indicated the formation of an Am–Hg intermetallic compound but no information on the stoichiometry or structure of such a compound was reported. Guminski (1995) recently reviewed and evaluated the equilibrium and thermodynamics of the Am–Hg system.

8.7 IMPORTANT COMPOUNDS

Inorganic compounds containing halides or oxygen-donor ligands are far more numerous than simple oxides, hydroxides, or other binary or ternary compounds. The structures and references to the preparation of about 180 compounds of americium with anionic inorganic ligands are listed in alphabetical order in Table 8.5; compounds of americium with organic ligand coordination are listed in Table 8.6. A group of compounds in which americium could be considered as part of the anionic constituent appears under the heading oxides, ternary.

8.7.1 Inorganic compounds

(a) Oxides and hydroxides

The binary americium oxides are limited to AmO, Am_2O_3, AmO_2, and non-stoichiometric phases between Am_2O_3 and AmO_2. Although the AmO (fcc) phase has been reported twice (Zachariasen, 1949a,c; Akimoto, 1967), the corresponding lattice parameters, 4.95 Å (Zachariasen, 1949a,c) and 5.045 Å (Akimoto, 1967), are not consistent. Accidental exposure of AmH_{2+x} to air at 300°C yielded a fcc phase (Roddy, 1973), which agrees with Akimoto's AmO (Akimoto, 1967) but may in fact be an oxynitride similar to the corresponding 'PuO' (Larson and Haschke, 1981). The difficulty in achieving Am(II) in solution and in solid compounds makes it likely that the monoxide can only be synthesized under high pressure by conproportionation of Am metal and Am_2O_3, analogous to the preparation of the lanthanide monoxide SmO (Leger *et al.*, 1981). Recent evidence that PuO and surface-layer lanthanide monoxides are really oxycarbides or nitrides (Larson and Haschke, 1981) reinforces the uncertainty of whether any claim for AmO is valid.

Phase relationships and thermodynamic data in the $AmO_{1.5}$–AmO_2 systems are well established. The red-brown ('persimmon') sesquioxide, Am_2O_3, is easily prepared in H_2 at temperatures as low as 600°C but it oxidizes very readily in air, even at room temperature. Baybarz (1973a) summarized the transition temperatures of the low-temperature (body-centered cubic (bcc), C-phase) to medium-temperature (monoclinic, B-phase) to high-temperature (hexagonal, A-phase) sesquioxides. The C→B transition temperature appears to be sluggish, occurring between 460 and 650°C and the B→A transition occurs between 800 and 900°C (Chikalla and Eyring, 1968; Hurtgen and Fuger, 1977). The pale tan hexagonal sesquioxide phase undergoes slight swelling with time and self-irradiation causes cubic Am_2O_3 to transform to the hexagonal phase at room temperature within about 3 years (Hurtgen and Fuger, 1977). It is possible that the monoclinic Am_2O_3 is stabilized by small amounts of rare earth impurities (Berndt *et al.*, 1974; Keller and Berndt, 1975) and that pure Am_2O_3 passes directly from the C- to the A-phase; it is also possible that the C→B transition occurs well below 650°C. The hexagonal sesquioxide is stoichiometric but the cubic form may have a lower oxygen limit of $AmO_{1.513}$ (Chikalla and Eyring, 1968). Studies on americium oxides include the measurement of the melting point of Am_2O_3, 2205 ± 15°C (Chikalla *et al.*, 1973), and the enthalpy of formation of AmO_2, -932.2 ± 3.0 kJ mol^{-1} (Morss and Fuger, 1981).

The dioxide AmO_2 was the first reported compound of americium (Zachariasen, 1949a,c). It can be prepared by heating a variety of americium compounds, e.g. hydroxides, carbonates, oxalate, or nitrate, in air or oxygen at

temperatures of 600–800°C (Eyring *et al.*, 1952; Baybarz, 1960; Chikalla and Eyring, 1967; Hurtgen and Fuger, 1977; Morss and Fuger, 1981). This stoichiometry of the black oxide is believed to be $AmO_{2.00}$ (Chikalla and Eyring, 1967, 1968) and is better than $AmO_{1.99}$ even at 1000°C in oxygen (Chikalla and Eyring, 1967). It undergoes an expansion of its fcc lattice constant due to radiation damage, which reversibly broadens the diffraction lines at low temperatures in both $^{241}AmO_2$ and $^{243}AmO_2$ (Hurtgen and Fuger, 1977; Benedict and Dufour, 1980). Benedict and Dufour (1980) studied the variation of the lattice parameter, of the thermal linear expansion, and of the coefficient of thermal linear expansion for AmO_2 in the range 38–300 K. Upon cooling, AmO_2 contracts more strongly than the dioxides of the lower actinides. The lattice parameters quoted in Table 8.3 represent an extrapolation to zero time for both $^{241}AmO_2$ and $^{243}AmO_2$ (Fahey *et al.*, 1974; Hurtgen and Fuger, 1977).

There is no evidence for any binary oxide of americium higher than AmO_2 (Katz and Gruen, 1949; Templeton and Dauben, 1953). However, ternary oxides are known for Am(III) through Am(VI) (Keller, 1964, 1965; Keller *et al.*, 1965b; Radzewitz, 1966; Mosley, 1970; Keller *et al.*, 1972; Keller and Berndt, 1975; Hoekstra and Gebert, 1978). Stabilization of high oxidation states in complex oxides is frequently observed (Keller, 1964, 1967; Morss, 1982); excellent examples are the thermally stable Am(VI) compounds Cs_2AmO_4 and Ba_3AmO_6. Most complex oxides of americium have been prepared by Keller and Hoekstra and their coworkers (Keller, 1964, 1967; Keller *et al.*, 1965b; Hoekstra and Gebert, 1978).

Initially, americium was prepared in significant quantities as $Am(OH)_3$ and to date hydroxide phases are known for the oxidation states III–VI. Isostructural to its chemical analog $Nd(OH)_3$, the Am(III) hydroxide is by far the most important americium hydroxide for separation and purification purposes and its solubility has been widely studied. The pinkish amorphous hydroxide precipitates by addition of dilute hydroxide to Am(III) solutions under ambient conditions. Rod-like microcrystalline $Am(OH)_3$, similar to $Nd(OH)_3$, is obtained in water after heating at 80°C for about 90 min (Milligan and Beasley, 1968). The transformation rate depends on various experimental parameters, such as solution composition, basicity, temperature, radiolysis, and the (pre)treatment of the precipitate. The crystalline phase can also be obtained by boiling a $^{241}Am(OH)_3$ suspension in 5 M NaOH (Silva, 1982) or hydration of Am_2O_3 with steam at 225°C (Morss and Williams, 1994). The destruction of the crystalline phase by its own alpha-radiation depends strongly on the specific activity of the isotope used: complete degradation is obtained within 1 day using ^{244}Cm(III) (specific activity 3000 MBq mg^{-1}) and 5 months with ^{241}Am(III) (specific activity 120 MBq mg^{-1}) (Haire *et al.*, 1977). The complex aging behavior of $Am(OH)_3$ in aqueous solutions and the changes in particle size result in large differences in its solubility. Nevertheless, two thermodynamic solubility products for the reaction

$$\mathrm{Am(OH)_3 + 3H^+ = Am^{3+} + 3H_2O}$$

have been recommended: $\log K^\circ = 15.2 \pm 0.6$ for crystalline $Am(OH)_3$ and 17.0 ± 0.6 for amorphous $Am(OH)_3$ (Silva *et al.*, 1995).

Few attempts to prepare and characterize $Am(OH)_4$ were reported, probably due to the instability of Am(IV). A black precipitate of $Am(OH)_4$ was obtained by heating $Am(OH)_3$ at 90°C in 0.2 M NaOH with NaOCl or in 7 M KOH with peroxydisulfate (Penneman *et al.*, 1961). The dissolution of this precipitate in sulfuric or nitric acid leads to a mixture of Am(III), Am(V), and Am(VI). Structural and thermodynamic data on $Am(OH)_4$ are not known. $AmO_2(OH)$ has been suggested to precipitate in slightly basic concentrated NaCl solutions under inert atmosphere but the amorphous character of the solid phase inhibited characterization (Magirius *et al.*, 1985; Stadler and Kim, 1988; Giffaut and Vitorge, 1993; Runde and Kim, 1994; Runde *et al.*, 1996). In more concentrated hydroxide solutions ternary Am(V) hydroxides, yellow $MAmO_2(OH)_2 \cdot nH_2O$ at 0.1–0.5 M OH^- and rose-colored $M_2AmO_2(OH)_3 \cdot nH_2O$ (M = Na, K, Rb, Cs) at 0.5–2.0 M OH^- (Tananaev, 1990b, 1991), form, and were characterized by X-ray diffraction. Only the lithium compound appeared to be stable over the entire range of hydroxide concentrations. No information on Am(VI) hydroxides is available.

(b) Hydrides

Olson and Mulford (1966) characterized the ^{241}Am–hydrogen system and found parallels to the lanthanides. The reported AmH_{2+x} (fcc) phase is isostructural with NpH_{2+x}, PuH_{2+x}, and most of the rare earth dihydrides (Roddy, 1973). There is also a phase that approximates hexagonal AmH_3. Although the lattice parameters were reported to be $a_0 = 3.77$ Å and $c_0 = 6.75$ Å (Olson and Mulford, 1966), Keller (1971) has pointed out that recent data on HoD_3 makes the most probable space group $P3c1$ (lattice parameters are given in Table 8.3). A study by Roddy (1973) with ^{243}Am essentially confirms this conclusion.

(c) Halides

A number of americium halides have been synthesized with americium in oxidation states II–VI and the halide systems have been studied extensively. Most remarkable are the halides of americium in extreme oxidation states, i.e. divalent and hexavalent. While solid structures are rare for divalent americium compounds, the black halides, $AmCl_2$ and $AmBr_2$ (Baybarz, 1973b), and AmI_2 (Figure 8.8) (Baybarz and Asprey, 1972) were prepared by reacting metallic americium with the corresponding mercuric halides at 300–400°C. The dihalides cannot be prepared by hydrogen reduction of the Am(III) halides, although hydrogen reduction is successful for the chemical analog lanthanides Sm, Eu, and Yb. Interestingly, all three compounds crystallize in different lattices: orthorhombic $AmCl_2$, tetragonal $AmBr_2$, and monoclinic AmI_2.

(1) Am(III): A number of Am(III) halides have been synthesized and their compositions range from binary AmX_3 adducts such as $AmCl_3 \cdot MCl$ where MCl is LiCl, CsCl, $(C_4H_9)_4NCl$, or $(C_2H_5)_4NCl$, to ternary complexes, i.e. $MAmX_4$, M_2AmX_5, KAm_2F_7, and M_2AmX_6 and M_3AmX_3. In addition, Bagnall *et al.* (1968) and Morss *et al.* (1970) made the cubic derivative $Cs_2NaAmCl_6$, in which the americium atoms are surrounded by six chlorides in an octahedral environment. The iodide AmI_3 is the only actinide triiodide known to be dimorphic; spectrophotometric observations indicate a pressure-induced phase transition from the rhombohedral to the orthorhombic structure (Haire *et al.*, 1985). The compound $(NH_4)_2AmCl_5$ decomposes at 300°C under vacuum to form $AmCl_3$ (Schleid *et al.*, 1987). Crystal structures have been reported for AmF_3 (Templeton and Dauben, 1953), $AmCl_3$ (Burns and Peterson, 1970) and $AmCl_3 \cdot 6H_2O$ (Burns and Peterson, 1971), $AmBr_3$ and AmI_3 (Zachariasen, 1948b; Baybarz and Asprey, 1972), and AmOX (X = Cl Figure 8.8 (Templeton and Dauben, 1953), Br (Weigel *et al.*, 1979) and I (Baybarz and Asprey, 1972)). Octahedral $AmCl_6^{3-}$ and $AmBr_6^{3-}$ can be prepared as triphenyl phosphonium salts in anhydrous ethanol (Ryan, 1967; Marcus and Bomse, 1970).

(2) Am(IV): Orange-pink crystals of orthorhombic Rb_2AmF_6 form in concentrated aqueous fluoride solutions with $RbAmO_2F_2$ or $Am(OH)_4$ (Kruse and Asprey, 1962).

(3) Am(V): The ternary Am(V) fluorides, $KAmO_2F_2$ (Asprey *et al.*, 1954a) and $RbAmO_2F_2$, precipitate from concentrated aqueous fluoride solutions of Am(V) and consist of $AmO_2F_2^-$ connected by K^+ or Rb^+ cations. In contact with acidic RbF solution, $RbAmO_2F_2$ reduces overnight to Rb_2AmF_6 (Kruse and Asprey, 1962). The green chloride $Cs_3AmO_2Cl_4$ precipitates with ethanol from 6 M HCl containing Am(V) hydroxide and CsCl (Bagnall *et al.*, 1968) and is isostructural with the analogous Np(V) compound (Bagnall *et al.*, 1967).

(4) Am(VI): The binary Am(VI) fluoride AmO_2F_2 was prepared by reacting solid sodium Am(VI) acetate with anhydrous HF containing a small amount of F_2 at −196°C (Keenan, 1968). The compound is isostructural with other actinyl(VI) fluorides. Dark-red $Cs_2AmO_2Cl_4$ is obtained by the unusual oxidation of $Cs_3AmO_2Cl_4$ in concentrated HCl (Bagnall *et al.*, 1967). The cubic form of $Cs_2AmO_2Cl_4$ appears to transform to a monoclinic form when washed with small volumes of concentrated HCl (Bagnall *et al.*, 1968). It is suggested that the cubic form is probably a mixed oxidation state compound of formula $Cs_7(AmO_2)(AmO_2)_2Cl_{12}$ (Melkaya *et al.*, 1982).

Conflicting claims have been put forth concerning the existence of AmF_6. Drobyshevskii *et al.* (1980) reported generating a solid by reaction of AmF_3

with KrF_2 in anhydrous HF and inferred its composition to be AmF_6 based upon its volatility, IR spectrum, and hydrolysis to AmO_2^{2+}; the IR absorption band at $604 \pm 3\ cm^{-1}$ is expected for the ν_3 mode of AmF_6. Fargeas *et al.* (1986) also inferred the existence of AmF_6 in their experiments from thermochromatography data. Most recently, Gibson and Haire (1992b) report that they were not able to confirm the existence of AmF_6; in their words, "... but have not been able to identify or provide evidence for the elusive and controversial AmF_6 species, despite having invoked several synthetic approaches and the sensitive analytical tool of mass spectrometry." Given these latest results, we have elected not to list AmF_6 among the identified inorganic compounds of americium in Table 8.5. It is interesting to note, however, that the proposed hexachloro compound of Am(VI) appears to be sufficiently stable to permit X-ray crystallographic studies.

(d) Chalcogenides and pnictides

The chalcogenides of americium comprise a number of compounds with the general formula AmX (X = S, Se, Te), $AmTe_2$, Am_3X_4 (X = S, Se, Te), AmX_3 (X = S, Se, Te), Am_2X_3 (X = S, Se, Te), and substoichiometric compounds AmX_{2-n} (X = S, Se). Some structural and synthetic properties of these chalcogenides, insofar as they have been determined, are briefly listed in Table 8.5; additional details concerning these compounds are provided in this section. The authors of this chapter are not aware that the chalcogenides are of any but academic interest.

The reaction of AmH_3 with stoichiometric amounts of selenium or telluride metal at 800°C in a vacuum yields the monochalcogenides AmSe and AmTe, respectively (Charvillat *et al.*, 1975a, 1977). Further heating of the monochalcogenides at 1100–1200°C produces Am_3X_4 and a second phase that was identified as (probably unreacted) AmX (Charvillat *et al.*, 1975a, 1977). In contrast, α-Am_2S_3 and not AmS is obtained when AmH_3 is heated with elemental sulfur at 500°C; it decomposes to γ-Am_2S_3 and AmS when heated in a vacuum above 650°C (Damien, 1971).

Americium sesquisulfide exhibits a complex structural chemistry and apparently exists in three different crystalline forms. α-Am_2S_3 is obtained by vapor-phase reaction for 4 days of a stoichiometric amount of sulfur with AmH_3 in a quartz and Pyrex tube sealed under high vacuum (Damien, 1971). The quartz end of the tube is heated at 500°C and the Pyrex part is maintained at 300°C to prevent sulfur from condensing. According to Damien *et al.* (1972), α-Am_2S_3 transforms into β-Am_2S_3 when heated at 1100°C. However, the existence of the β-form of americium sesquisulfide is seriously in doubt since the same French scientists believe that β-Am_2S_3 is better considered an oxysulfide, namely $Am_{10}S_{14}O$. When heated in a vacuum at 1300°C, α-Am_2S_3 changes to pure γ-Am_2S_3 (Damien, 1971). The pure γ-Am_2S_3 can also be prepared by passing a mixture of H_2S and CS_2 over heated (1400–1500°C) AmO_2 for 5 min

(Fried, 1951). Zachariasen (1949d) determined the crystal structure of γ-Am_2S_3. Am_2Te_3 is formed by dissociation of $AmTe_2$ at 600°C and is isostructural with the rare earth sesquitellurides (η-form) (Damien and Charvillat, 1972). The Am_2Te_3 phase is stable up to around 850°C and transforms into Am_3Te_4 above 900°C. No sesquiselenide of americium has been reported.

The only americium trichalcogenide yet reported, $AmTe_3$, is prepared by vapor-phase reaction of AmH_3 with excess tellurium for 120 h at 350°C (Damien, 1972; Burns *et al.*, 1979). Orthorhombic $AmTe_3$ is isostructural with the corresponding rare earth tritellurides and is used as a precursor for the synthesis of a number of americium/tellurium compounds. In a high vacuum at 400°C, $AmTe_3$ dissociates to tetragonal $AmTe_2$, which is the only stoichiometric americium dichalcogenide. $AmTe_2$ is isostructural with the rare earth ditellurides and most likely has the Fe_2As-type structure. Roddy (1974) prepared what appeared to be tetragonal $AmSe_2$ by heating ^{243}Am metal or hydride with selenium metal for 24 h at 950°C. However, although two research groups (Charvillat *et al.*, 1977; Burns *et al.*, 1979) reported the preparation and properties of $AmTe_2$, Damien and Jove (1971) state that the $AmTe_2$ prepared as described above is rather a tellurium-deficient compound $AmTe_{2-x}$ with a large homogeneity range between 400 and 600°C. The same homogeneity range seems to exist in the Am–S and Am–Se system and the dichalcogenides actually have a composition near $AmS_{1.9}$ and $AmSe_{1.8}$. The black non-stoichiometric compounds are prepared by heating an excess of sulfur or selenium metal with AmH_3 for 1 week at 400°C under high vacuum (Damien and Jove, 1971).

The americium chalcogenides Am_3Se_4 and Am_3Te_4 are isostructural (bcc) with Th_3P_4 and are without magnetic ordering down to 4.2 K (Dunlap *et al.*, 1972). Both compounds can be prepared by heating ^{243}Am metal with elemental selenium or tellurium for 24 h at 950°C (Roddy, 1974). However, X-ray diffraction measurements show that this synthesis contains at least one other phase (Dunlap *et al.*, 1972). Am_3Se_4 (bcc) is also formed when a mixture of 50 mass% americium metal and 50 mass% elemental selenium is heated for 1 h at 217°C and then for 7 h at 850°C before cooling to room temperature (Mitchell and Lam, 1970a). Am_3Te_4 also forms by decomposition of η-Am_2Te_3 at 900°C (Damien and Charvillat, 1972).

Compounds of americium with all group VB elements N, P, As, Sb, and Bi have been prepared. While AmN is of most interest due to its potential use as nuclear reactor fuel, the americium pnictides are mainly of academic interest. Ogawa *et al.* (1997) note that certain actinide nitrides, e.g. UN, NpN, PuN, can be fabricated by carbothermic reduction of their oxides in a nitrogen atmosphere. Based upon the thermodynamics of the carbothermic synthesis of AmN, calculations indicate that the carbothermic preparation of AmN would be much more difficult than preparation of either UN or PuN.

Americium nitride, AmN, was first prepared by reacting AmH_3 (above 800°C) or americium metal (at 750°C) with nitrogen (Akimoto, 1967; Tagawa, 1971) or in a 99.9% N_2/0.1% H_2 atmosphere (Radchenko *et al.*, 1982). Potter and Tennery (1973) disclosed a cyclic process to prepare finely divided AmN, which consists of incrementally dehydriding AmH_3 and nitriding the metal. Charvillat *et al.* (1975a, 1977) prepared milligram quantities of AmN by heating AmH_3 at 550°C under high-purity nitrogen in a sealed tube. A review of the phase behavior and crystal structure of actinide nitrides has been published (Tagawa, 1971).

The only reported synthesis of AmP was published a quarter of a century ago. Charvillat *et al.* (1975a,b, 1977) synthesized AmP by reacting red phosphorus with AmH_3 in a sealed quartz tube at 580°C.

The product of the vapor-phase reaction of excess elemental arsenic with $^{241}AmH_3$ at 330°C contains both unreacted elemental arsenic and a cubic phase that was assigned as AmAs by analogy with the corresponding NpAs and PuAs (Charvillat and Damien, 1973). Heating ^{243}Am metal and elemental arsenic for 24 h at 675°C and then 7 days at 400°C produces AmAs with slightly higher lattice parameters (Roddy, 1974). However, a slight decrease in the lattice parameters is observed after heating AmAs for 10 h at 1000°C. Weak lines that correspond to AmO are observed in the X-ray diffraction pattern of the resulting product indicating the existence of a solid solution between AmAs and AmO. The slight difference in lattice parameters may have been the result of an isotope effect or may be attributed to other minor americium oxide impurities.

The reaction of ^{243}Am metal with elemental antimony for 23 h at 775–900°C in an evacuated quartz bulb yielded cubic AmSb (Roddy, 1974). Cubic AmSb with almost the same lattice parameters was obtained by heating equimolar amounts of ^{241}Am metal and high-purity elemental antimony under vacuum for 1 h at 630°C (Mitchell and Lam, 1970a). The temperature was gradually raised to 850°C and held at this temperature for 7 h before cooling to room temperature. Finally, the resulting AmSb was heated at 1000°C for 24 h, cooled, and then heated again at 400°C for 10 days. The reaction of a 4:3 stoichiometric ratio of $^{241}AmH_3$: elemental antimony in a Pyrex tube at 550°C produced two phases, AmSb and a second phase with the bcc structure of anti-Th_3P_4-type (Charvillat *et al.*, 1975b).

Like AmP, AmBi has also been investigated. Roddy (1974) produced AmBi by reaction of metallic bismuth vapor with either americium metal or americium hydride in a sealed, evacuated quartz tube for 48 h at 975°C.

The magnetic susceptibilities of actinide chalcogenides and pnictides can be fit by the modified Curie–Weiss law:

$$\chi_{\text{measured}} = \chi_{\text{Curie+Weiss}} + \chi_0 = (C/(T - \theta_{\text{para}})) + \chi_0$$

where C is the Curie constant, θ_{para} is the paramagnetic Curie temperature, and χ_0 is a generally temperature-independent additional term. For the americium compounds, the Curie–Weiss term vanishes and experimentally determined values for χ_0 are reported to be 777 for AmN, 550 for AmAs, 1250 for AmSb, and 500 for AmBi (Kanellakopulos *et al.*, 1975; Vogt *et al.*, 1998).

The effective magnetic moment of AmN is 136 Bohr magnetons (Nellis and Brodsky, 1974; Kanellakopulos *et al.*, 1975) and that of AmAs is 1.14 Bohr magnetons (Kanellakopulos *et al.*, 1975). Kanellakopulos measured the magnetic susceptibility of AmAs between liquid helium and room temperature and observed an antiferromagnetic transition at 13 K. Magnetic susceptibility measurements on AmSb show a temperature-independent value of $\chi_0 = (1250 \pm 100) \times 10^{-6}$ emu mol^{-1} for the range 4.2 K $< T <$ 320 K (Dunlap *et al.*, 1972).

(e) Carbides and carbonates

The binary Am(III) carbide, Am_2C_3, is the only known carbide of americium and is prepared by arc melting americium metal with high-purity graphite in an argon–helium atmosphere (Mitchell and Lam, 1970b). The compound is isostructural with Pu_2C_3.

Carbonate compounds of Am(III) and Am(V) have been synthesized and characterized. They are applied in separation processes and also may form under environmental conditions. No solid carbonates of Am(IV) or Am(VI) are known.

(1) Am(III): The binary Am(III) carbonate, $Am_2(CO_3)_3$, precipitates from a CO_2-saturated solution of $NaHCO_3$ (Meinrath and Kim, 1991b; Runde and Kim, 1994). Thermogravimetric analysis of the precipitated binary compound suggests the formula $Am_2(CO_3)_3 \cdot 2H_2O$ (Weigel and ter Meer, 1967) or $Am_2(CO_3)_3 \cdot 4H_2O$ (Keller and Fang, 1969). The ternary compounds $NaAm(CO_3)_2 \cdot 4H_2O$ and $Na_3Am(CO_3)_3 \cdot 3H_2O$ precipitate from 0.5 M $NaHCO_3$ and 1.5 M Na_2CO_3 solutions, respectively (Keller and Fang, 1969). In analogy to neodymium and europium hydroxycarbonates, orthorhombic $AmOHCO_3$ was characterized by X-ray powder diffraction data (Meinrath and Kim, 1991b; Runde *et al.*, 1992), but the formation of its hexagonal form (Standifer and Nitsche, 1988) could not be confirmed.

(2) Am(V): A number of 'double carbonates' of general formula $MAmO_2CO_3$ where M = K (Nigon *et al.*, 1954; Volkov *et al.*, 1974), Na (Nigon *et al.*, 1954; Runde and Kim, 1994), Rb, Cs, NH_4 (Nigon *et al.*, 1954) have been synthesized by precipitation of Am(V) in dilute bicarbonate solutions of the corresponding cation. The use of large excess of alkali carbonate yields the $K_3AmO_2(CO_3)_2$ and $K_5AmO_2(CO_3)_3$ solids (Yakovlev and Gorbenko-Germanov, 1955; Volkov *et al.*, 1981).

(f) Phosphates and sulfates

Light pink $AmPO_4 \cdot xH_2O$ precipitates by adding dilute solutions of H_3PO_4, Na_2HPO_4, or $(NH_4)_2HPO_4$ to a weakly acidic Am^{3+} solution (Lawaldt *et al.*, 1982; Fedoseev and Perminov, 1983; Rai *et al.*, 1992). Rai and coworkers suggest the precipitation of $AmPO_4 \cdot xH_2O$ from dilute acidic solution but the study lacks characterization of the solid phase. Dehydration of the hydrous precipitate yields hexagonal $AmPO_4 \cdot 0.5H_2O$ at 200°C and $AmPO_4$ at higher temperatures up to 1000°C. The anhydrous compound can also be obtained by reacting AmO_2 with stoichiometric amounts of $(NH_4)_2HPO_4$ at 600–1000°C.

Because of the tendency of Am(VI) towards reduction to Am(V) at near-neutral pH, Am(VI) phosphates can be precipitated only in the narrow pH range of 3.5–4. Four ternary Am(VI) phosphates $MAmPO_4 \cdot xH_2O$ with M = NH_4, K, Rb, Cs have been prepared by Lawaldt *et al.* (1982) by precipitating Am(VI) in 0.1 M H_3PO_4 after adjusting the pH with the corresponding carbonate solution.

Binary sulfate compounds are known for Am(III), Am(V), and Am(VI), especially a large number of double sulfates of Am(III).

(1) Am(III): Evaporation of a neutral solution of ^{243}Am(III) sulfate yields thick, up to 0.5 mm long, tabular, pale yellow-pink crystals of $Am_2(SO_4)_3 \cdot 8H_2O$ (Burns and Baybarz, 1972). Crystals of the octahydrate, after being dried in air, are stable to change in their degree of hydration for several days. On the basis of analyses for americium, sulfate, and water, Yakovlev *et al.* (1958) assign the formula $Am_2(SO_4)_3 \cdot 5H_2O$ to the precipitate obtained by adding ethanol to a solution of Am(III) in 0.5 M H_2SO_4. The white anhydrous Am(III) sulfate, $Am_2(SO_4)_3$, is prepared by heating the hydrate to a temperature of 500–600°C in air (Hall and Markin, 1957). Anhydrous americium sulfate does not take up water when cooled to room temperature in air.

A number of double sulfates of Am(III) with formulas $MAm(SO_4)_2 \cdot xH_2O$ (M = K, Na, Rb, Cs, Tl; x = 0, 1, 2, 4), $K_3Am(SO_4)_3 \cdot xH_2O$, and $M_8Am_2(SO_4)_7$ (M = K, Cs, Tl) have been prepared by adding a metal sulfate solution to a solution of Am^{3+} in 0.5 M H_2SO_4. The concentration ratios M^+/Am^{3+} for the preparation of the various double sulfates as well as the absorption spectra of some Am(III) double sulfates at 80, 200, and 300 K are given by Yakovlev *et al.* (1958). Surprisingly, no X-ray diffraction data were reported for these double sulfates. Coprecipitation of trace amounts of Am(III) with K_2SO_4 and $La_2(SO_4)_3$ has also been published (Grebenshschikova and Babrova, 1958, 1961; Grebenshschikova and Cheinyavskaya, 1962).

(2) Am(V): Fedoseev and Budentseva (1989) claimed the preparation of three solid sulfates of Am(V). $(AmO_2)_2(SO_4) \cdot xH_2O$ crystallizes upon evaporation of an Am(V)-containing sulfuric acid solution. Am(V) sulfate also crystallizes from an ozonated solution of $Am(OH)_3$ after addition of sulfuric acid and subsequent evaporation. Two double salts have been reported: Large light green crystals of $CsAmO_2SO_4 \cdot xH_2O$ were obtained by evaporating a solution containing $(AmO_2)_2(SO_4)$ and Cs_2SO_4 in a 3:1 ratio. According to Fedoseev and Budentseva $Co(NH_3)_6AmO_2(SO_4)_2 \cdot 2H_2O$ can be easily

made by simply including Am(v) among the reagents used to prepare $Co(NH_3)_6(SO_4)_2$.

(3) Am(vi): Addition of hexamine cobalt(iii) ions to an aqueous sulfate solution containing hexavalent americium yields orange cubic crystals of $Co(NH_3)_6(HSO_4)_2(AmO_2(SO_4)_3) \cdot nH_2O$ (Ueno and Hoshi, 1971). The compound is isostructural with the corresponding uranyl and neptunyl compounds. No precipitate forms, however, in an ammonium sulfate solution containing Am(iii) and hexamine cobalt(iii) ions.

(g) Other inorganic compounds

Shirokova *et al.* (2001) reported the complexation of Am(iii) with *N*,*N*-dimethylacetamide and the Keggin-type heteropolyanion $PW_{12}O_{40}^{3+}$. Lawaldt *et al.* (1982) applied the same procedures as used to prepare Am(vi) phosphates for the precipitation of Am(vi) arsenates. The obtained compounds were isostructural to the analogous Am(vi) phosphates.

Only two phases, AmB_4 and AmB_6, have been reported in the boride system in contrast to the richer Np–B system with four phases (Eick and Mulford, 1969).

Weigel *et al.* (1977, 1984) reported the formation of several silicide phases upon reacting AmF_3 with elemental Si at different temperatures. Up to 950°C, the phases Am_5Si_3, AmSi, Am_2Si_3, and $AmSi_2$ have been characterized by X-ray powder diffraction. Orthorhombic AmSi is also prepared at 1050°C and the substoichiometric tetragonal phase $AmSi_x$ ($1.87 < x < 2.0$) forms at 1150–1200°C.

The only silicate known to date, $AmSiO_4$, is obtained as a brown solid by reacting $Am(OH)_4$ with excess SiO_2 in 1 M $NaHCO_3$ solution at 230°C for 1 week (Katz and Seaborg, 1957). $^{241}AmSiO_4$ is patented for the use in manufactured alpha sources.

Large orange needle-like crystals thought to be $AmO_2CrO_4 \cdot H_2O$ were prepared by slowly evaporating a chromic acid (H_2CrO_4) solution containing Am(v) (Fedoseev *et al.*, 1991). Although there is some spectroscopic evidence for the presence of Am(v) in the solid chromate (electronic absorbances at about 518 and 728 nm) the suggested formula of $AmO_2CrO_4 \cdot H_2O$ appears to be erroneous and should rather be $(AmO_2)_2CrO_4 \cdot H_2O$.

Tabuteau and coworkers (Tabuteau *et al.*, 1972; Tabuteau and Pages, 1978) investigated the Am–molybdate and Am–tungstate systems. The solid state reaction of stoichiometric amounts of AmO_2 and MoO_3 or WO_3 at 1080°C resulted in the formation of monoclinic $Am_2(MoO_4)_3$ and $Am_2(WO_4)_3$. Two ternary phases, $KAm(MoO_4)_2$ and $K_5Am(MoO_4)_4$, were found to form at 650°C in the presence of potassium. Fedoseev and Budantseva (1990) report the synthesis of $AmO_2Mo_2O_7 \cdot 3H_2O$ at 100°C, however, no information on the phase characterization was provided.

8.7.2 Compounds of americium with organic ligands

Relatively few solid compounds of americium with organic ligands have been prepared; these are listed in Table 8.6. For detailed reviews of this chemistry see Kanellakopulos (1979) and also Chapters 23 and 25.

(a) Oxalate

Because of its importance for americium separation chemistry $Am_2(C_2O_4)_3 \cdot xH_2O$ (Weigel and ter Meer, 1967) is the most important organic compound of americium. The pink solid precipitates from slightly acidic or neutral solutions of Am^{3+} on addition of oxalic acid or alkali oxalate solution. The hydration number x was previously thought to vary with conditions of preparation and drying and values of 7 (Markin, 1958), 9 (Yakovlev and Kosyakov, 1958a), and 11 (Staritzky and Truitt, 1954) have been reported. Based on their X-ray diffraction studies and in analogy to Nd(III), Pu(III), and Cm(III), Weigel and ter Meer (1967) concluded that the hydration number x is 10. The decahydrate decomposes to the anhydrous form at 340°C through several hydrates and further decomposes to carbonate $Am_2(CO_3)_3$ at about 430°C. The oxalate complexes with general formula $MAm(C_2O_4)_2 \cdot xH_2O$ have been prepared from Am(III) oxalate and $M_2C_2O_4$ ($M = NH_4$, Na, K, Cs) in neutral solution (Zubarev and Krot, 1982, 1983a,b).

(b) Formate

Pink crystals of hexagonal $Am(HCOO) \cdot 0.2H_2O$ form upon evaporation of a concentrated formic acid solution (Weigel and ter Meer, 1967). The formate decomposes at 300–350°C to AmO(HCOO), and at 400–500°C to the oxycarbonate $Am_2O_3CO_3$, which forms at 520°C the sesquioxide Am_2O_3 (Weigel and ter Meer, 1971).

(c) Acetate

Addition of sodium acetate to an acidic Am(VI) solution precipitates lemon-yellow cubic crystals of $NaAmO_2(OOCCH_3)_3$ (Asprey *et al.*, 1950, 1951). The force constant of the Am–O bond in $NaAmO_2(OOCCH_3)_3$ is determined to be 6.12 megadynes/Å (Jones, 1953). The refractive index is 1.528 ± 0.002 (Asprey *et al.*, 1951).

(d) Acetone derivate compounds

Addition of ammonia to aqueous Am^{3+} solution that contains a small amount of acetylacetone precipitates pale-rose $Am(C_5H_7O_2)_3 \cdot H_2O$ at pH 6. The precipitate can be recrystallized in ethanol and dried in air over silica gel or P_2O_5 (Keller and Schreck, 1969). Dropwise addition of aqueous Am^{3+} (pH 4.5) to warm, slightly less than stoichiometric amounts of ammonium benzoylacetone yields pale-rose $Am(C_{10}H_6F_3O_2)_3 \cdot 3H_2O$. Both compounds decompose in air at

Table 8.6 *Organic compounds of americium.*

Organic ligand	*Formula of compound*	*Comments*	*References*
Acetate	$NaAmO_2(OOCCH_3)_3$	lemon yellow	[1]
acetylacetone	$Am(C_5H_7O_2)_3 \cdot H_2O$	pale rose	[2]

salicylate	$Am(C_7H_5O_3)_3 \cdot H_2O$		[15]
thenoyltrifluoroacetate	$Am(C_5H_4F_3O_2S)_3 \cdot 3H_2O$	pale rose	[2]

[a] THF, tetrahydrofuran.

[1] (Asprey *et al.*, 1950, 1951, 1954b); [2] (Keller and Schreck, 1969); [3] (Karraker, 1975, 1977); [4] (Baumgärtner *et al.*, 1966a, 1977; Kanellakopoulos *et al.*, 1970, 1978; Seaborg, 1972); [5] (Danford *et al.*, 1970; Moore, 1970; Sakanoue and Amano, 1975); [6] (Lebedev *et al.*, 1960b, 1962); [7] (Burns and Danford, 1969; Danford *et al.*, 1970; Bagnall, 1972; Sakanoue and Amano, 1975); [8] (Davydov *et al.*, 1975); [9] (Keller *et al.*, 1965a, 1966); [10] (Eyring *et al.*, 1952; Yakovlev and Kosyakov, 1958b; Lebedev *et al.*, 1960a; Weigel *et al.*, 1966; Burney and Porter, 1967; Chikalla and Eyring, 1967; Weigel and ter Meer, 1967, 1971); [11] (Zubarev and Krot, 1982, 1983a); [12] (Kirin *et al.*, 1967; Lux, 1973); [13] (Eberle and Robel, 1970; Robel, 1970); [14] (Robel, 1970); [15] (Burns and Baldwin, 1977).

above 200°C to AmO_2. Yellow $CsAm(C_5HF_6O_2)_4 \cdot H_2O$ crystallizes from $AmCl_3$ solution after addition of excess cesium hexafluoroacetylacetone in 50 vol% ethanol (Burns and Danford, 1969; Danford *et al.*, 1970).

(e) Cyclooctatetraene and cyclopentadiene

Reaction of $^{241}AmI_3$ with $K_2C_8H_8$ in tetrahydrofuran (THF) solution yields the adduct $KAm(C_8H_8)_2 \cdot 2THF$, which is isostructural with its plutonium analog $KPu(C_8H_8)_2 \cdot 2THF$ (Karraker, 1975). The compound decomposes in water and burns in air. Reacting the halides AmF_3 (Moore, 1970) or $AmCl_3$ (Baumgärtner *et al.*, 1966a,b; Kanellakopoulos *et al.*, 1970; Seaborg, 1972) with molten $Be(C_5H_5)_2$ at 65–70°C produces $Am(C_5H_5)_3$ (Moore, 1970). The pure compound can be obtained by fractional sublimation at 10^{-5} Torr and 160–205°C (Baumgärtner *et al.*, 1966a,b). Unlike $Pu(C_5H_5)_3$, $Am(C_5H_5)_3$ is not pyrophoric and decomposes only slowly in air. The IR and absorption spectra of $Am(C_5H_5)_3$ have been reported (Pappalardo *et al.*, 1969a; Kanellakopoulos *et al.*, 1970).

(f) Others

Reaction of AmI_3 at 200°C with phthalodinitride in 1-chloronaphthalene yields the dark violet phthalocyanine compound $Am(C_{32}H_{16}N_8)_2$, which was the first synthesized Am(IV) compound with an organic ligand (Lux, 1973). There is evidence that americium also forms the monophthalocyaninato complex.

Danford *et al.* (1970) precipitated the dipivaloylmethane compound $Am(C_{11}H_{19}O_2)_3$ by adding aqueous Am(III) sulfate to a solution of dipivaloylmethane and NaOH in 70% aqueous ethanol. Sakanoue and Amano (1975) determined the volatility of $Am(C_{11}H_{19}O_2)_3$ and several lanthanide and actinide analog complexes at 180°C and 10^{-3} torr and observed that $Am(C_{11}H_{19}O_2)_3$ is less volatile than its analog compounds of Th, Pu, Cf, or Eu, Gd, or Sc.

The only recorded aliphatic compounds of americium appear to be the citrates $Am(C_6H_5O_7) \cdot xH_2O$ and $[Co(NH_3)_6][Am(C_6H_5O_7)_2] \cdot xH_2O$ (Bouhlassa, 1983), and the salicylate $Am(C_7H_5O_3)_3 \cdot H_2O$ (Burns and Baldwin, 1976); its structure is described in Section 8.9.2.

Hölgye (1982) studied the coprecipitation of Am(III) with various metal cupferrates. With cupferrates of lanthanides and Sc(III), Am(III) coprecipitated quantitatively. But Am(III) coprecipitated only partially with cupferrates of Fe(III), Cu(II), Al(III), In(III), Pb(II), and Bi(III).

8.8 AQUEOUS SOLUTION CHEMISTRY

8.8.1 Oxidation states

In aqueous solutions, americium exhibits the III, IV, V, and VI oxidation states. All four oxidation states can coexist under certain conditions in carbonate media (Bourges *et al.*, 1983). In dilute acid, only the aquo ions Am^{3+} and

AmO_2^{2+} ions are stable, whereas in alkaline solution, americium can exist in all four valence states. In the III and IV oxidation states, americium forms Am^{3+} and Am^{4+} ions in solution, respectively. The highly charged ions in the V and VI states are unstable and hydrolyze instantly to form the linear *trans*-dioxo americyl cations, AmO_2^+ and AmO_2^{2+}, respectively. Analogous to Np(VII) and Pu(VII), americium reportedly can be oxidized to the VII oxidation state in highly alkaline media (Krot *et al.*, 1974a,b; Myasoedov and Kremliakova, 1985).

(a) Preparation

(1) Am(II): In contrast to its chemical analog of the lanthanide series, europium, the divalent state of Am is unstable in aqueous solution. Conditions that stabilize Yb^{2+}, Eu^{2+}, or Sm^{2+} do not reduce Am^{3+} to Am^{2+} (Keenan, 1959). Milyukova *et al.* (1980) claimed electrochemical evidence for unstable Am(II) in acetonitrile; they found that Am(II) was rapidly oxidized to Am(III) by water in the solvent. Sullivan *et al.* (1976, 1978) formed transient Am(II) by pulse radiolysis with an absorption maximum at 313 nm and $t_{1/2} \sim 5 \times 10^{-6}$ s for disappearance. Am(II) can be accessed in the solid state and as dilute solution in CaF_2 (Zachariasen, 1948b; Fried, 1951; Pappalardo *et al.*, 1969b; Baybarz, 1973b; Peterson, 1973). The solid compounds $AmCl_2$ (Baybarz, 1973b), $AmBr_2$ (Baybarz, 1973b), and AmI_2 (Baybarz and Asprey, 1972) have been prepared and characterized.

(2) Am(III): Trivalent americium is the most common and stable oxidation state in aqueous solution. It can be easily prepared by dissolving the metal in acid, dissolving AmO_2 in hot HCl, or by reducing higher valent americium compounds with most common reducing agents, such as NH_2OH, SO_2, or KI (Coleman *et al.*, 1963). Acidic solutions of Am^{3+} are pink in mineral acids but are yellow in concentrated $HClO_4$ or when the Am^{3+} concentration exceeds 0.1 M. Numerous solid compounds of Am(III) have been prepared and characterized.

(3) Am(IV): Tetravalent americium is unstable in non-complexing solutions and is reduced spontaneously to its more stable III oxidation state. Stable Am(IV) can be prepared by dissolving $Am(OH)_4$ in concentrated NH_4F solutions (Asprey and Penneman, 1962). Yanir *et al.* (1969) demonstrated that Am(IV) remains stable in phosphoric and pyrophosphate media. Myasoedov *et al.* (1977) reported that pure Am(IV) is obtained in 8–15 M phosphoric acid by anodic oxidation, while at lower phosphoric acid concentrations impurities of Am(VI) are formed. Similar stability of Am(IV) was reported in an oxidizing mixture of Ag_3PO_4 and $(NH_4)_2S_2O_8$. Electrolytic oxidation of ^{243}Am(III) (<1 V) in 2–5.5 M carbonate solutions resulted in the formation of a golden-yellow Am(IV) carbonate species, which was slowly reduced to Am(III) (Hobart *et al.*, 1982). At potentials exceeding 1.1 V, Am(IV) is oxidized to Am(V) and Am(VI). Am(IV) can be stabilized with heteropolyanions and reduction to Am(III) is caused solely by radiolytic effects

(Saprykin *et al.*, 1976; Kosyakov *et al.*, 1977; Erin *et al.*, 1979). Transient Am(IV) has been observed by pulse radiolysis (Sullivan *et al.*, 1976, 1978).

(4) Am(V): Am(III) can be oxidized to Am(V) in near-neutral and alkaline solution. In acidic media, oxidation of Am(III) yields only Am(VI) because Am(V) is more easily oxidized to Am(VI) than Am(III) is oxidized to Am(V). Solutions of Am(V) can be prepared by oxidation of Am(III) with ozone (Keenan, 1965), hypochlorite (Yakovlev and Gorbenko-Germanov, 1955), and peroxydisulfate (Nigon *et al.*, 1954), or by reduction of Am(VI) with bromide, or by electrolysis (Hobart *et al.*, 1983b). Solid sodium Am(V) carbonate can be precipitated by heating a 2 M Na_2CO_3 Am(VI) solution for 60 min to 60°C (Coleman *et al.*, 1963). Dissolution of the solid in near-neutral solutions yields pure Am(V) solution free of Am(III) and Am(VI). AmO_2^+ solutions free of Am^{3+} can be prepared by first extracting AmO_2^+ from buffered 1 M acetate (pH 3) solutions into 0.1 M thenoyltrifluoroacetone in isobutanol and back-extraction into an aqueous phase (Hara, 1970). More exotic methods include the dissolution of solid Li_3AmO_4 in dilute perchloric acid or the electrolytic oxidation of Am(III) in 2 M $LiIO_3$/0.7 M HIO_3 solutions (pH 1.5) (Keller, 1971).

(5) Am(VI): Powerful oxidants, i.e. peroxydisulfate or Ag(II), oxidize Am(III) and Am(V) in dilute, non-reducing acidic solution to Am(VI) (Myasoedov and Kremliakova, 1985). At acidities above 0.5 M, peroxydisulfate will not oxidize Am(III) completely to Am(VI) because of the interference of acid hydrolysis of $S_2O_8^{2+}$ (Penneman and Asprey, 1955). Ce(IV) oxidizes Am(V) to Am(VI) but only partially oxidizes Am(III) to Am(VI) (Penneman and Asprey, 1955). Electrolytic oxidation of Am(III) in 2 M H_3PO_4 and 6 M $HClO_4$ leads to Am(VI) (Myasoedov *et al.*, 1977) while ozone does not oxidize Am(III) to Am(VI) in acidic medium. In aqueous 2 M carbonate solutions oxidation of Am(III), Am(IV), or Am(V) with ozone or oxidation with $Na_2S_2O_8$ yields an intensely colored red-brown carbonate complex of Am(VI) (Coleman *et al.*, 1963). This complex is also obtained electrolytically at a potential of 1.3 V vs NHE in sodium carbonate solutions (Hobart *et al.*, 1982) or by dissolution of sodium americyl(VI) acetate in sodium carbonate solutions. Ozone oxidation in carbonate solution yields Am(VI) only at 25°C or below while at 90°C oxidation does not proceed past Am(V). Ozone does not oxidize $Am(OH)_3$ or $KAmO_2CO_3$ in 0.1–0.5 M $KHCO_3$ and $K_2S_2O_8$ does not oxidize $Am(OH)_3$ or $NaAmO_2CO_3$ in 0.1 M $NaHCO_3$ (Coleman *et al.*, 1963). This difference to the easy oxidation by $Na_2S_2O_8$ is attributed to the lower solubility of $KAmO_2CO_3$ compared to $NaAmO_2CO_3$. In 0.1–0.5 M $NaHCO_3$, Am(VI) is stable at 90°C to reduction by H_2O, Cl^-, or Br^-, but is easily reduced by I^-, N_2H_4, H_2O_2, NO_2^-, and NH_2OH. Very slow reduction of Am(VI) occurs in 2 M Na_2CO_3. Yellow-colored solutions of Am(VI) in any alkali hydroxide solutions can be prepared by oxidation of solid $Am(OH)_3$ with ozone (Cohen, 1972). Am(VI) in alkali hydroxide solutions undergoes

gradual reduction to form a light-tan solid, which yields Am(v) when dissolved in mineral acid. It is claimed that Am(vi) disproportionates into Am(vii) and Am(v) in >10 M NaOH (Nikolaevskii *et al.*, 1975).

The reaction of KrF_2 with AmF_3 in anhydrous HF yields a dark-brown solid of AmF_6 with a vapor pressure that is similar to that of UF_6 (Drobyshevskii *et al.*, 1980).

(6) Am(vii): While attempts to synthesize Am(vii) from Li_2O–AmO_2 mixtures at 300–400°C failed, oxidation of 3–4 M NaOH solutions containing 0.001–0.002 M Am(vi) with ozone at 0–7°C yields a green-colored solution of Am(vii) (Krot *et al.*, 1974a,b; Myasoedov and Kremliakova, 1985). A similar green-colored solution can be obtained by ^{60}Co gamma irradiation at 0°C of a N_2O-saturated 3 M NaOH solution. (N_2O scavenges hydrated electrons by the reaction $N_2O + e^- (aq) \rightarrow N_2 + O^-$; $S_2O_8^{2-}$ may be substituted for N_2O.) Spectrophotometric studies showed the oxidation of Np(vi) to Np(vii) and Pu(vi) to Pu(vii) under similar conditions, which provides strong evidence that the green solutions indeed contain a powerful oxidant such as Am(vii) (Krot *et al.*, 1974a,b).

(b) Hydration and coordination numbers

Information on the structure of the $Am^{3+}(aq)$ ion has been obtained indirectly from a variety of spectroscopic techniques. From the similar absorption spectra of Am^{3+} in aqueous solution, $AmCl_3$, and Am^{3+} doped into $LaCl_3$, Carnall (1989) concluded that there were nine inner-sphere water molecules associated in $Am^{3+}(aq)$. Horrocks and Sudnick (1979, 1981) and Choppin and coworkers (Barthelemy and Choppin, 1989; Choppin and Peterman, 1998) developed a linear relationship between the decay rate of the lanthanide(iii) and the Am(iii) fluorescence and the number of inner-sphere water molecules: $n_{H_2O} = (x/\tau) - y$. Kimura and Kato (Kimura and Kato, 1998) determined $x = 2.56 \times 10^{-7}$ s and $y = 1.43$ for Am(iii) by measuring the fluorescence lifetime of Am^{3+} in H_2O and D_2O and using Carnall's proposed nine hydration waters. Runde *et al.* (2000) used Kimura's parameters and calculated from the fluorescence lifetime 11 coordinated water molecules for the Am^{3+} ion. Allen *et al.* (2000) determined ten coordinated water molecules around the Am^{3+} aquo ion in dilute aqueous chloride solution using X-ray absorption fine structure (XAFS) spectroscopy. Recently, Matonic *et al.* (2001) crystallized the isostructural Am(iii) and Pu(iii) triflate (trifluoromethanesulfonic acid) salts where the Am^{3+} ion bonds to nine water molecules in a tricapped, trigonal prismatic geometry (Fig. 8.4).

Shilov and Yusov (1999) analyzed reported variations in the Am(v)/Am(vi) potentials and the stability constants of the actinyl(v) oxalate complexes and proposed that the $NpO_2^+(aq)$ and $AmO_2^+(aq)$ ions are coordinated with five water molecules in the equatorial plane, in contrast to the coordination of four waters by $PuO_2^+(aq)$ and $UO_2^+(aq)$.

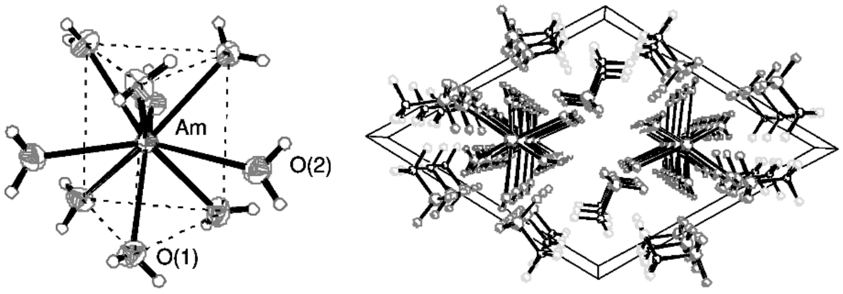

Fig. 8.4 *Coordination environment of* Am^{3+} *and crystal packing in* $[Am(H_2O)_9][CF_3SO_3]$ (*Matonic* et al., 2001).

(c) Electrode potentials and thermodynamic properties

A critical evaluation of available enthalpy and electromotive force (EMF) data were reported (Musikas, 1973b; Fuger and Oetting, 1976; Schulz, 1976; Fuger *et al.*, 1992; Silva *et al.*, 1995). Table 8.7 lists the electrode potentials for americium couples in various aqueous media. The diagram reflects the latest values and data evaluation of Martinot and Fuger (1985), which were accepted with minor changes by the recent Nuclear Energy Agency (NEA) review (Silva *et al.*, 1995). Except for the standard electrode potential ($E°$) of the Am(VI/V) couple, the electrode potentials of all redox couples were measured indirectly.

1. Am(III)/(0): Fuger *et al.* (1972) measured the enthalpy of dissolution of Am metal (dhcp) in hydrogen-saturated HCl solutions and, using the estimated entropy of Am^{3+}(aq), estimated $E°$ to be -2.06 ± 0.01 V in 1 M $HClO_4$; later Martinot and Fuger (1985) recommended -2.07 V.
2. Am(III)/(II): Nugent *et al.* (1973a) estimated the potential to be -2.3 V as a best value by comparing the properties of lanthanide and actinide chloro complexes in relation to their M(II)/M(III) potentials. The estimated value is close to the -2.4 V estimated by Bratsch and Lagowski (1986).
3. Am(IV)/(III): Due to the difficulties in preparing Am(IV) in appreciable amounts, estimating its thermodynamic properties is difficult. The originally estimated 2.44 V in 1 M $HClO_4$ appeared to be too small compared to data on the reduction of $Am(OH)_4$ to $Am(OH)_3$ (Penneman *et al.*, 1961). While the reported electrode potentials in concentrated H_3PO_4 are in agreement, 1.75 ± 0.03 V (Marcus *et al.*, 1972) and 1.78 V in 10 M H_3PO_4 (Nugent *et al.*, 1971a), their extrapolated values, $E° = 2.50 \pm 0.06$ and 2.34 ± 0.22 V, respectively, differ significantly, most likely due to uncertainties in solution speciation. A value of 2.6 ± 0.09 V has been calculated from enthalpy measurements (Morss and Fuger, 1981), and has been confirmed by electrochemical data in carbonate solutions (Hobart *et al.*, 1982). Stabilization by carbonate and phosphotungstate decreases the electrode

Table 8.7 *Electrode potentials of americium redox couples.*

\end{tikzcd}$$

(c) 1 M NaOH (Standard potentials were calculated based on the solubility products of $K_{sp}(Am(OH)_3) = 10^{23.3}$ and $K_{sp}(Am(OH)_4) = 10^{64}$) (Penneman *et al.*, 1961; Musikas, 1973b; Schulz, 1976):

$$\begin{tikzcd}
\text{Am(VI)} \arrow[r, dash, "0.9"] & \text{Am(V)} \arrow[r, dash, "0.7"] & \text{Am(IV)} \arrow[r, dash, "0.5"] & \text{Am(III)} \arrow[r, dash, "-2.5"] & \text{Am(0)}
\end{tikzcd}$$

(d) Carbonate media (Bourges *et al.*, 1983; Hobart *et al.*, 1983b; Berger *et al.*, 1988):

$$\begin{tikzcd}
\text{Am(VI)} \arrow[r, dash, "0.975", "2\ \mathrm{M}\ \mathrm{Na_2CO_3}"'] & \text{Am(V)}
\end{tikzcd} \text{ and } \begin{tikzcd}
\text{Am(IV)} \arrow[r, dash, "0.92", "2\ \mathrm{M}\ \mathrm{Na_2CO_3}"'] & \text{Am(III)}
\end{tikzcd}$$

potential to 0.92 V (Hobart *et al.*, 1982; Bourges *et al.*, 1983) and 1.52 V (Kosyakov *et al.*, 1977), respectively.

(4) Am(VI)/(V): Penneman and Asprey (1950) measured directly the potential of the AmO_2^{2+}/AmO_2^+ couple to be 1.600 ± 0.0005 V in 1 M $HClO_4$ and 1.614 ± 0.001 V in 0.3 M $HClO_4$. From studies of Am(VI) with Pu(VI) in NaOH, Nikolaevskii *et al.* (1974) estimated that the potential for the Am(IV)/Am(V) couple is about 0.65 V rather than 1.1 V.

(5) Am(VII)/(VI): Shilov (1976) reported a value of 1.05 V for the Am(VII)/Am(VI) couple in 1 M NaOH, while Peretrukhin and Spitsyn (1982) reported 0.78 V for this couple in 10 M hydroxide.

The heat of dissolution of americium metal in HCl at 298 ± 0.05 K was redetermined by Fuger *et al.* (1972) with pure americium metal prepared by distillation. Combined with earlier results, Fuger and Oetting (1976) calculated a standard enthalpy of formation of $Am^{3+}(aq)$ at 198 K of -616.7 ± 1.3 kJ mol^{-1}.

The following enthalpies of formation, free Gibbs energies of formation, and standard entropies for the americium aquo ions have been accepted by the NEA review (Silva *et al.*, 1995):

	$\Delta_f H^\circ_m$(298.15 K) (kJ mol^{-1})	$\Delta_f G^\circ_m$(298.15 K) (kJ mol^{-1})	S°_m(298.15 K) (kJ mol^{-1})
$Am^{2+}(aq)$	-355 ± 16	-377 ± 15	-1 ± 15
$Am^{3+}(aq)$	-616.7 ± 1.5	-598.7 ± 4.8	-201 ± 15
$Am^{4+}(aq)$	-406 ± 6	-346 ± 9	-406 ± 21
$AmO_2^+(aq)$	-804.3 ± 5.4	-739.8 ± 6.2	-21 ± 10
$AmO_2^{2+}(aq)$	-650.8 ± 4.8	-585 ± 5.7	-88 ± 10

A correlation function of *P*(M) that connects the trivalent gaseous lanthanide atoms with their aqueous ions changes systematically as a function of atomic number (Nugent *et al.*, 1973b). The same property is moderately well-behaved for trivalent actinides (Nugent *et al.*, 1973b; David *et al.*, 1978; Morss, 1983). The calculated *P*(Am) is about 20 kJ greater than expected from neighboring actinides. This anomaly was attributed to the large positive change in entropy of vaporization of Am (Ward and Hill, 1976).

(d) Autoreduction

Radiolytically produced species in aqueous solution, e.g. H_2O_2 and HO_2 radicals, reduce the higher oxidation states of americium to Am(III). Because of its lower specific activity, the rates of autoreduction of ^{243}Am species are much less than those of ^{241}Am. Zaitsev *et al.* (1960b) account for the autoreduction kinetics of aqueous AmO_2^{2+} and AmO_2^+ ions by assuming that H_2O_2 is consumed only in reducing Am(VI) and Am(V) is reduced only by HO_2 radicals, but that Am(V) may be oxidized to Am(VI) by OH radicals.

All investigators concur that autoreduction is kinetically zero order with respect to the AmO_2^{2+} ion and first order with respect to the total americium concentration:

$$-\mathrm{d}[\mathrm{Am(VI)}]/\mathrm{d}t = \mathrm{d}[\mathrm{Am(V)}]/\mathrm{d}t = k_1[\mathrm{Am_{total}}]$$

In both perchloric and sulfuric acid media, the value of the rate constant k_1 decreases with increasing acid concentration, 0.04 h^{-1} in dilute acid to zero in 12 M $HClO_4$ (Zaitsev *et al.*, 1960b). The autoreduction rate of ^{241}Am(VI) approaches 10% per hour in 9 M HNO_3 (Zaitsev *et al.*, 1960b); a slower rate was found in a later study (Myasoedov *et al.*, 1974b). The rate of autoreduction of ^{243}Am(VI) in 2 M $HClO_4$ solution at 76°C is about six times greater than that at room temperature (Zaitsev *et al.*, 1960b).

The autoreduction of Am(V) to Am(III) is usually stated to depend only on the total americium concentration but to be independent of the Am(V) concentration.

Zaitsev *et al.* (1960b) disagreed and found that under some conditions the rate of autoreduction of Am(v) to Am(iii) does depend on the Am(v) concentration. The autoreduction of $^{241}AmO_2^+$ proceeds more slowly in 0.5 M HCl than in 0.2 M $HClO_4$. The maximum reduction rate of AmO_2^+ is about 1% per hour in 0.5 M HNO_3 and 0.8% per hour in 3 M HNO_3 (Zaitsev *et al.*, 1960b).

In 13 M NH_4F, ^{241}Am(iv) is autoreduced at a rate of about 4% per hour (Asprey and Penneman, 1962), increasing to 10% per hour in 3 M fluoride solution (Yanir *et al.*, 1969). Self-reduction of Am(iv) to Am(iii) in phosphoric acid solution follows first-order reaction kinetics (Yanir *et al.*, 1969; Myasoedov *et al.*, 1973, 1975;). In acidic peroxydisulfate solution, no Am(iii) is observed until all Am(vi) is reduced to Am(v). In the presence of $S_2O_8^{2-}$ ions, the radiolytic reduction of Am(v) proceeds more slowly than that of Am(vi) (Rykov *et al.*, 1970).

(e) Disproportionation

1. Am(iv): Tetravalent americium rapidly disproportionates in nitric and perchloric acid solutions according to the following reaction (Penneman *et al.*, 1961):

$$2\mathrm{Am(IV)} \rightarrow \mathrm{Am(III)} + \mathrm{Am(V)}.$$

Assuming a reaction that is second order in Am(iv) concentration, Penneman *et al.* (1961) estimated k_1 in the equation

$$-\mathrm{d}[\mathrm{Am(IV)}]/\mathrm{d}t = k_1[\mathrm{Am(IV)}]^2$$

to be greater than $3.7 \times 10^{+4}$ L mol^{-1} h^{-1} in 0.05 M HNO_3 at 0°C. The dissolution of $Am(OH)_4$ in 0.05–2 M H_2SO_4 at either 0 or 25°C or of AmO_2 in 1 M H_2SO_4 yields solutions containing Am^{3+} and AmO_2^{2+} (Yakovlev and Kosyakov, 1958b; Penneman *et al.*, 1961). These results are explained by the following mechanism:

$$\text{Disproportionation of Am(IV)}: \ 2\mathrm{Am(IV)} \ \rightarrow \ \mathrm{Am(III)} + \ \mathrm{Am(V)}$$

and

$$\text{Redox Reaction}: \ Am^{4+} \ + \ AmO_2^+ \ \rightarrow \ Am^{3+} \ + \ AmO_2^{2+}$$

The AmO_2^{2+} fraction increases with SO_4^{2-} and HSO_4^- concentrations at constant H^+ concentration, possibly as a result of SO_4^{2-} (or HSO_4^-) stabilization of an Am(iv) complex. Am(iv) is stable only in concentrated H_3PO_4, $K_4P_2O_7$, phosphotungstate, and fluoride (NH_4F, KF) solutions. The average oxidation number of americium remains iv when $Am(OH)_4$ is dissolved in either perchloric, nitric, or sulfuric acids (Penneman *et al.*, 1961), indicating no significant reduction by water, in contrast to the reduction of Cm(iv) (Kosyakov *et al.*, 1977).

2. Am(V): The most thorough study of the disproportionation kinetics of Am(V) was performed by Coleman (1963), who used ^{243}Am to minimize the radiolytically induced redox reactions associated with ^{241}Am. Coleman investigated the disproportionation of Am(V) in 3–8 M $HClO_4$ at 25°C, in 1–2 M $HClO_4$ at 75.7°C, and in about 2 M HCl, H_2SO_4, and HNO_3 solutions at 75.7°C. The disproportionation of Am(V) in 5 M $HClO_4$ and 5 M HCl at 25°C is shown in Fig. 8.5. The disproportionation of Am(V) in all media except HCl follows the reaction

$$3\ \mathrm{AmO_2^+} + 4\mathrm{H^+} \rightarrow \mathrm{Am^{3+}} + 2\mathrm{AmO_2^{2+}} + 2\mathrm{H_2O},$$

reflecting the fourth power dependence on the H^+ concentration. The rate law for this disproportionation reaction is

$$-\mathrm{d[Am(V)]/d}t = k_1\,[\mathrm{AmO_2^+}]^2[\mathrm{H^+}]^4 = k_2\,[\mathrm{AmO_2^+}]^2[\mathrm{H^+}]^2 + k_3\,[\mathrm{AmO_2^+}]^2[\mathrm{H^+}]^3,$$

with $k_2 = (6.94 \pm 1.01) \times 10^{-4}$ $\mathrm{L^3\,mol^{-3}\,s^{-1}}$ and $k_3 = (4.63 \pm 0.71) \times 10^{-4}$ $\mathrm{L^3mol^{-3}s^{-1}}$. The disproportionation rates at 75.7°C in 2 M HNO_3, HCl, and H_2SO_4 are, respectively, 4.0, 4.6, and 24 times greater than in 1 M $HClO_4$, whereas at 25°C the reaction rate increased 450 times in going from 3 to 8 M $HClO_4$. Using the temperature-dependence data from Coleman, Newton (1975) estimated thermodynamic quantities of activation for the disproportionation of Am(V). Note that the formation of Am(VI) in $HClO_4$ reaches a maximum after 5–6 h and then decreases successively with the main end product being Am(III). In 0.5 and 5 M HCl, Am(V) disappears much faster than in the non-complexing perchlorate medium. The formation of Am(VI) has not been observed in HCl media, indicating a fast reduction of Am(VI) by chloride (Hall and Herniman, 1954; Runde and Kim, 1994).

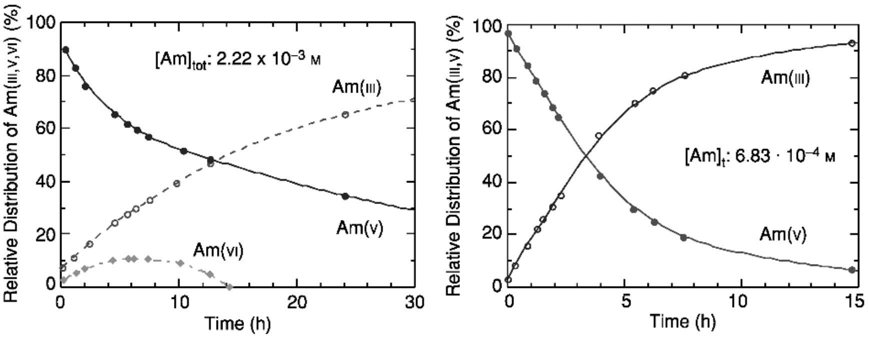

Fig. 8.5 *Disproportionation of Am(V) in 5 M $HClO_4$ (left) and 5 M HCl (right) (Runde and Kim,* 1994).

(f) Kinetics of oxidation–reduction reactions

Data for the few oxidation–reduction reactions that have been studied in detail can now be summarized. This summary supplements information presented by Hindman (1958), Newton and Baker (1967), and Gourisse (1966). An important recent reference on this subject is the critical review by Newton (1975).

(*i*) *Peroxydisulfate oxidation of Am*(III) *in acid media*

Early exploratory work by Asprey *et al.* (1950), the discoverers of the reaction between $S_2O_8^{2-}$ and Am(III) that produces Am(VI), established that the reaction proceeded in the concentration range from 10^{-8} to 10^{-1} M Am(III), implying a low-order dependence of the rate on Am(III) concentration. They further found that acidities greater than a few tenths molar were deleterious, presumably due to the acid-catalyzed decomposition path of $S_2O_8^{2-}$ (Penneman and Asprey, 1955). The general pattern of the oxidation (Fig. 8.6) represents an induction period and a linear region of constant rate followed by a region of gradually decreasing rate at high nitric acid concentrations. Reaction rates are dependent on temperature and on the concentration of HNO_3, $S_2O_8^{2-}$, and, when present, Ag^+. Newton (1975) states that the stoichiometry of the oxidation reaction is

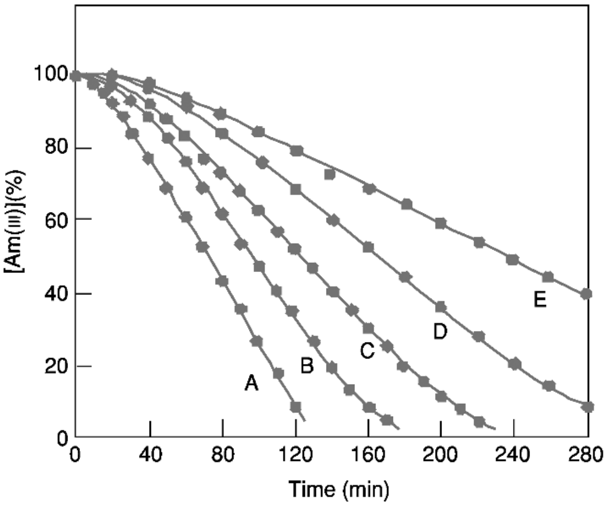

Fig. 8.6 *Kinetics of Am*(III) *oxidation by peroxydisulfate in nitric acid at* 50.6°C ($[S_2O_8^{2+}]_0 = 0.40$ M (*Ermakov* et al., 1971a, 1973, 1974)). *HNO_3 concentrations: A,* 0.09 M; *B,* 0.14 M; *C,* 0.19 M; *D,* 0.24 M; *E,* 0.28 M.

$$3/2\mathrm{S_2O_8^{2-}} + \mathrm{Am^{3+}} + 2\mathrm{H_2O} \rightarrow 3\mathrm{SO_4^{2-}} + \mathrm{AmO_2^{2+}} + 4\mathrm{H^+}$$

All researchers concur that the oxidizing agent is not the $S_2O_8^{2-}$ ion itself but its thermal decomposition products (e.g. $SO_4^{\bullet-}$ or $HS_2O_8^-$).

In contrast to conclusions from studies using micromolar Am(III), Ermakov *et al.* (1971a, 1973, 1974), on the basis of studies with millimolar amounts of ^{243}Am(III), claim that (in the absence of Ag^+) the rate of oxidation of Am(III) in the linear portion of kinetic curves does not depend on the Am(III) concentration and that the rate is given by:

$$\begin{aligned}-\mathrm{d}[\mathrm{Am(III)}]/\mathrm{d}t &= (a + b[\mathrm{H^+}])[\mathrm{S_2O_8^{2-}}][\mathrm{Am(III)}]_0\\ &= 2/3k_1 - (k_4[\mathrm{H^+}]/(1+x))[\mathrm{S_2O_8^{2-}}]_0 = k_{\mathrm{III}}\end{aligned}$$

At 50.6°C, $a = 4.9 \times 10^{-5}$ min^{-1} and $b = 0.9 \times 10^{-4}$ L mol^{-1} min^{-1}. In this equation $[S_2O_8^{2-}]_0$ is the initial concentration of the peroxydisulfate ion, $x = k_5/k_6[H_2O]$, and k_1, k_4–k_6 are rate constants for the following reactions:

$$\mathrm{S_2O_8^{2-}} \xrightarrow{k_1} 2\mathrm{SO_4^{\bullet-}}$$

$$\mathrm{S_2O_8^{2-}} + \mathrm{H^+} \xrightarrow{k_4} \mathrm{HSO_4^-} + \mathrm{SO_4^{\bullet}}$$

$$\mathrm{SO_4^{\bullet}} \xrightarrow{k_5} \mathrm{SO_3} + \mathrm{O}$$

$$\mathrm{SO_4^{\bullet}} + \mathrm{H_2O} \xrightarrow{k_6} \mathrm{H_2O_2} + \mathrm{SO_3}$$

(*ii*) *Peroxydisulfate oxidation of Am*(*V*) *in* HNO_3

Ermakov *et al.* (1971a, 1973, 1974) also investigated the kinetics of the oxidation of Am(V) by $S_2O_8^{2-}$ ion in 0.09–0.6 M HNO_3 media at 45.6–60°C. According to Newton (1975) the stoichiometry of this reaction is

$$1/2\ \mathrm{S_2O_8^{2-}} + \mathrm{AmO_2^{+}} \rightarrow \mathrm{SO_4^{2-}} + \mathrm{AmO_2^{2+}}$$

Ermakov gives the law:

$$-\mathrm{d}[\mathrm{Am(V)}]/\mathrm{d}t = (a' + b'[\mathrm{H^+}])[\mathrm{S_2O_8^{2-}}][\mathrm{Am(V)}]_0$$

At 50.6°C, $a' = 15 \times 10^{-5}$ min^{-1} and $b' = 2.7 \times 10^{-4}$ L mol^{-1} min^{-1}. It follows from this result and the rate data given in the preceding section that

$$-\mathrm{d}[\mathrm{Am(III)}]/\mathrm{d}t = -(1/3)\mathrm{d}[\mathrm{Am(V)}]/\mathrm{d}t$$

The results of Rykov *et al.* (1970) indicate that the mechanism of reduction of Am(VI) in the presence of $S_2O_8^{2-}$ ions is identical with that proposed for the oxidation of Am(V).

(*iii*) *Peroxydisulfate oxidation of Am*(*III*) *in carbonate media*

Peroxydisulfate oxidation of Am(III) in carbonate solutions proceeds through the intermediate formation of Am(V). Ermakov *et al.* (1971a, 1973, 1974) found that the rate of oxidation of Am(III) to Am(V) is independent of the total Am and K_2CO_3 concentrations and is equal to the rate of decomposition of $S_2O_8^{2-}$ ions. However, the rate of oxidation of Am(V) to Am(VI) is directly proportional to both the total americium concentration and the $S_2O_8^{2-}$ concentration, and is inversely proportional to the K_2CO_3 concentration. The effective activation energy of the $S_2O_8^{2-}$ oxidation of Am(III) to Am(V) in K_2CO_3 solutions is close to the activation energy (140 kJ mol^{-1}) of the thermal decomposition of $S_2O_8^{2-}$ ions. Recall that $Na_2S_2O_8$ will oxidize either Am(III) or Am(V) to Am(VI) in Na_2CO_3 or $NaHCO_3$.

(*iv*) *Reduction of Am*(*VI*) *by hydrogen peroxide*

Using ^{243}Am in $LiClO_4$–$HClO_4$ media, Woods *et al.* (1974) studied the kinetics of the reaction of AmO_2^{2+} with H_2O_2 and found the reduction of Am(VI) to be first order in both Am(VI) and H_2O_2 concentrations:

$$2AmO_2^{2+} + H_2O_2 \rightarrow 2AmO_2^{+} + 2H_2$$

(*v*) *Reduction of Am*(*VI*) *by other reductants*

Woods and Sullivan (1974) studied the reaction between AmO_2^{2+} and NpO_2^{+} in 1 M (H,Li)ClO_4. The rate law is:

$$-\mathrm{d}[\mathrm{Am(VI)}]/\mathrm{d}t = k[\mathrm{Am(VI)}][\mathrm{Np(V)}]$$

At 25°C, k is $(2.45 \pm 0.4) \times 10^4$ L mol^{-1} s^{-1}; for this reaction, $\Delta H^* = 27.87 \pm 0.33$ kJ mol^{-1} and $\Delta S^* = -67.8 \pm 1.3$ J K^{-1} mol^{-1}. Oxalic acid reduces Am(VI) rapidly to approximately equal mixtures of Am(III) and Am(V), whereas reagents such as H_2O_2, HCl, HCOOH, HCHO, etc., reduce Am(VI) initially only to Am(V). The reduction of Am(VI) by nitrous acid is first order in each (Woods *et al.*, 1976).

(*vi*) *Reduction of Am*(*V*) *by* H_2O_2

From studies of the reduction of AmO_2^{+} to Am^{3+} by H_2O_2 in 0.1 M $HClO_4$, Zaitsev *et al.* (1960a) deduced the rate law:

$$-\mathrm{d}[AmO_2^{+}]/\mathrm{d}t = k[AmO_2^{+}][H_2O_2]$$

where $k = 14.8 \pm 1.5, 21.6 \pm 2.2$, and 30.3 ± 3.01 mol^{-1} h^{-1} at 25, 30, and 35°C, respectively. The activation energy deduced for the reduction reaction is 55.2 kJ mol^{-1}. The only other reported studies of the Am(III)–Am(V)–H_2O_2–$HClO_4$ system have been made by Damien and Pages (1969, 1970). They reported that the rate at which AmO_2^+ is reduced is inversely proportional to the perchloric acid concentration and is also strongly dependent on the initial $[Am^{3+}]_0/[AmO_2^+]_0$ and $[H_2O_2]_0/[AmO_2^+]_0$ concentration ratios.

(*vii*) *Reduction of Am*(v) *in NaOH solutions*

Shilov *et al.* (1997) investigated the reduction rate of Am(v) in 1.5 and 3 M NaOH at room temperature. Slow reduction of Am(v) is observed in the presence of 0.005–0.4 M of dithionite ($Na_2S_2O_4$), sulfite (Na_2SO_3), or thiourea dioxide ($(NH_2)_2CSO_2$) with a half-reduction time ranging between 0.2 and 9 h. The reduction of Am(v) in 3–14 M NaOH with about 0.01 M hydrazinium nitrate or hydroxylamine is accelerated with reductant concentration and temperature.

(*viii*) *Reduction of Am*(v) *by Np*(iv) *in perchloric acid media*

Blokhin *et al.* (1973) used spectrophotometry to study the kinetics of the Np(iv)–Am(v) reaction in 0.23–1.97 M $HClO_4$ at temperatures in the range 35.0–54.6°C. Depending on the initial concentrations of Np(iv) and Am(v), the reaction products are either Np(v) and Am(iii) or Np(vi) and Am(iii). The reaction rate falls rapidly with increasing acidity. Under the assumption of constant Am(iv) concentration, the kinetic data follow the rate law:

$$d[Am^{3+}]/dt - k'1[Np^{4+}][AmO_2^+] + k'2[NpO_2^+][AmO_2^+]$$

The authors report the following thermodynamic activation parameters: $\Delta H^* = 126 \pm 4$ kJ mol^{-1}, $\Delta G^* = 87 \pm 4$ kJ mol^{-1}, and $\Delta S^* = 130 \pm 13$ J K^{-1} mol^{-1}.

(*ix*) *Reduction of Am*(v) *by Np*(v) *in perchloric acid*

Rykov *et al.* (1973) determined spectrophotometrically the rate of the reaction:

$$2NpO_2^+ + AmO_2^+ + 4H^+ \rightarrow 2NpO_2^{2+} + Am^{3+} + 2H_2O$$

Kinetic data were collected in perchlorate ($\mu = 2.0$ M) at temperatures in the range 24.7–44.1°C. These researchers claim that reduction of Am(v) by Np(v) is an irreversible second-order reaction.

(*x*) *Reduction of Am*(v) *by Np*(v) *in Na_2CO_3*

Kinetics of the reduction of Am(v) by Np(v) in Na_2CO_3 solutions were investigated spectrophotometrically (Chistyakov *et al.*, 1974). The stoichiometry of the reduction is

$$4H^+ + AmO_2^+ + 2NpO_2^+ \rightarrow Am^{3+} + 2NpO_2^{2+} + 2H_2O$$

The kinetics of the Am(v) reactions in aqueous Na_2CO_3 follow the same rate law as in $HClO_4$ media.

(*xi*) *Reduction of Am*(*V*) *by U*(*IV*) *in perchloric acid*

At 11.2 and 3.60°C in 0.51–2.60 M $HClO_4$, the reaction between Am(v) and U(iv) proceeds according to the equation:

$$AmO_2^+ + U^{4+} \rightarrow Am^{3+} + UO_2^{2+}$$

Blokhin *et al.* (1974) derived the following rate law:

$$d[Am^{3+}]/dt = k[AmO_2^{2+}][U^{4+}]$$

In 2.0 M $HClO_4$ at 9.5°C, $k = 725 \pm 30$ L mol^{-1} min^{-1}. Standard thermodynamic activation parameters are $\Delta H^* = 75 \pm 4$ kJ mol^{-1}, $\Delta G^* = 63.6 \pm 0.8$ kJ mol^{-1}, and $\Delta S^* = 37.7 \pm 12.5$ J K^{-1} mol^{-1}.

(*xii*) *Oxidation of Am*(*II*) *by water*

In an elegant experiment carried out at the U.S. Argonne National Laboratory, the absorption spectra of both divalent americium and tetravalent americium were obtained (Sullivan *et al.*, 1976, 1978). This technique involved irradiation of Am(iii) solutions with single electron pulses and recording the spectra with a streak camera at postirradiation times of 50 μs for Am(ii) and 100 μs for Am(iv). Am(ii) disappeared via reaction with water, while the Am(iv) species disproportionated to yield Am(iii) and Am(v).

(g) Radiolysis

The most commonly used americium isotopes, ^{241}Am and ^{243}Am, decay primarily by emitting high-energy alpha particles of about 5.4 and 5.2 MeV, respectively (see Table 8.1). In solution, the energy (1 mg ^{241}Am releases about 7×10^{14} eV s^{-1}) is released in dense tracks producing radicals, ions, and electrons; thus can impact the stability of americium oxidation states in aqueous solutions. There are numerous reports on the effect of the intense alpha radiation of transuranium elements on their chemical behavior in acidic, basic, and highly concentrated chloride solutions. In acidic media, Am(iii) is the most stable oxidation state and Am(v) and Am(vi) are rather rapidly reduced (Vladimirova *et al.*, 1977; Kornilov *et al.*, 1986). The reduction rate is closely related to the dose rate and electrolyte concentration. Vladimirova and coworkers (Vladimirova *et al.*, 1977; Vladimirova, 1986) suggested that Am(v) and Am(vi) reduction in nitric acid solutions cannot be explained by involving only radiolytically produced radicals but also require consideration of chemical reactions with radiolytically produced H_2O_2 and HNO_2:

$$2AmO_2^{2+} + HNO_2 + H_2O \rightarrow 2AmO_2^{+} + 3H^{+} + NO_3^{-}$$

$$2AmO_2^{+} + HNO_2 + 6H^{+} \rightarrow 2Am^{4+} + 3H_2O + HNO_3$$

In perchlorate solutions, alpha-radiolysis produces multiple species, such as Cl_2, ClO_2, or Cl^- that are effective reductants for Am(vi) (Kornilov *et al.*, 1986). A radiolytically enhanced chemical oxidation of Am(iii) to Am(v) and Am(vi) (at large gamma doses) is observed in perchlorate solutions at pH 3–6 in the presence of excess of N_2O, $S_2O_8^{2-}$, or XeO_3 (Pikaev *et al.*, 1977). As expected the stability of higher oxidation states increases with pH and Am(iii) is radiolytically oxidized to Am(v) in carbonate solutions under the exposure of intense alpha-radiation from ^{244}Cm (3–8 KCi L^{-1}) (Osipov *et al.*, 1977). The formation of oxidizing species in concentrated chloride solutions, i.e. Cl_2 and ClO^-, leads to the autoradiolytical oxidation of Am(iii) to Am(v) (Magirius *et al.*, 1985; Runde and Kim, 1994). The radiolytical formation of hypochlorite in basic 5 M NaCl is directly correlated with the alpha-specific activity of ^{241}Am.

8.8.2 Complexation reactions

A critical review of the chemical thermodynamics of experimental data and chemical thermodynamics for americium inorganic compounds was recently published by the NEA (Silva *et al.*, 1995). Nearly all formation constants listed in Table 8.8 are for complexes formed by Am(iii), as little work has been done on complexes with Am in higher oxidations states. Color changes of Am(iii)-containing solutions indicate existence of Am(vi) nitrate, sulfate, and fluoride complexes. Some spectroscopic evidence exists for a Am(v) peroxide complex in 1 M NaOH (Musikas, 1973a). In agreement with the behavior of other actinide (iii) and (iv) ions, the stability of Am(iii) complexes with monovalent inorganic ligands follows the sequence:

$$F^- > H_2PO_4^- > SCN^- > NO_3^- > Cl^- > ClO_4^-.$$

As a Chatt–Ahrland ‘A’ type or Pearson ‘hard’ cation, Am^{3+} association with inorganic ligands proceeds initially through electrostatic interactions to form outer-sphere complexes, such as chlorides or perchlorates. Spectrophotometric results suggested the inner-sphere formation of chloride and nitrate ions in concentrated Na/LiCl and $LiNO_3$ solutions (Marcus and Shiloh, 1969; Allen *et al.*, 2000). Inner-sphere complexes are also found to form with harder ligands, such as fluoride or sulfate. In most cases, the stability of Am(iii) complexes is similar to those that contain lanthanide ions with similar ionic radii, e.g. Nd(iii) and Eu(iii). In some cases, the stability of the Am(iii) complex is slightly greater than that of the corresponding lanthanide complex presumably because of the participation of f-electrons in the bonding (Moskvin, 1967, 1971, 1973). As discussed earlier, this difference in stability can be used to separate Am(iii) effectively from lanthanide elements.

(a) Hydrolysis

(1) Am(III): The hydrolysis of Am(III) has been studied extensively, partly because the hydrolysis reactions are strongly favored in aqueous systems. It is established that Am(III) is complexed by hydroxide above pH 5 to form complexes of general formula $Am(OH)_n^{3-n}$ where $n = 1$–3. Thermodynamic stabilities of these complexes were calculated from data obtained by a variety of methods, such as solubility studies, solvent extraction, and potentiometric and electromigration measurements. Spectroscopic characterization or structural information of these complexes is absent because of their low solubilities. The existence of the anionic species $Am(OH)_4^-$ has been postulated, which would increase the Am(III) solubility at high pH. However, an increase in solubility is not observed at pH > 13 and contamination of the solution by carbonate may have produced anionic carbonate complexes that increase

the overall Am(III) solubility. There is substantial uncertainty about the formation of polynuclear complexes, as common in the U(VI) hydrolysis system.

(2) Am(V): Kim and coworkers (Magirius *et al.*, 1985; Stadler and Kim, 1988) measured the solubility of autoradiolytically formed $^{241}AmO_2(OH)$ (s) in 3 and 5 M NaCl. Runde and coworkers (Runde and Kim, 1994; Runde *et al.*, 1996) reported an increased solubility of $^{241}AmO_2(OH)(s)$ over $^{237}NpO_2(OH)(s)$ in 5 M NaCl. Slope analysis of the solubility data indicated formation of only two americyl(V) hydrolysis products in solution, $AmO_2(OH)(aq)$ and $AmO_2(OH)_2^-$. Tananaev (1990a) suggested the formation of $AmO_2(OH)_3^{2-}$ (with an absorption peak at 750 nm) and $AmO_2(OH)_4^{3-}$ in highly alkaline media based on spectroscopic measurements of Am(V) in 0.001–1 M LiOH solutions. Because of the radiolytic formation of oxidizing species (such as OCl^-) and the subsequently increased stability of Am(V), the few solubility studies of Am(V) were performed in concentrated chloride solutions. The reported apparent stability constants for $AmO_2(OH)(aq)$ and $AmO_2(OH)_2^-$ are close to those for the analogous Np(V) species (Runde *et al.*, 1996). However, the solubility of $^{241}AmO_2OH$ appears to be higher than that of $^{237}NpO_2OH$, probably due to higher alpha-radiation damage of the Am(V) solid.

(3) Am(IV) and Am(VI): The hydrolysis of Am(IV) and Am(VI) remains rather unexplored because of the instabilities of these oxidation states in aqueous solutions under ambient conditions. There is spectroscopic evidence for the formation of Am(VI) hydrolysis species of general formula $AmO_2(OH)_n^{2-n}$ where $n = 1$–4.

(b) Carbonate complexation

(1) Am(III): The carbonate complexation of Am(III) has been widely investigated using a variety of methods, such as solvent extraction, spectrophotometry, electromigration, and solubility. Meinrath and Kim (1991a) monitored the solubility and complexation reactions of Am(III) in carbonate-containing solutions spectroscopically. Three solution species, $Am(CO_3)_n^{3-2n}$ with $n = 1$–3, were characterized by their distinct absorbances at 505.4 nm ($\varepsilon = 385$ L mol^{-1} cm^{-1}), 506.5 nm ($\varepsilon = 350$ L mol^{-1} cm^{-1}), and 507.8 nm ($\varepsilon = 330$ L mol^{-1} cm^{-1}), respectively. Wruck *et al.* (1999) determined the formation constant of the monocarbonato complex, $Am(CO_3)^+$, at 25, 50, and 75°C at 0.1 m ionic strength using laser-induced photoacoustic spectroscopy. There is no experimental or spectroscopic proof for the proposed formation of bicarbonato complexes, $Am(HCO_3)_n^{3-2n}$, and mixed hydroxocarbonato species, $Am(OH)_m(CO_3)_n^{3-m-2n}$ (Bernkopf and Kim, 1984). These complexes were used to explain extraction and solubility data although the experimental data can be explained by pure carbonato

and hydroxo species. The solid phases $AmOHCO_3$ and $Am_2(CO_3)_3$ were found as solubility-controlling phases in aqueous carbonate solutions (Meinrath and Kim, 1991b; Runde *et al.*, 1992). The double carbonate $NaAm(CO_3)_2 \cdot nH_2O$ was identified by X-ray diffraction to form at increased NaCl concentrations (Runde and Kim, 1994; Rao *et al.*, 1996).

(2) Am(IV): There is only one carbonato complex of Am(IV) discussed in the literature. From combined spectroscopy and cyclic voltammetry data in bicarbonate/carbonate solutions (Bourges *et al.*, 1983), it was concluded that $Am(CO_3)_5^{6-}$ is the limiting carbonate complex of Am(IV). Its logarithmic stability constant, $\log \beta_5^{\circ} = 39.3 \pm 2.1$ (Silva *et al.*, 1995), is comparable to those of the analogous U(IV) (34.0 ± 0.9 (Grenthe *et al.*, 1992)) and Np(IV) complexes (33.9 ± 2.6 (Kaszuba and Runde, 1999)).

(3) Am(V): Giffaut and Vitorge (1993) studied the solubility of $NaAmO_2CO_3$ in carbonate-containing 4 M NaCl solution and claimed the formation of two Am(V) carbonate complexes, $AmO_2(CO_3)^-$ and $AmO_2(CO_3)_2^{3-}$. Runde and coworkers (Runde and Kim, 1994; Runde *et al.*, 1996) reported identical solubility and speciation behavior of Am(V) and Np(V) in carbonated 3 and 5 M NaCl solutions. In analogy to the well-characterized Np(V) system in 5 M NaCl, the solubility data were interpreted with the formation of $AmO_2(CO_3)_n^{1-2n}$ ($n = 1$–3) in solution and $NaAmO_2CO_3 \cdot nH_2O$ as the solid equilibrium phases.

Spectroscopic evidence suggests that an Am(V) carbonate complex in $NaHCO_3$, presumably the triscarbonato complex $AmO_2(CO_3)_3^{5-}$, has an absorbance at 727 nm (Tananaev, 1990a).

(4) Am(VI): The appearance of a burgundy-red color upon introducing Am(VI) into carbonate-containing solutions indicates the coordination of AmO_2^{2+} with carbonate ions. However, spectroscopic studies of the carbonate complexation of Am(VI) are few. Based on electrochemical measurements, it is assumed that the limiting complex is the $AmO_2(CO_3)_3^{4-}$ anion (Bourges *et al.*, 1983; Silva *et al.*, 1995).

(c) Organic ligands

With few exceptions, the data in Table 8.9 are for complexes of Am(III). Generally, the higher oxidation states of americium are reduced by organic complexing agents. Aminopolycarboxylic acids complex Am(III) more strongly than either hydroxycarboxylic or aminoalkylpolyphosphoric acids (e.g. ethylenediamine bis(methylene)phosphonic acid). Keller (1971) observed that in the series of α-hydroxycarboxylic acids (e.g. glycolic and lactic), the stability of the Am(III) complex decreases with increasing number of carbon atoms. The logarithm of the stability constant of the Am(III) complexes with aminopolycarboxylic acids increases linearly (Fig. 8.7) with the number of bound donor atoms of the ligand.

Methods are being sought to estimate and correlate the strengths of Am(III) complexes and other trivalent actinides and lanthanides with various organic ligands. Shalinets and Stepanov (1971, 1972) suggests a 'rule of additivity of the strength of rings' according to which, under similar conditions, the logarithm of the thermodynamic formation constant of the complex is proportional to the sum of the strengths of the individual rings. In a few cases, formation constants of americium chelates calculated by Shalinets are in good agreement with experimental data. For a more detailed discussion of the nature and stability of organic complexes of americium, refer to Chapters 23 and 25.

It is not surprising that a number of studies focus on the complexation of Am(III) with natural organic substances because of its importance for the assessment of nuclear waste disposal in geologic formations. The majority of naturally occurring organic materials derive from the decomposition of organic matter to soluble polymeric HA and fulvic acid (FA). The surfaces of these substances have a number of hydrophilic functional groups, such as amine, hydroxyl, carboxyl, and phenolic. As a hard cation, Am^{3+} interacts predominantly with the oxygen-donating phenolic and carboxylic groups. A large number of experimental data exist that are usually interpreted by the charge neutralization model or a polyelectrolyte model (Choppin and Labonne-Wall, 1997). The charge neutralization model is based on the cation complexation by a number of carboxylate groups expressed as an experimentally determined loading capacity of the organic substance. The polyelectrolyte model can better accommodate the chemical behavior of the humic/fulvic acids and takes into account the nature of the binding functional group (carboxylate). The concentration of binding sites and the ionization degree is determined experimentally via pH titration. For a more detailed discussion of these two models and of the impact of humate and fulvate complexation on the environmental behavior of americium, refer to Chapters 27 and 29.

Choppin and coworkers (Bertha and Choppin, 1978) performed ion-exchange studies at pH 4.5 to determine log $\beta_1 = 6.83$ and log $\beta_2 = 10.58$ for a Lake Bradford, Florida (USA), humic substance. These results agree well with log $\beta_1 = 6.4$ and log $\beta_2 = 10.58$ determined for HA from Mount Kanmuri, Japan (Yamamoto and Sakanoue, 1982). Applying a degree of ionization of the HA, Choppin and coworkers (Torres and Choppin, 1984) reported log $\beta_1 =$ 6.8–11.6 and log $\beta_2 =$ 11.9–14.3 for the Am(III)—HA (Lake Bradford) complex determined at pH 3.75–5.7. Using UV–VIS and laser-induced photoacoustic spectroscopy Kim *et al.* (1993) determined log $\beta_1 = 6.4 \pm 0.1$ at pH = 6 ($I = 0.1$) for HAs obtained from natural water at the German Gorleben (Gohy-573) site and from a commercial HA (Aldrich Chemical Co.). For the calculation of the Am(III)–HA stability constant, Kim *et al.* determined a loading capacity of 62.2% for Gohy-573 HA and of 81.5% for Aldrich HA. The Am(III) absorption band at 506 nm was assigned to an Am(III)–HA complex and was used for data analysis. Moulin *et al.* (1987) spectroscopically monitored the complexation of Am(III) with Aldrich HA at pH 4.65 ($I = 0.1$) and calculated log $\beta_1 =$ 7–7.5.

The stability constants found for Am(III) fulvate are slightly smaller than those found for humate. Buckau *et al.* (1992) determined log $\beta_1 = 5.9$ for FA extracted from the Gohy-573 groundwater using UV–VIS absorption spectroscopy. This FA is characterized by a proton exchange capacity of 5.7 meq g^{-1} and a loading capacity of 64.9% at pH 6.0. Interestingly, the stability constant of the Am(III)–FA complex is constant in the Am(III) concentration range of 4×10^{-5} to 5×10^{-8} mol L^{-1} at [HA] = 10^{-6} mol L^{-1}.

Complexation of Am(III) with the hexadentate ligand *N*,*N*,*N*′,*N*′-tetrakis (2-pyridylmethyl)ethylenediamine (TPEN) in 0.1 M $NaClO_4$ at 25°C to form $Am(TPEN)^{3+}$ is about two orders of magnitude higher than that of Sm(III), reflecting the stronger bonding of the trivalent actinide cations with softer ligands as compared to lanthanides (Jensen *et al.*, 2000).

(d) Others

The stability constants of Am(III) fluoride complexes are much larger than for the other halides (Silva *et al.*, 1995). Positive enthalpies for the reaction of Am^{3+} with F^- anions indicate that the AmF_n^{3-n} are inner-sphere complexes.

Two Am(III) fluoride solution species have been identified, AmF^{2+} and AmF_2^+, with recommended formation constants of log $\beta_1^o = 3.4 \pm 0.4$ and log $\beta_2^o = 5.8 \pm 0.2$, respectively. In contrast, the recommended formation constant for $AmCl^{2+}$, log $\beta_1^o = 1.05 \pm 0.06$, suggests a very weak bonding of chloride ions.

Few reliable data have been reported for the sulfate complexation of Am(III). Stability constants for two complexes, $AmSO_4^+$(log $\beta_1^o = 3.85 \pm 0.03$) and $Am(SO_4)_2^-$(log $\beta_2^o = 5.4 \pm 0.7$), were recommended (Silva *et al.*, 1995). There is no evidence for the formation of $Am(III) - HSO_4^-$ complexes.

The formation of Am(III) thiocyanate complexes was studied intensively because of the use of such complexes in separation of lanthanide and actinide elements. Three complexes of general formula $Am(SCN)_n^{3-n}$ (n = 1–3) have been identified from spectroscopic and solvent extraction data. The complexation of Am(III) by thiocyanate is quite weak and the accepted thermodynamic constant for the 1:1 complex is log $\beta_1^o = 1.3 \pm 0.3$ (Silva *et al.*, 1995).

Nitrate complexes of Am(III) are weak complexes and two complexes, $AmNO_3^{2+}$ and $Am(NO_3)_2^+$, have been used to interpret solvent extraction data in nitric acid media. The recommended formation constant of the 1:1 complex is log $\beta_1^o = 1.33 \pm 0.20$ (Silva *et al.*, 1995).

A number of studies of Am(III) complexation in phosphate media have been reported with only a few reliable data interpretations and complex characterizations. The system is complicated by the presence of multiple (hydrogen) phosphate species in solution. The solution complexes $AmHPO_4^+$ and $Am(H_2PO_4)_n^{3-n}$ (n = 1–4) have been used to interpret cation exchange, solvent extraction, and spectroscopic data. Lebedev *et al.* (1979) attributed the changes of the characteristic absorption band of Am^{3+} at 503 nm to the formation of $Am(III) - H_2PO_4^-$ complexes. With increasing phosphoric acid concentration (up to 13 M), the absorbance maximum is shifted to about 502 nm and the characteristic shoulder in the Am^{3+} band at 506 nm almost disappears. It remains unclear if these changes are due to inner-sphere complexation with phosphate or to changes in the number of coordinated water molecules in these extreme experimental conditions. The NEA recommends a stability constant only for the complex $AmH_2PO_4^{2+}$, log $\beta_1^o = 3.0 \pm 0.5$ (Silva *et al.*, 1995).

Am(IV) can be stabilized in acidic media by complexation with heteropolyanions. Chartier *et al.* (1999) reported spectroscopic evidence for the formation of $AmP_2W_{17}O_6^{16-}$ and $Am(P_2W_{17}O_{61})_2^{16-}$ via their absorbance bands at 789 and 560 nm, respectively. Chartier *et al.* reported log $\beta_1 = 19.2 \pm 0.2$ and log $\beta_2 = 22.8 \pm 0.2$ in 1 M HNO_3. The rate of autoradiolytic reduction of Am(IV) in these complexes is independent of the complex composition. Th(IV) causes the destruction of the complexes and subsequent disproportionation of free Am(IV) into Am(III) and Am(VI). Complex formation of Am(III) with $W_{10}O_{36}^{12-}$, $PW_{11}O_{39}^{7-}$, and $SiW_{11}O_{39}^{8-}$ was discussed qualitatively by Yusov (1989). Chartier *et al.* (1999) determined the apparent formation constants for $AmSiW_{11}O_{39}^{4-}$ and for $Am(SiW_{11}O_{39})_2^{12-}$ in 1 M HNO_3, log $\beta_1 = 21.3 \pm 0.3$ and log $\beta_2 = 26.2 \pm 0.2$, respectively. In contrast, Williams *et al.* (2000) used extended X-ray absorption fine structure (EXAFS) to determine that the Am center cation is trivalent when integrated in the Preyssler anion, $AmP_5W_{30}O_{110}^{12-}$.

Sullivan *et al.* (1961) discovered cation–cation interaction between pentavalent and hexavalent actinides. Subsequently, Guillaume *et al.* (1981) found spectroscopic evidence for the Am(V)–U(VI) interaction in perchlorate medium where the interaction between AmO_2^+ and UO_2^{2+} shifts the main absorbance peak of AmO_2^+ at 716–733 nm and a new band appears at 765 nm. Both bands are close to the absorbances reported for the solid $KAmO_2CO_3$ (733 and 770 nm (Varga *et al.*, 1971)). Upon interaction of Am(V) with U(VI), the symmetrical stretching (Raman) frequency of AmO_2^+ at 732 cm^{-1} is shifted to 719 cm^{-1} (Guillaume *et al.*, 1982). The Am(V)–U(VI) ($K = 0.35 \pm 0.07$ at $I = 10$) and Am(V)–Np(VI) ($K = 0.095 \pm 0.03$ at $I = 6$) (Guillaume *et al.*, 1981, 1982) complexes appeared to be much weaker than the corresponding Np(V) complexes: Np(V)–U(VI) ($K = 3.7 \pm 0.1$ at $I = 7$) and Np(V)–Np(VI) ($K = 3.0 \pm 0.1$ at $I = 7$ (Madic *et al.*, 1979)).

8.9 COORDINATION CHEMISTRY AND COORDINATION COMPLEXES

Although over 250 compounds of americium have been synthesized and characterized, the coordination chemistry of americium is relatively unknown. As of 2001, the crystal structures of 39 americium compounds with inorganic ligands and only seven americium compounds with organic ligands have been structurally characterized. However, the majority of phase identification and characterization relied on X-ray powder diffraction and comparison to isostructural lanthanide, neptunium, or plutonium compounds. Certainly, the application of EXAFS provides useful insight into coordination and bonding of solution complexes and amorphous solid phases. As hard metal ions Am(III to VI) have a high affinity for hard donor atoms, such as O or N, and the light halides, and their coordination will be discussed in this section. Because of its high redox stability, trivalent americium coordination complexes are the most common. Generally, higher dimensional structures are found containing Am^{2+}, Am^{3+}, or Am^{4+} while the introduction of the linear americyl unit forces Am(V) and Am(VI) to form layered structures.

8.9.1 Compounds with inorganic ligands

(a) Halides

Americium exhibits different coordination environments in halide complexes with coordination numbers of 7, 8, 9, and 11. In the orthorhombic M_2AmCl_5 ($M = K, NH_4$, or Rb) trivalent americium is seven-coordinate in $AmCl_5^{2-}$ chains with two of the five chlorides bridging to adjacent Am atoms. In the monoclinic hexahydrate, $AmCl_3 \cdot 6H_2O$, americium is coordinated to two chlorides and six water molecules forming $AmCl_2(H_2O)_6^+$ cations that are linked through chloride anions in the lattice and an extensive hydrogen bond network (Burns and Peterson, 1971). Considering the inner-sphere bonding of the water molecules, the formula of this compound is better represented by $AmCl_2(H_2O)_6 \cdot Cl$. Eight-coordinate americium is also found in the tetrafluoride AmF_4. $AmO_2F_2^-$ layers held together by K^+ ions form the rhombohedral $KAmO_2F_2$, in which americium is eight-coordinate with two axial oxygen atoms (Am–O = 1.936 Å) and six fluorides (Am–F = 2.473 Å) in the equatorial plane (Asprey *et al.*, 1954a). The isostructural oxyhalides AmOCl (Weigel *et al.*, 1975) and AmOI (Asprey *et al.*, 1964, 1965) also contain nine-coordinate americium that is surrounded by four oxygen (2.343 Å) and five iodine atoms (4 Am–I of 2.994 Å and 1 Am–I of 3.0035 Å). Interestingly, AmOBr (Weigel *et al.*, 1979) is reported to be built up from linear Br–Am–O units stacked along the *c*-axis with reported interatomic distances of 2.415 Å for Am–O and 3.21 and 3.36 Å for Am–Br. Using the atomic coordinates reported for AmOBr, we calculate 2.339 and 2.979 Å for Am–O and 3.145 and 3.801 Å for Am–Br bond distances. Considering the discrepancies in the bond distances and the structural anomaly within the AmOX series, there are serious doubts about the reported structure of AmOBr. The trifluoride AmF_3 crystallizes in the 11-coordinate LaF_3 structure (Templeton and Dauben, 1953). In the anhydrous $AmCl_3$, the americium atom is bonded to six chlorine atoms at 2.874 Å and three chlorine atoms at 2.915 Å (Burns and Peterson, 1970) (Fig. 8.8).

(b) Oxides

Several americium oxides of varying stoichiometry have been prepared and structural data rely principally on X-ray powder diffraction powder data. The binary oxide AmO (CN 6) crystallizes in a cubic structure with octahedral O and Am atoms (Zachariasen, 1949b). Interatomic distances are calculated to be 2.480 Å for Am–O and 3.507 Å for Am–Am. However, AmO may be an oxynitride, as discussed in Section 8.7.1. As discussed in Section 8.7.1, three Am_2O_3 phases are known. Templeton and Dauben (1953) report the lattice parameters $a = 11.03 \pm 0.01$ Å for the low-temperature cubic form and $a = 3.817 \pm 0.005$ Å, $c = 5.971 \pm 0.010$ Å for the high-temperature hexagonal form. In the cubic phase two crystallographically different americium atoms exist: distorted $[Am(1)O_6]$ octahedra with Am(1)–O bond lengths of 2.369 Å are bridged through their oxygens to six Am(2) atoms. The Am(2) atoms are centered within a distorted octahedral environment of six oxygen atoms with Am–O distances of 1.984, 2.678, and 2.774 Å. The Am(2)–O distances of 1.984 Å are unusually short for trivalent actinide–oxygen bonds and only slightly longer than the reported bond lengths of about 1.935 Å for the linear Am=O bonds in Am(v) compounds (Asprey *et al.*, 1954a; Ellinger and Zachariasen, 1954). The intermediate-temperature monoclinic AmO_2 is isostructural with

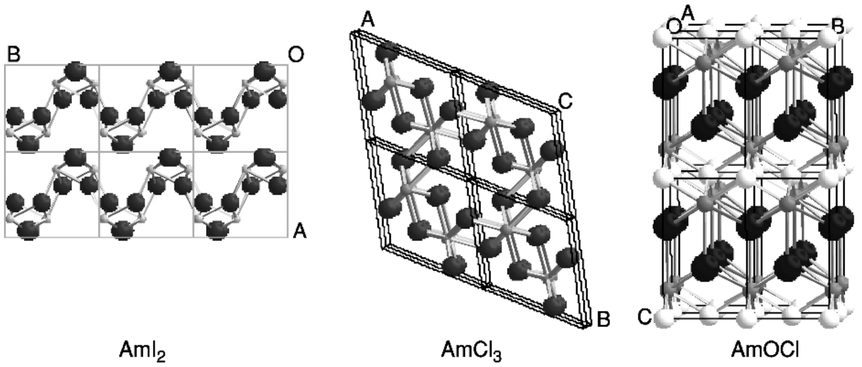

Fig. 8.8 *Structures of americium halide compounds: AmI_2 (Baybarz and Asprey,* 1972), *$AmCl_3$ (Burns and Peterson,* 1970), *and AmOCl (Templeton and Dauben,* 1953).

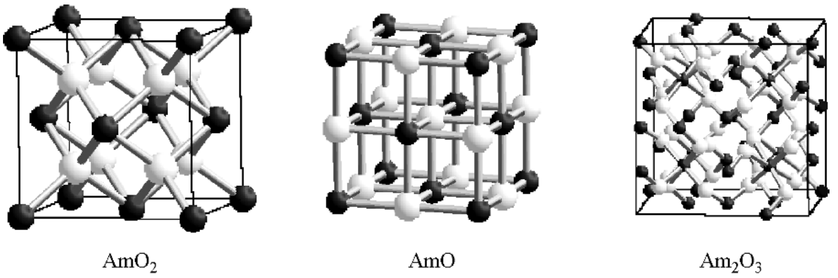

Fig. 8.9 *Unit cells of americium oxides: AmO_2 (Templeton and Dauben,* 1953; *Chikalla and Eyring* 1967, 1968), *AmO (Zachariasen,* 1949a,b), *and Am_2O_3, (Templeton and Dauben,* 1953).

PuO_2 with eight Am–Am distances of 3.803 Å and a tetrahedral arrangement of four Am atoms around each oxygen atom (Am–O is 2.480 Å) (Templeton and Dauben, 1953). The three-dimensional ternary oxide $BaAmO_3$ (cubic perovskite structure, $a = 4.35$ Å, although possibly distorted as are $BaPuO_3$ and $BaLnO_3$) is built from edge-sharing $[AmO_6]$ octahedra with large Ba^{2+} cations in 12-coordinated sites (Keller, 1964). Each AmO_6 octahedron shares all oxygen atoms with six adjacent octahedra. The Am–O distances are calculated to be 2.175 Å (Fig. 8.9).

(c) Chalcogenides and pnictides

The americium monochalcogenides AmX (X = S, Se, Te) crystallize in the cubic NaCl-type structure (CN 6) with the lattice parameters increasing with chalcogen atomic number. Early work of Zachariasen (1949d) concluded from powder

X-ray diffraction data that the sesquisulfide Am_2S_3 is isostructural with cubic Ce_2S_3 and contains 16 sulfur atoms and $10^{2/3}$ americium atoms per unit cell. The calculated interatomic Am–S distances of 2.94 Å are indicative of an ionic bonding between Am^{3+} and S^{2-} and compare well with the value of 2.93 Å reported by Damien and Jove (1971) in the substoichiometric compound $AmS_{1.9}$. The substoichiometric ditelluride, $AmTe_{1.73}$ (CN 9), crystallizes in a tetragonal anti-Fe_2As-type structure (Burns *et al.*, 1979). Layers of Te atoms are interleaved with puckered double layers of AmTe. The bond length between Te atoms in the pure Te layer is much shorter than the Te^{2-} interionic distances, suggesting some covalency within the pure Te layer. Random vacancy at sites within the pure Te layers causes the variable stoichiometry in Am–Te_2. The Am–Te bond lengths within the AmTe layers are only slightly shorter (3.258 and 3.208 Å) than the 3.269 Å from the Am atoms to the nearest Te atoms in the pure Te layer.

The structural information on the known pnictides of general formula AmX (X = N, P, Sb, As) was obtained from X-ray powder diffraction data. All binary pnictides crystallize in the cubic NaCl-type structure; both lattice parameters and Am–X bond length increase along the series: in AmN (a = 5.005 Å) Am–N is 2.503 Å, in AmP (a = 5.711 Å) Am–P is 2.856 Å, in AmAs (a = 5.875 Å) Am–As is 2.938 Å, and in AmSb (a = 5.6.24 Å) Am–Sb is 3.120 Å.

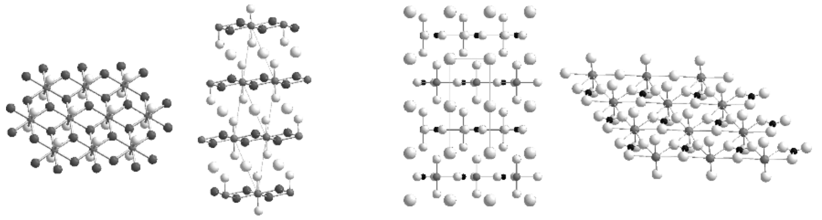
(d) Silicides

Weigel *et al.* (1977, 1984) reported structural information of several silicide phases. The layered structure of the binary AmSi is built up from corner-sharing [$AmSi_3$] pyramids with μ_3-Si atoms and Am–Si distances of 2.56 and 2.66 Å. The tetragonal $AmSi_2$ is isostructural with α-$ThSi_2$ and Am–Si distances range between 2.01 and 2.70 Å. In the sesquisilicide Am_2Si_3 americium atoms are coordinated to Si atoms at Am–Si distances of 3.04 Å.

(e) Oxoanionic ligands

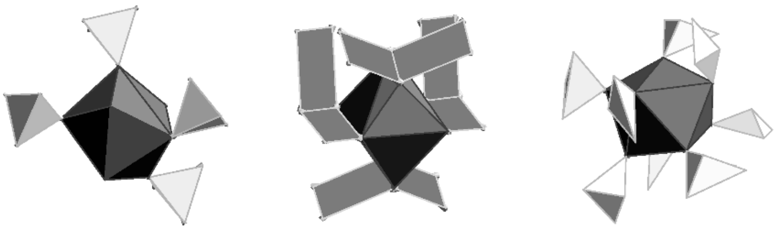
Six oxygen atoms from three bidentately bonded carbonate ligands in the equatorial plane and two axial americyl oxygens form the inner coordination sphere of Am(V) in $RbAmO_2CO_3$ (Ellinger and Zachariasen, 1954) (Fig. 8.10). The Am=O and Am–O_{eq} bond distances are calculated from X-ray powder diffraction data to be 1.935 and 2.568 Å, respectively. Both distances are significantly longer than those in the Np(V) compounds, i.e. 1.75 Å for Np=O and 2.46 Å for Np–O_{eq} in aqueous $NpO_2(CO_3)_n^{1-2n}$ complexes (Clark *et al.*, 1996).

In the pseudotetragonal molybdate $Am_2(MoO_4)_3$ one-third of the Am sites are replaced by ordered vacancies (Tabuteau and Pages, 1978). The molybdate is isostructural to several lanthanide molybdates that crystallize in the pseudo-scheelite structure. The Am(III) tungstate, $Am_2(WO_4)_3$, is structurally analogous to $Eu_2(WO_4)_3$ and is built up from [AmO_8] dodecahedra and [WO_4] tetrahedra.



$KAmO_2F_2$ $RbAmO_2CO_3$

Fig. 8.10 *Sheet structures and crystal packing of the Am*(V) *compounds* $KAmO_2F_2$ (*Asprey* et al., 1954a) *and* $RbAmO_2CO_3$ (*Ellinger and Zachariasen*, 1954).



$Am_2(SO_4)_3 \cdot 8H_2O$ $Am_2(MoO_4)_3$ α-$Am(IO_3)_3$

Fig. 8.11 *Coordination of oxyanions in the Am*(III) *compounds* $Am_2(SO_4)_3 \cdot 8H_2O$ (*Burns and Baybarz*, 1972), $Am_2(MoO_4)_3$ (*Tabuteau and Pages*, 1978), and α-$Am(IO_3)_3$ (*Bean* et al., 2003).

Burns and Baybarz (1972) reported the synthesis and single-crystal structure analysis of $Am_2(SO_4)_3 \cdot 8H_2O$. Eight-coordinate americium bonded to eight O atoms from four sulfate ligands (Am–O distances range from 2.381 to 2.951 Å) and four water molecules (Am–O range from 2.406 to 2.553 Å). The sulfate tetrahedra share edges and bridge americium atoms within the layers; extensive hydrogen bonding involving the lattice waters occurs between the layers.

Very recently, Bean *et al.* (2003) synthesized the anhydrous Am(III) iodate, α-$Am(IO_3)_3$, which is isostructural to the Gd(III) compound (Liminga *et al.*, 1977), and a new f-element iodate of composition $K_3Am_3(IO_3)_{12} \cdot HIO_3$ (Runde *et al.*, 2003) (Fig. 8.11). In both compounds, oxygens from eight iodate pyramids and Am^{3+} ions are located within a distorted $[AmO_8]$ dodecahedron that form a three-dimensional network with Am–O bond distances ranging from 2.34 to 2.60 Å and averaged I–O distances of 1.80 Å. Runde and coworkers also reported the synthesis of β-$Am(IO_3)_3$, that exhibits a novel two-dimensional architecture type within the f-element iodates. The nine-coordinate Am atoms are coordinated with only 7 iodate ligands via a combination of edge-sharing and corner-sharing $[IO_3]$ groups (Bean *et al.*, 2003).

(f) Others

The hydride AmH_3 crystallizes in a cubic structure with eight hydrogen atoms surrounding each Am atom and a tetrahedral arrangement of four Am atoms around each H atom. The bond lengths for Am–H and Am–Am are calculated to be 2.316 and 3.782 Å (Olson and Mulford, 1966).

8.9.2 Compounds with organic ligands

Only seven compounds of americium are listed in the Cambridge Structural Database (version 5.22, October 2001) that compiles complexes of metal cations with organic molecules. However, it is noteworthy that structures obtained from single crystal X-ray diffraction are reported only for two compounds. For the other five compounds, only cell constants and space groups were obtained from X-ray powder patterns and information on bond distances remains unavailable. Information on the overall structure was obtained by analogy to the corresponding compounds of rare earth elements. For a more detailed discussion of the preparation and reactivity of organic americium compounds, refer to Chapters 23 and 29.

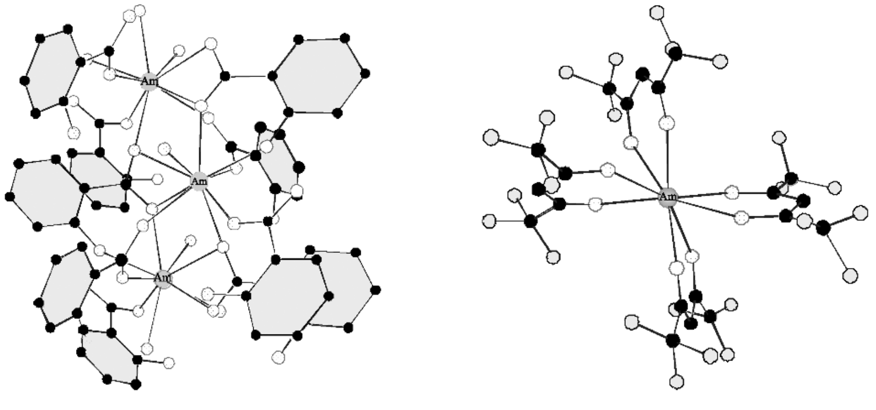
(a) Oxygen-donor ligands

A wide variety of oxygen-donor ligands have been used to complex and separate americium. The most synthesized compounds of Am(III) are those with carboxylic acids, because of their applications in separation (Weigel and ter Meer, 1967). However, only the single-crystal structure of the hydrated Am(III) salicylate, $Am(C_7H_5O_3)_3(H_2O)$, has been reported. In this compound, americium is nine-coordinate to one water molecule and six salicylato ligands (Burns and Baldwin, 1976). The six salicylato ligands display three different coordination modes: (i) monodentate binding through the carboxylic oxygens of four ligands; (ii) bidentate binding through its carboxyl group; and (iii) and bidentate binding through a combination of carboxylic and phenolic oxygens. Salicylato complexes have been reported for rare earths and plutonium and are important because the ligands contain carboxylic and hydroxo functional groups, which are typical for the more complex natural humic materials.

The sodium acetate, $NaAmO_2(CH_3CO_2)_3$, is the only characterized complex of americyl(VI) (Jones, 1955). Lychev *et al.* (1980) synthesized the cesium salt of Am(V), $CsAmO_2(CH_3CO_2)_3$, but solved the crystal structure only of the isostructural analogous Np(V) compound. In both americyl acetate compounds, three carboxylates are coordinated bidentately in the equatorial planes of AmO_2^+ and AmO_2^{2+}. Burns and Danford (1969) obtained single crystals of orthorhombic $CsAm(hfa)_4$ (hfa = hexafluoro-acetylacetone) when recrystallizing monoclinic $CsAm(hfa)_4 \cdot H_2O$ (Danford *et al.*, 1970) in 1-butanol. The compound is composed of Am(hfa)-chains that interact with Cs^+ ions. The Am^{3+} ion is chelated by the eight acetone–oxygen atoms of the four hfa ligands with Am–O bond distances between 2.36 and 2.45 Å. $CsAm(hfa)_4$ and CsAm $(hfa)_4 \cdot H_2O$ sublimes at about 135°C. Both hydrated and the anhydrous compounds are metastable and degrade after about 1 week with AmF_3 identified as one of the degradation products (Fig. 8.12).

EXAFS studies of the structure of the solvent-containing $Am(NO_3)_3$ $(TEMA)_2$ complexes (TEMA = *N*,*N*,*N*,*N*′-tetraethylmalonamide) resulted in Am–O distances of 2.52 ± 0.01 Å and a coordination polyhedron similar to that of the corresponding Nd compound, where Nd is ten-coordinate (DenAuwer *et al.*, 2000).

In recent years, the reactions of americium ions with a number of organic molecules were studied in the gas phase. As an example, the gas-phase reaction of laser-ablated americium ions with alcohols yields a mixture of hydroxides and alkoxides, i.e. $Am(OR)^+$ and $Am(OR)^{2+}$ (Gibson, 1999b). The reaction with dimethylether yields the methoxy ion $Am(OCH_3)^+$ as the primary product. Although these reactions do not reveal any structural details, they provide some understanding of potential interaction mechanisms in americium organometallic chemistry. Other products of laser-ablated Am^+ or AmO^+ ions reacting with polyimide, nitriles, or butylamines are AmC_2H^+, $AmC_2H_4^+$, $AmC_2H_2^+$, several cations of general formula $AmC_xH_yN_z^+$, and metal oxide clusters such as Am_2O^+ an $Am_2O_2^+$ (Gibson, 1998a, 1999a). An interesting anomaly was the observation of dimeric Am_2^+ clusters that were not formed by any other actinides studied (Gibson, 1999a).



$Am(C_7H_5O_3)_3(H_2O)$ $CsAm(hfa)_4$

Fig. 8.12 *Nine-fold coordination of Am(III) in* $Am(C_7H_5O_3)_3(H_2O)$ *(Burns and Baldwin,* 1976) *and eight-coordinate Am(III) in* $CsAm(hfa)_4$ *(Burns and Danford,* 1969).

(b) Nitrogen donors

Only a few complexes of americium with N-donating ligands have been studied yet; structural details are limited. The bis-phthalocyanine complex has been synthesized and displays a sandwich-type complex with eight-coordinate americium (Moskalev *et al.*, 1979). Yaita *et al.* (2001) studied the Am(III) benzimidazole complex using XAFS spectroscopy and found a bidentate coordination of Am through two nitrogen atoms with the bond distance Am–N of 2.63 Å. The overall coordination number of Am(III) is reported to be close to 10.

(c) Sulfur donors

Only few structural studies are reported involving compounds with Am–S bonds. Gibson (1999b) observed SH abstraction from thiols and formation of the hydrosulfide $Am(SH)^+$ in the gas phase. The gas-phase reaction with propanethiol yielded the thiolate $Am(PrS)^+$. Tian *et al.* (2002) used EXAFS to study the structure of extraction complexes of Am(III) with di-*n*-octyldithiophosphinic acid and di(2,4,4-trimethylpentyl)dithiophosphinic acid in kerosene. The two extraction complexes appear to be similar in coordination with eight sulfur atoms in the inner sphere and four phosphorus atoms in the second shell with average Am–S and Am–P bond distances of 2.9 and 3.5 Å, respectively.

(d) Cyclopentadienyl and cyclooctatetraenyl compounds

The organometallic chemistry of americium remains essentially unstudied. The most studied compound is the cyclopentadiene complex, $Am(C_5H_5)_3$, which crystallizes in the orthorhombic *Pbcm* space group and is isostructural with, but not pyrophoric like $Pu(C_5H_5)_3$ (Baumgärtner *et al.*, 1966a). Pappalardo *et al.* (1969a) reported the absorbance spectrum of $Am(C_5H_5)_3$ films from which Nugent *et al.* (1971b) calculated a bond covalency of only 2.8 ± 0.2% (relative to the corresponding bands of $Am(aq)^{3+}$) indicating that the organometallic bonding in $Am(C_5H_5)_3$ is highly ionic. Consequently, Nugent *et al.* suggested that the compound should be designated as a tris-cyclopentadienide rather than a tricyclopentadienyl compound. Bursten and coworkers (Bursten *et al.*, 1989; Li and Bursten, 1997) calculated the electronic structure of $AnCl_3$, $An(C_7H_7)_2$, and $An(C_5H_5)_3$, and discussed the relative role of the 5f and 6d atom orbitals. Karraker (1975, 1977) reported the synthesis of the potassium salt of a bis-cyclooctatetraenyl Am(III) complex, $KAm(C_8H_8)_2$, and obtained the absorbance spectrum in THF. The compound $KAm(C_8H_8)_2 \cdot 2THF$ decomposes in water and burns when exposed to air. The X-ray powder diffraction data show that $Am(C_8H_8)_2$ is isostructural with the analogous Np and Pu compounds and the sandwich complex uranocene. The gas-phase reaction of Am^+ ions with 1.5-cyclooctadiene and cyclooctatetraene produced the dehydrogenation complexes $Am-C_8H_8^+$ and $Am-C_8H_6^+$ that were detected by mass spectrometry

(Gibson, 1998b). The gas-phase reaction of laser-ablated Am^+ with pentamethylcyclopentadiene (HCp*) yielded the fragments $AmC_8H_{14}^+$, $AmC_9H_{12}^+$, and $AmC_{10}H_{14}^+$ (Gibson, 2000). In contrast to the multiple dehydrogenation reactions observed with Np^+ and Pu^+, the Am^+ ion appeared unreactive and induced exclusively single hydrogen loss. Gibson concludes from this finding that the valence 5f electrons of Am^+ are too inert to form σ-bonds with carbon or hydrogen atoms and therefore do not participate in the Am–HCp interaction.

8.10 ANALYTICAL CHEMISTRY AND SPECTROSCOPY

8.10.1 Radioanalytical chemistry

(a) Alpha spectroscopy

Common analytical procedures include alpha spectrometry for the detection of ^{241}Am and ^{243}Am. The typical alpha-spectrum of ^{241}Am exhibits a peak at 5.49 MeV. The energy of the main alpha particles of ^{243}Am (5.28 MeV) differs by only about 0.2 MeV, which can result in peak broadening and overlap with α-peaks of other radionuclides (Lin *et al.*, 2002). Quantitative analysis by alpha spectrometry requires extensive radiochemical purification, preparation of a high-quality americium source by a skilled radiochemist, and correction for absorption and backscattering from the planchet. Scintillation counting has largely replaced alpha spectrometry in many radioanalytical procedures.

(b) Gamma spectroscopy

Nuclide identification and analysis of biological and environmental samples mainly use high-sensitivity gamma counting in a germanium multichannel detector. ^{241}Am emits two main γ-rays at 59.5 (36%) and 26.3 keV (2.4%). Scintillation counting is also commonly used when only one γ-emitting isotope is in the sample.

8.10.2 Spectroscopy

(a) Solution absorption

(1) Am(III): UV–VIS–NIR absorption spectroscopy has been widely used to characterize americium solution species. The major absorbance that has been measured to speciate Am(III) corresponds to the transition $^7F_0 \rightarrow {}^5L_6$ with its maximum at 503.2 nm ($\varepsilon \sim 410$ L mol cm^{-1}) for Am^{3+}(aq). The molar absorptivity may change with spectral slit widths, temperature, and ionic strength of the solution. Shifts in the position of the absorbance bands

and changes in molar absorbance are evidence of changes in the number of inner-sphere coordinated water molecules and/or coordination of ligands, i.e. carbonate or sulfate. Theoretical calculations of the electronic energy bands in the Am^{3+} ion have been performed by a number of investigators (Conway, 1963, 1964; Carnall and Wybourne, 1964; Carnall *et al.*, 1964; Carnall and Fields, 1967). An unexpected predicted $^7F_0 \rightarrow {}^5D_1$ transition was found in more concentrated Am(III) solution. Carnall (1989) analyzed the energy levels of the Am^{3+} ion by comparing the absorption spectra of $AmCl_3$ and $LaCl_3$ that was doped with Am(III).

Barbanel *et al.* (1997, 2001) studied the transitions in the octahedral complexes AmX_6^{3+} in the Cs_2NaLuX_6 (X = Cl, Br) crystal. The absorption spectra showed excitation to the ground level states $^7F_2$, $^7F_4$, $^7F_6$ and to the exited states $^5L_6$, $^5G_2$, and $^5D_2$. Absorbance spectra have been recorded in H_2SO_4, H_3PO_4, HNO_3, HCl, $HClO_4$, and in carbonate media (Keenan, 1959; Marcus and Shiloh, 1969; Shiloh *et al.*, 1969; Stadler and Kim, 1988; Meinrath and Kim, 1991a; Runde and Kim, 1994) (Fig. 8.13).

(2) Am(IV): The spectrum of Am(IV) in acid media is characterized by broad absorption features and has been measured in 13 M HF (Asprey and Penneman, 1961, 1962), 12 M KF (Varga *et al.*, 1973), 12 M H_3PO_4 (Myasoedov *et al.*, 1977), and in 2 M Na_2CO_3 (Bourges *et al.*, 1983; Hobart *et al.*, 1983b). The spectrum of Am(IV) in concentrated fluoride solution resembles very closely that of solid AmF_4 (Fig. 8.14).

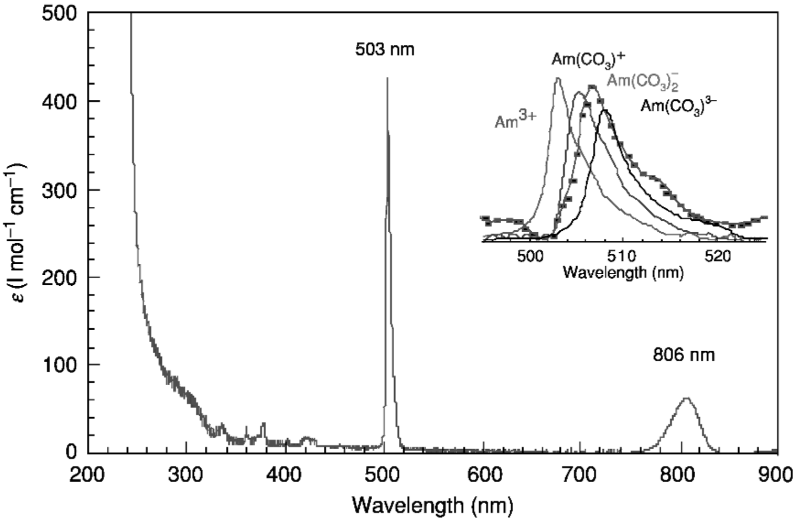


Fig. 8.13 *Electronic absorption spectra of* Am^{3+} *in* 1 M $HClO_4$ *and of the predominant Am*(III) *species in carbonate-containing solutions* (*inset*) (*Meinrath and Kim*, 1991a).

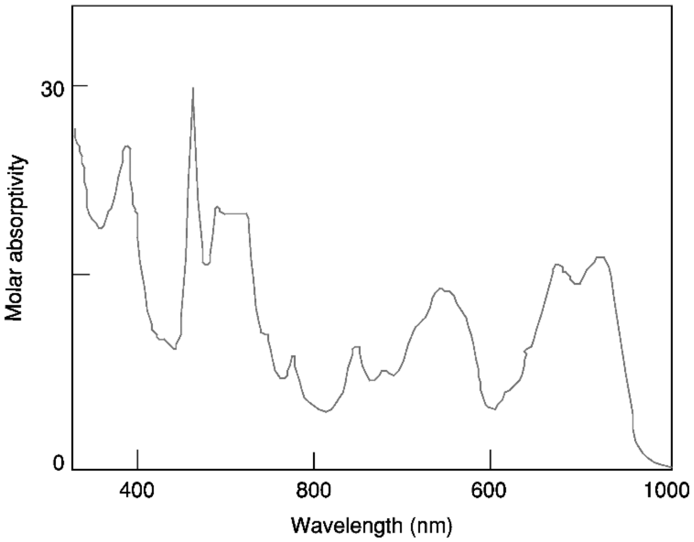

Fig. 8.14 *Absorption spectrum of Am(IV) in* 13 M NH_4F (*Asprey and Penneman*, 1962).

(3) Am(v): The Am(v) transitions $^5I_4 \rightarrow ^3G_5$ and $^5I_4 \rightarrow ^3I_7$ with their absorbance peaks at 513.7 nm ($\varepsilon \sim 45$ L mol cm^{-1}) and 716.7 nm ($\varepsilon \sim 60$ L mol cm^{-1}), respectively, are the main absorbance bands of the AmO_2^+ ion in aqueous solutions. Absorbance spectra of Am(v) have been recorded in H_2SO_4 (Werner and Perlman, 1950), HCl (Hall and Herniman, 1954; Stadler and Kim, 1988; Runde and Kim, 1994), $HClO_4$ (Asprey *et al.*, 1951; Stephanou *et al.*, 1953), NaCl (Stadler and Kim, 1988; Runde and Kim, 1994), and in 2 M Na_2CO_3 (Bourges *et al.*, 1983; Hobart *et al.*, 1983b) (Fig. 8.15).

(4) Am(vi): The spectrum of Am(vi) in acid media is characterized by the sharp absorption band at about 996 nm with $\varepsilon \sim 100$ L mol cm^{-1} in $HClO_4$ and ~100 L mol cm^{-1} in H_3PO_4. A less intense absorbance appears at 666 nm. Bell (1969) has compared band positions of transuranium actinyl spectra, including those of AmO_2^+ and AmO_2^{2+}, with the spacings between positions of the UO_2^{2+} bands. His results indicate that a single molecular orbital model can represent any of the actinyl ions when the uranyl ion is assumed to have the bonding orbitals exactly filled; the transuranium actinyl ions are represented with the uranyl core and a progressive increase of electrons in the first two lowest unoccupied molecular orbitals (LUMOs). Although the Am(vi) absorbance appears when Am(v) disproportionates in $HClO_4$, the absorbance is absent in HCl media potentially because of the formation of chloride complexes of lower molar absorptivity or due to the instability of Am(vi) in acidic chloride media (Fig. 8.16).

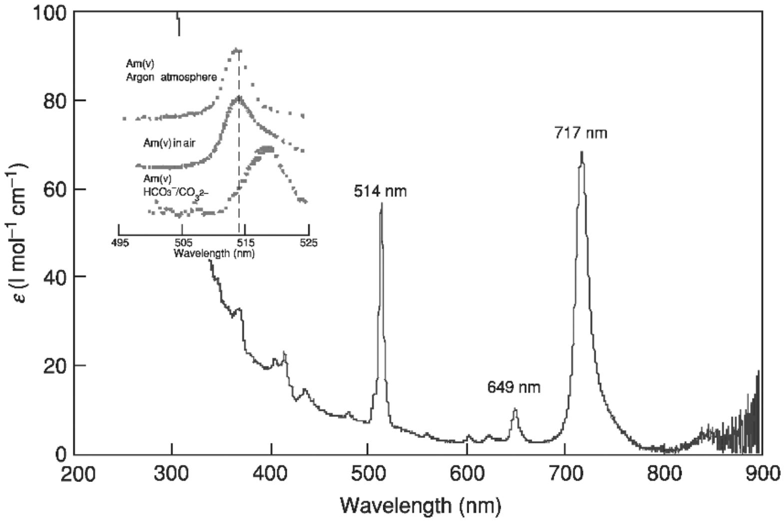

Fig. 8.15 *Electronic absorption spectra of AmO_2^+ in* 1 M *$HClO_4$ and in carbonate-containing solutions* (*inset*) (*Stadler and Kim*, 1988).

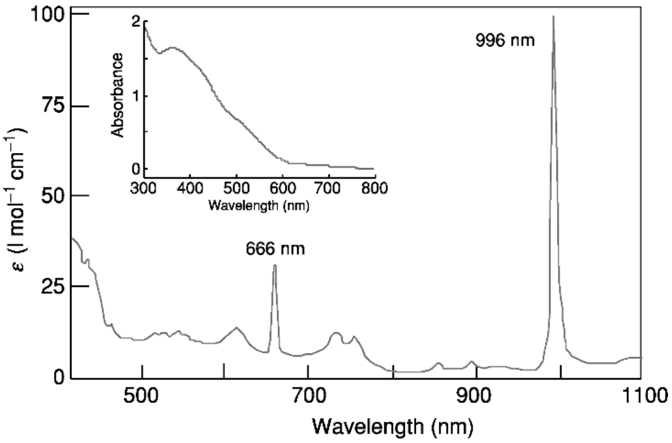

Fig. 8.16 *Absorption spectrum of Am*(*VI*) *in* 1 M *$HClO_4$ and in carbonate solution* (*inset*) (*Penneman and Asprey*, 1955).

(5) Am(VII): Green-colored solutions, believed to be Am(VII), are prepared by oxidation of Am(VI) in 3–5 M NaOH at 0–7°C with either ozone or the O^- radical. The spectrum of Am(VI) and Am(VII) was measured in 3.5 M NaOH solution by Krot *et al.* (1974a,b) and exhibited a broad absorbance

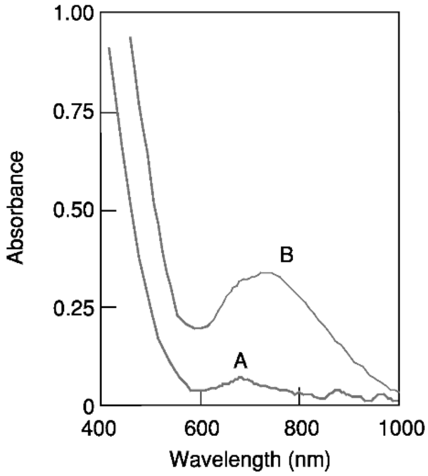

Fig. 8.17 *Absorption spectra of Am*(*VI*) *and Am*(*VII*) *in* 3.5 M *NaOH* (*Krot* et al., 1974a). *A*, 0.0194 M *Am*(*VI*); *B*, 0.0194 M Am_{tot} *with* 50% *Am*(*VI*) *and* 50% *Am*(*VII*).

at 740 nm (Fig. 8.17). Heptavalent americium is unstable and reduces to Am (VI) within minutes. It can be easily reduced by hydrogen peroxide, hydrazine, hydroxylamine, sulfite, and ferrocyanide ions, and Np(VI) and Pu(VI) (Shilov, 1976). A review on the chemistry of heptavalent transplutonium elements can be found in Mikheev and Myasoedov (1985).

(b) Luminescence

Luminescence has been observed only for Am(III). Reviews of Am(III) luminescence studies can be found in Beitz (1994) and Yusov (1993). The first study on the luminescence properties of Am(III) was reported by Beitz *et al.* (1989). Excitation of Am(III) from the $^7F_0$ ground state to the $^5L_6$ state at 503 nm results in the emission from the lowest luminescent level to the ^7F_J ground-state manifold. From seven expected transitions only two are experimentally accessible. The two most populated transitions are the $^5D_1 \rightarrow {}^7F_1$ band at 685 nm and the $^5D_1 \rightarrow {}^7F_2$ band at 836 nm. These transitions can be used for the determination of trace concentrations of Am(III) in solution or solid-state matrices (Thouvenot *et al.*, 1993). Beitz and coworkers (Liu *et al.*, 1997) investigated the crystal field splitting and hyperfine energy level structure in the $^5D_1$ level of $^{243}Am^{3+}$ in $LaCl_3$ and $CaWO_4$.

The fluorescence lifetime of the Am^{3+} ion(aq) is reported to be 20.4 ± 2.1 ns (Runde *et al.*, 2000), 24.6 ± 0.6 ns (Kimura and Kato, 1998), and 22 ± 3 ns (Beitz, 1994) in aqueous systems. The lifetime increases dramatically to 155 ± 4 ns (Beitz, 1994) in D_2O. Complexation of the Am^{3+} ion changes the position of the emission bands and the duration of the fluorescence lifetime; e.g. the fluorescence of the triscarbonato complex, $Am(CO_3)_3^{3+}$, is observed at 693 nm with a lifetime of 34.5 ± 2.4 ns (Runde *et al.*, 2000). The luminescence spectra of Am^{3+} have been also measured in Am-doped powdered ThO_2 (Hubert and Thouvenot, 1992), $Cs_2NaLuCl_6$ (Barbanel *et al.*, 1998), $LiYF_4$ (Cavellec *et al.*, 1997), heavy metal fluoride glass containing AmF_3 (Beitz, 1994), and in fluorozirconate glass (Valenzuela and Brundage, 1990; Brundage, 1994) (Fig. 8.18) .

(c) Vibrational (IR and Raman)

There are few data on the IR spectra of americium compounds. Tananaev (1991) reported the antisymmetric vibration frequency of the AmO_2^+ group in $CsAmO_2(OH)_2 \cdot nH_2O$ at 802 cm^{-1}. Hobart *et al.* (1983a) reported the Raman spectra of $AmPO_4$ and $Am(PO_3)_3$ with the most intense Raman frequencies for the symmetric stretching mode of PO_4^{3-} at 973 cm^{-1} and of PO_3^- groups at 1195 cm^{-1}. Jones and Penneman (1953) studied the infrared absorption assigned to the infrared O–An–O asymmetric stretch of actinyl(v) and (vi) ions, concluding that these ions were linear or very nearly so. For the solid $NaAmO_2(CH_3COO)_2$ the vibrational frequencies $\nu_1 = 749$ and $\nu_2 = 914$ cm^{-1} were reported (Jones, 1955). Data on Raman scattering of americyl(v) and (vi) ions have been reported in non-complexing perchloric acid and complexing carbonate solutions (Basile *et al.*, 1974). The values for the polarized symmetric stretching frequencies (ν_1) of AmO_2^+ and AmO_2^{2+} were found to be 730 and 796 cm^{-1}, respectively (Basile *et al.*, 1974). The Raman scattering in carbonate solutions showed a shift of ν_1 to 747 cm^{-1} for Am(v) (Madic *et al.*, 1983) and to 760 cm^{-1} for Am(vi) (Basile *et al.*, 1978). A study of the correlation of the Raman spectra of actinyl(v) and (vi) ions in perchlorate and carbonate

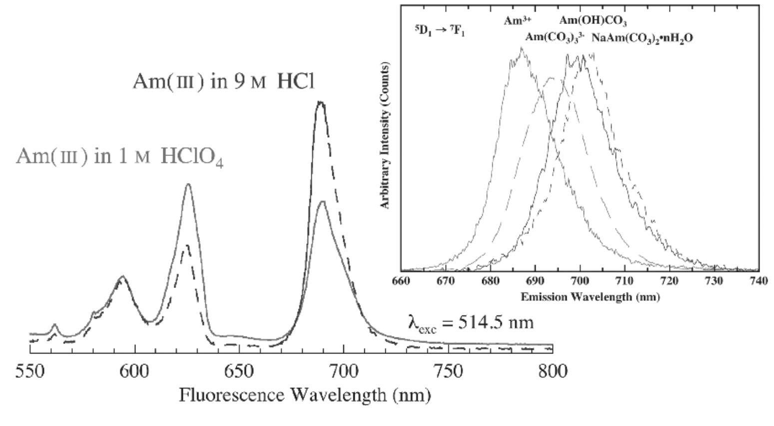

Fig. 8.18 *Luminescence spectrum of Am^{3+} in acidic media and of Am(III) carbonate complexes*. (*Runde* et al., 2000, 2002).

solutions, as well as the spectra of solid actinide(v) double carbonate compounds, $Na_3AnO_2(CO_3)_2 \cdot H_2O$, was published by Madic *et al.* (1983).

(d) X-ray absorption

Although X-ray absorption spectroscopy (XAS, see Chapter 28) has been increasingly used since 1990 to obtain structural information of actinide compounds, only a small number of XAS studies on americium compounds have been reported. Bearden and Burr (1967) reported the edge energy of americium metal at 18 504 eV. Soderholm *et al.* (1996) observed the Am edge energy at 18515 eV in the Am(IV) compound $Pb_2Sr_2AmCu_3O_8$, which is about 4 eV higher in energy compared to the solid Am(III) reference compounds AmF_3 and $Cs_2NaAmCl_6$. EXAFS has been used to study the coordination of americium in organic complexes (DenAuwer *et al.*, 2000; Yaita *et al.*, 2001) and inorganic complexes with $P_5W_{30}O_{110}^{15-}$ (Williams *et al.*, 2000), chloride (Allen *et al.*, 2000), and carbonate (Runde *et al.*, 2002).

CHAPTER NINE

CURIUM

Gregg J. Lumetta, Major C. Thompson, Robert A. Penneman,
and P. Gary Eller

9.1 HISTORICAL

Curium, element 96, is named after Pierre and Marie Curie, by analogy with its lanthanide congener, gadolinium (named after the Finnish chemist, J. Gadolin). Curium is not a naturally occurring terrestrial element.

The first curium isotope, ^{242}Cm, was prepared by Seaborg, James, and Ghiorso in mid-1944 by cyclotron helium ion (He^{2+}) bombardment of ^{239}Pu, and was identified by its characteristic alpha radiation (Seaborg *et al.*, 1949). The discovery of curium preceded that of americium (element 95). G. T. Seaborg described this discovery in a fascinating historical account (Seaborg, 1985). Werner and Perlman (1951) separated the first weighable quantity of curium (40 μg of impure ^{242}Cm oxide), which was prepared by prolonged neutron irradiation of ^{241}Am.

Curium is the element of highest atomic number that is available on the gram scale. However, chemical studies are typically done on the milligram scale using glove boxes, although microchemical techniques were originally used (Seaborg, 1972; Stevenson and Peterson, 1975). Larger scale work usually requires remote handling. Because of the limited availability of long-lived isotopes (especially ^{248}Cm), the high radioactivity of its most common isotopes (^{242}Cm and ^{244}Cm), and its general occurrence in aqueous systems as a 3+ ion, considerably less physical and chemical information about curium is available than for americium. Excellent reviews have been published on various aspects of curium chemistry (Katz and Seaborg, 1957; Brown, 1968; Keller, 1971; Bagnall, 1972; Gmelin, 1972–74; Penneman *et al.*, 1973; Edelstein *et al.*, 1985; Navratil and Schulz, 1993).

This chapter provides an overview of curium chemistry, with emphasis on advances since the publication of the 1986 version of this chapter (Eller and Penneman, 1986). The technical literature indicates that chemical investigations during this period have focused on the following general areas:

- Separations chemistry related to high-level waste management: This topic is addressed in Section 9.5.
- High-temperature superconductivity studies of curium compounds: Soderholm (1992) has provided an excellent review in this area. Additional discussion can be found in Section 9.7 and in Chapter 20.
- Behavior of curium in the environment: This topic is addressed in Chapter 27.
- Use of curium isotopes as targets to prepare superheavy elements: Hoffman (1985) and Lobanov *et al.* (1997) provide examples. This subject is discussed in Chapter 14.
- Use of curium isotopes in analytical space applications: Radchenko *et al.* (1999, 2000), Abramychev *et al.* (1992), and Vesnovskii *et al.* (1996) provide illustrative examples of this type of work applied to alpha spectrometry analysis of extraterrestrial rocks and soils.
- Transmutation in reactors and accelerators: Artisyuk *et al.* (1999), Gerasimov *et al.* (2000), and Raison and Haire (2001) describe this topic.

9.2 NUCLEAR PROPERTIES

Properties of the known curium isotopes, which range in mass from 238 to 251, are summarized in Table 9.1. Additional information is available in the appendix. Electron binding energies, radiation energies, X-ray spectra, and L-shell fluorescence data are available, as well as both alpha and spontaneous fission data (see Chu, 1972; Kerrigan and Banick, 1975; Lederer and Shirley, 1978; Lougheed *et al.*, 1978; Holden, 1989). Three isotopes (^{242}Cm, ^{244}Cm, and ^{248}Cm) are available in quantities sufficient for chemical study. Macroscopic studies with ^{242}Cm and ^{244}Cm are complicated by the high specific alpha activities of these isotopes (half-lives of 163 days and 18.1 years, respectively). The practical limit for chemical operations with ^{248}Cm in glove boxes is 10–20 mg because of the significant neutron exposure hazard from the 8% spontaneous fission yield of this isotope.

Both ^{242}Cm and ^{244}Cm have been used in power sources (thermal and electrical) for space and medical applications (Groh *et al.*, 1965; Abramychev *et al.*, 1992; Vesnovskii *et al.*, 1996). The isotope ^{242}Cm has a specific heat output (122 W g^{-1}) about 43 times higher than that of ^{244}Cm (2.8 W g^{-1}),

Table 9.1 *Nuclear properties of curium isotopes.*

Mass number	*Half-life*	*Mode of decay*	*Main radiations* (MeV)	*Method of production*

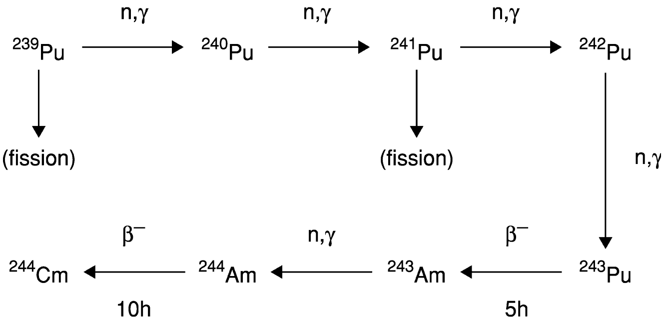
This table is reproduced directly from the compilations in Appendix II of this volume by I. Ahmad.

and a cake of $^{242}Cm_2O_3$ weighing a few grams can be photographed using its own incandescence for illumination. These isotopes provide convenient energy sources for short-period/high-output and long-period/moderate-output applications. However, because of its greater availability and high-energy density, ^{238}Pu has supplanted both ^{242}Cm and ^{244}Cm for many such uses. The isotope ^{248}Cm has been a favored nuclide for accelerator studies attempting to form superheavy elements (Hoffman, 1985; Lobanov *et al.*, 1997).

9.3 PRODUCTION

Intense neutron exposure of ^{242}Pu and ^{243}Am in nuclear reactors forms significant quantities of the isotopes ^{244}Cm, ^{246}Cm, and ^{248}Cm, with lesser amounts of the odd-mass isotopes, ^{245}Cm and ^{247}Cm. Most curium isotopes heavier than ^{244}Cm have longer half-lives, but cannot be prepared isotopically pure by neutron capture. Except for ^{248}Cm, which is available as an essentially pure isotope from the decay of ^{252}Cf, curium isotope enrichment is accomplished in mass separators. The isotope ^{248}Cm is particularly desirable for chemical studies because of its long half-life (3.48×10^5 years). Approximately 100 mg of ^{248}Cm was produced in the 1970s and 1980s in the United States by purification from parent ^{252}Cf.

By far, the greatest quantity of curium exists as the isotope ^{244}Cm, which has been produced on the several kilogram scale at the Savannah River Site (Groh *et al.*, 1965; Baybarz, 1970; Gmelin, 1972–74). This isotope is produced by successive neutron capture starting with ^{239}Pu, ^{242}Pu, or ^{243}Am:



For 20 years following the discovery of curium, only milligram amounts of curium were available from the irradiation of ^{241}Am. It was not until Glenn T. Seaborg became Chairman of the US Atomic Energy Commission that a large-scale national program was instituted. Kilograms of ^{239}Pu were transferred from the weapons program for irradiation at Savannah River Site. This 'expenditure' of plutonium required a Presidential Directive. The authors note that, especially in 1960, this transfer from programmatic use was extraordinary and stands in striking contrast to current views regarding the disposition of many tons of excess weapons-grade plutonium. The aim of the irradiation campaign was to produce major amounts of the higher-mass isotopes of plutonium and elements of higher atomic number for research. The demand for large quantities of higher isotopes has diminished, resulting in the disposal of 2–3 kg of Cm from the Savannah River Site in 2002 (Peters *et al.*, 2002).

Initially, 8.5, then 12.0 kg for a total of 20.5 kg of ^{239}Pu, was staged in a Savannah River reactor. This approach was necessary to remove the immense heat produced (3×10^6 Btu h^{-1} ft^{-2}) from ^{239}Pu and ^{241}Pu fission. The yield from 20.5 kg of initial ^{239}Pu was 930 g of ^{242}Pu and 630g of ^{243}Am and ^{244}Cm combined (Penneman and Ferguson, 1971). The mixture was sent for separation to the Oak Ridge National Laboratory (ORNL), where the high-mass plutonium was fabricated into cermet targets for the High Flux Isotope Reactor (HFIR). A neutron flux of 5×10^{15} neutrons cm^{-2} s^{-1} was used for the specific purpose of creating higher-mass/higher-atomic-number isotopes. The plutonium feed composition was initially ^{238}Pu (0.43%), ^{239}Pu (1.12%), ^{240}Pu (1.8%), ^{241}Pu (0.91%), and ^{242}Pu (95.7%) (Bigelow, 2002).

At the height of production, about 1 g of ^{252}Cf was produced per year. Its short alpha decay half-life (2.6 years) yields ^{248}Cm. Production of ^{252}Cf has diminished, but continues because it is desirable for neutron irradiation in health applications. Its decay currently yields 35–50 mg of ^{248}Cm annually (Knauer, 2002).

The relatively stable isotope ^{248}Cm can be obtained in multi-milligram quantities by milking aged, prepurified ^{252}Cf materials that have undergone alpha decay. This method routinely yields milligram amounts of ^{248}Cm with an isotopic purity of 97%. Even so, 99.9% of the alpha activity arises from ^{244}Cm and ^{246}Cm impurities.

$$^{252}\mathrm{Cf} \xrightarrow[2.6\ \mathrm{y}]{\alpha} {}^{248}\mathrm{Cm}$$

Small (microgram) amounts of ^{245}Cm have been separated from alpha decay products of ^{249}Cf, itself a daughter of ^{249}Bk.

To isolate ^{244}Cm, irradiated material is dissolved in nitric acid and tetravalent plutonium is removed by solvent extraction (Groh *et al.*, 1965; Baybarz, 1970). The trivalent species (americium, curium, and the lanthanides) remaining in the aqueous phase are then extracted with 50% tributyl phosphate (TBP) in kerosene, and then back-extracted into dilute acid. For purification from lanthanides, Am/Cm chlorides are extracted with tertiary amines from slightly acidic 11 M LiCl (Tramex process), and then back-extracted into aqueous 7 M HCl. Subsequent precipitation of Am(V) as the potassium double carbonate effectively separates americium, leaving soluble Cm(III) in the K_2CO_3 medium.

The isotope ^{242}Cm is best obtained by neutron irradiation of ^{241}Am at an intermediate flux level. High neutron fluxes diminish the yield of ^{242}Cm because of the increased fission of ^{242}Am:

$$^{241}\mathrm{Am} \xrightarrow{\mathrm{n},\gamma} {}^{242}\mathrm{Am} \xrightarrow[16\,\mathrm{h}]{\beta^-} {}^{242}\mathrm{Cm}$$

Following irradiation of $\mathrm{AmO_2/Al}$ cermet targets, hot NaOH is used to dissolve the aluminum. Dissolution in HCl also can be used, in which case $\mathrm{Al^{3+}}$ must be removed before further processing. For small-scale separations, the Am/Cm/lanthanide fraction is dissolved in HCl; the solution is then made 11 M in LiCl, and passed through an anion-exchange column. Under these conditions, trivalent actinides (but not rare earth elements) are retained on the column. Alternatively, a tertiary amine extractant can be substituted for the anion-exchange resin to provide a group separation between actinides (extracted) and lanthanides (Baybarz, 1970). A subsequent americium/curium separation step is then required. A combination of anion and cation exchange was used successfully to separate about 1 g of $^{242}\mathrm{Cm}$ from neutron-irradiated $^{241}\mathrm{Am}$ (Thompson, 1972).

Numerous other techniques, including high-pressure ion exchange, extraction chromatography, and di(2-ethylhexyl)phosphoric acid (HDEHP) extraction also have been used for Cm separation and purification (Dedov *et al.*, 1965; Baybarz, 1970; Gmelin, 1972–74; Thompson, 1972; Buijs *et al.*, 1973; Haug, 1974; Lebedev *et al.*, 1974; Bigelow *et al.*, 1980; Bond and Leuze, 1980). Pressurized displacement ion-exchange chromatography has been applied to large-scale $^{244}\mathrm{Cm}/^{243}\mathrm{Am}$ separation and purification using Dowex® 50 resin in the $\mathrm{Zn^{2+}}$ form and diethylenetriaminepentaacetic acid (DTPA) as eluant (Stephanou and Penneman, 1952). Where sufficient quantities of Cm are present to give a substantial band, a pure curium cut can be obtained, since it leads the americium band.

9.4 ATOMIC PROPERTIES

Selected properties of curium-free atoms and ions are summarized in Table 9.2. A set of recommended thermodynamic parameters is available in the recent publication of Konings (2001b). Thermodynamic properties of actinides are addressed in Chapter 19.

The great stability of the $5f^7$ configuration of Cm(III) and its lanthanide congener Gd(III) is shown by the large M(III)–(IV) oxidation potentials (see Section 9.7.1). In contrast, it is noteworthy that the tendency of americium to attain the $5f^7$ configuration by assuming a divalent state is much weaker than that displayed by europium. Isolated Cm(II) compounds are unknown and a value of –2.78 V has been estimated for the Cm(III)/Cm(II) redox potential (Mikheev *et al.*, 1992).

The spectra of the Cm(III) aquo ion and of a metastable Cm(IV) aqueous fluoride solution complex ion are shown in Figs. 9.1 and 9.2, respectively. In contrast to solutions of Gd(III) (Moeller and Moss, 1951), aqueous solutions of

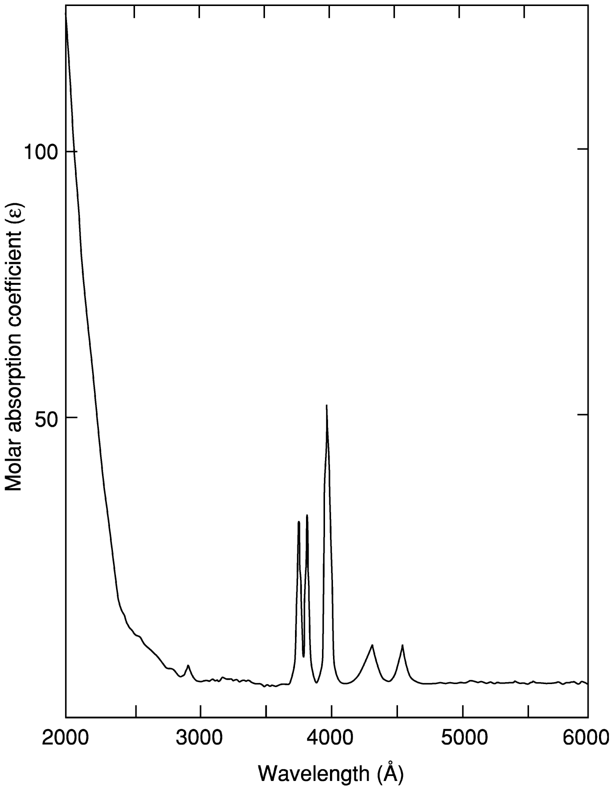

Fig. 9.1 *The absorption spectrum of Cm(*III*) in* 0.04 N *HclO*$_4$ *(aq). (Adapted from Carnall* et al., 1958.)

Cm(III) have weak absorption bands in the near-violet region, although intense absorptions are present in the ultraviolet region (Asprey and Keenan, 1958; Keenan, 1961; Barbanel *et al.*, 1977). The absorption spectra of metastable Cm(IV) was measured at Los Alamos by dissolving CmF_4 prepared by fluorination of dry CmF_3, and that of Cm(III) was measured at both Los Alamos and Argonne using curium solutions carefully purified from rare earths and americium. The principal peaks of Cm(IV) strongly resemble those of Am(III), with which it is isoelectronic (Carnall *et al.*, 1958).

Electronic transitions for Cm(III) solutions are shifted 20–30 Å to longer wavelengths compared to the solid state. The addition of complexing ions normally produces a diminution of intensities, and small changes in band positions. The transition energies for CmF_3 are considerably lower than those of GdF_3, due to smaller electrostatic repulsion terms and larger spin–orbit coupling in Cm(III). The spectra in both cases may be interpreted in terms of a $5f^7$ ground-state configuration. The spectrum of $Cs_2NaCmCl_6$, which

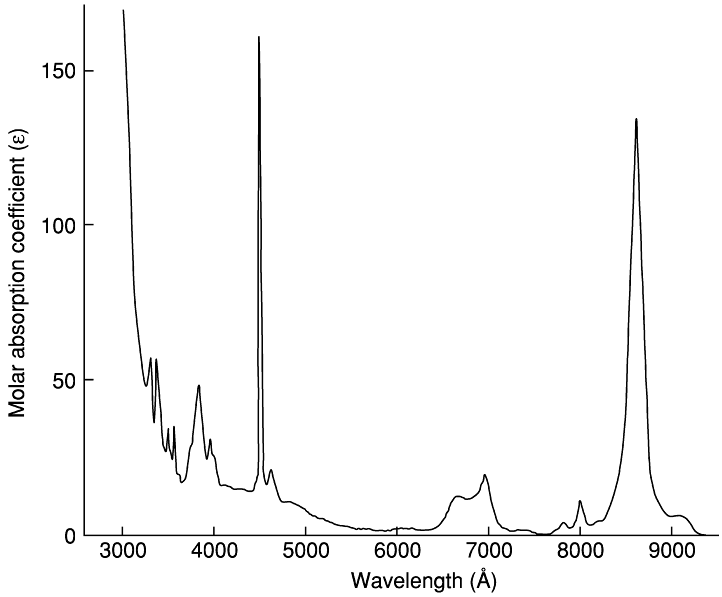

Fig. 9.2 *The absorption spectrum of Cm*(IV) *in* 15 M *CsF* (*aq*). (*Adapted from Keenan,* 1961.)

contains octahedrally coordinated Cm(III), was reported for both the solid and molten phases (Barbanel *et al.*, 1977). The most notable spectral effect is a sharp diminution in intensity compared to that of aqueous Cm(III) because of the highly symmetric curium coordination, which precludes observation of symmetry-forbidden f–f electronic transitions.

Time-resolved laser-induced fluorescence spectroscopy has been shown to be an especially valuable tool for determining curium concentration and speciation (Elesin *et al.*, 1973; Dem'yanova *et al.*, 1986; Yusov *et al.*, 1986b; Decambox *et al.*, 1989; Kim *et al.*, 1991; Myasoedov and Lebedev, 1991; Myasoedov, 1994; Moulin *et al.*, 1997; Dacheux and Aupais, 1998). Curium solutions have the unique property of strongly fluorescing in the range of 595–613 nm when irradiated with a laser or a mercury-discharge lamp (Myasoedov and Lebedev, 1991; Myasoedov, 1994). The broad unresolved fluorescence emission band is attributed to relaxation from the $^6D_{7/2}$ (*A*) state to the $^8S_{7/2}$ (*Z*) ground state (Kim *et al.*, 1991).

The energy of the emission band is dependent on the ligands attached to the curium ion. Taking advantage of this feature, time-resolved laser-induced fluorescence spectroscopy has been used extensively since the mid-1980s to investigate the fundamental solution chemistry of Cm (see Section 9.8). The method has been used to determine the hydration number for curium in solution (Kimura *et al.*, 1996) and complexation constants for a number of ligands. Furthermore,

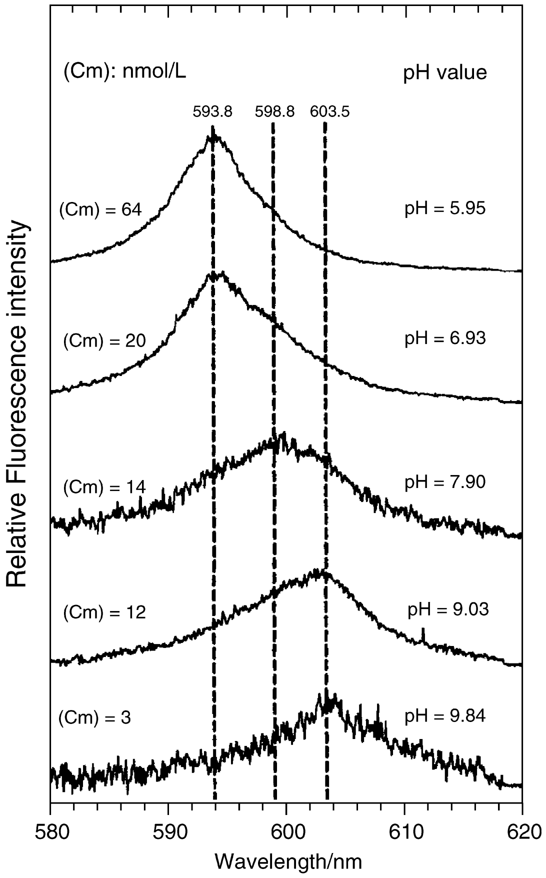

Fig. 9.3 *Curium(III) fluorescence emission spectra taken in the course of hydrolysis reaction in the pH range of* 5.05–9.84. *Used with permission from Wimmer* et al. (1992).

time-resolved laser-induced fluorescence spectroscopy has been used to characterize the Cm species present in groundwater taken from sites being considered for disposition of nuclear wastes (Wimmer *et al.*, 1992). Fig. 9.3 displays examples of fluorescence spectra for aqueous Cm species (Wimmer *et al.*, 1992). The examples presented are for Cm(III) as a function of pH and indicate the successive conversion of Cm(III) ion to $[Cm(OH)]^{2+}$ and $[Cm(OH)_2]^+$ (see Section 9.8 for a more detailed discussion of this topic).

For more thorough discussions of actinide ion absorption and luminescence spectra, see the sections on this subject by Carnall and Crosswhite (Gmelin, 1972–74). Chapter 18 of this work covers additional recent spectroscopic studies, including high-resolution spectra.

9.5 SEPARATION AND PURIFICATION OF PRINCIPAL ISOTOPES

The chemistry of curium in separation and purification is similar to that of other trivalent actinides and lanthanides and involves a series of steps, the number depending on the source of the curium. For example, separation of curium from irradiated uranium or plutonium materials requires more steps than separation of ^{248}Cm from decay of ^{252}Cf. Section 9.3 covers separation of curium from irradiated fuels and targets. This section covers separation and purification from high-level waste and other solutions, which has received more emphasis in recent years. In addition, Section 9.9 contains references to separations done for analysis of curium. Some of the analytical separations are also applicable to separation and purification.

9.5.1 Solvent extraction

Myasoedov and Kremliakova (1985) reviewed Russian literature up to the mid–1980s on americium and curium chemistry, including separations. A subsequent review has updated the work up to 1994 (Myasoedov, 1994). A recent book on separations for nuclear waste management contains reviews of work in the United States, France, and Russia (Choppin, 1999; Jarvinen, 1999; Musikas, 1999).

Extractions with organic phosphates (e.g. TBP, phosphine oxides, dialkylphosphoric acids, high-molecular-weight amines, β-diketones, and combinations of these) have been studied. Extraction by alkylphosphates depends on the structure and nature of the alkyl groups (Myasoedov, 1994; Zhu and Jiao, 1994). For example, mixed alkylphosphates with alkyl chains of six to eight carbons in length are reported to have properties superior to TBP (Zhu and Jiao, 1994). Extraction also depends on the salting agent present in solution. HDEHP has been widely studied for americium and curium extractions from both HNO_3 and LiCl solutions (Myasoedov and Kremliakova, 1985; Choppin, 1999). The latter solution has been used to separate the actinides from the lanthanides. Trioctylamine has been used to separate americium and curium from the lanthanides, with the salting agent and the diluent being important factors for extraction of curium, but not the lanthanides (Myasoedov and Kremliakova, 1985; Choppin, 1999). Russian researchers have studied the β-diketone, 1-phenyl-3-methyl-4-benzoyl-pyrazol-5-one, extensively (Myasoedov and Kremliakova, 1985). More recently, studies have been done with 1-phenyl-3-methyl-4-acylpyrazol-5-one in which the length of the carbon chain for the acyl group was varied from 2 to 22 (Takeishi *et al.*, 2001). A flowsheet was demonstrated with an acyl chain length of 8, which resulted in separate uranium, plutonium, and transplutonium fractions. All actinides were extracted from a 1 M HNO_3 solution and sequentially stripped by adjusting the pH with NaOH (Takeishi *et al.*, 2001).

Extensive studies have been done using bifunctional extractants, especially compounds such as octyl(phenyl)-*N*,*N*-diisobutyl carbamoylmethylphosphine oxide (CMPO) to recover transuranium elements, including curium, from high-level waste solutions (Horwitz and Schulz, 1991; Ozawa *et al.*, 1992; Myasoedov, 1994; Felker and Benker, 1995; Choppin, 1999; Musikas, 1999). This class of extractants can extract all the actinides from acid solutions, with separation of uranium, plutonium, and trivalent cations, by using selective stripping solutions. The separation results in a product with both the trivalent lanthanides and the actinides in the same solution, which requires further processing to isolate a pure curium stream.

French researchers have done extensive work on diamides for the extraction of trivalent actinides and lanthanides from plutonium and uranium recovery by extraction (Purex) waste solutions (Musikas, 1999). These bifunctional ligands are stronger extractants than monofunctional ligands and can be destroyed thermally without leaving a solid residue (phosphorus-containing ligands leave a solid residue when incinerated). They have also investigated nitrogen donor ligands for separation of actinides from lanthanides. The neutral tridentate ligand 2,4,6-tris-(2-pyridyl)-1,3,5-triazine has promise, but requires an additive to increase nitrate ion solubility in the organic phase (Musikas, 1999).

The largest separation factors for actinides and lanthanides have been shown with ligands containing sulfur, a ‘soft’ donor that forms stronger covalent bonds with the actinides than with lanthanides (Jarvinen, 1999; Musikas, 1999). Thio derivatives of acylpyrazolones containing both nitrogen and sulfur donor atoms are good extractants, but give best separation when combined with TBP or a phosphine oxide (Jarvinen, 1999). Dithiophosphoric or phosphinic acids have shown the highest separation factors for actinides and lanthanides (Jarvinen, 1999; Musikas, 1999).

Separation of actinides has also been done with salt mixtures and polyethylene glycol (Myasoedov and Kremliakova, 1985; Myasoedov, 1994). Cm(III) has been extracted from sulfate, carbonate, phosphate, and nitrate solutions. Extraction requires addition of complexants to the salt solutions, with arsenazo-III and xylenol orange being the most effective solution (Molochnikova *et al.*, 1992). Potassium phosphotungstate in salt solution aids in the separation of neptunium from trivalent actinides (Myasoedov, 1994).

Recovery of curium from carbonate and hydroxide solutions has been demonstrated with quaternary ammonium bases, primary amines, alkylpyrocatechols, β-diketones, and *N*-alkyl derivatives of amino-alcohols or phenols (Myasoedov and Kremliakova, 1985; Bukina *et al.*, 1988; Karalova *et al.*, 1988; Novikov *et al.*, 1988; Myasoedov, 1994). This method requires the addition of a complexant to the aqueous phase to maintain the solubility of the actinides in the solutions. The strength of the complexant must differ depending on the mechanism for extraction. Some extractants form ion pairs in the organic phase, while others extract the complexes. In the case of alkylpyrocatechols, the kinetics of extraction of lanthanides and actinides are significantly different, allowing group separation (Novikov *et al.*, 1988).

Am(iii) and Cm(iii) have also been separated using supported liquid membranes with 1 m HDEHP in hexane (Novikov and Myasoedov, 1987). The separation factor between Am and Cm was increased from 1.1 for simple extraction to 5.0 with the membrane in which potassium phosphotungstate is added to one solution to increase the chemical potential of the membrane and speed the kinetics of the process (Novikov and Myasoedov, 1987).

9.5.2 Ion exchange

Ion exchange in almost all forms has been used for curium separation from americium and the lanthanides. Organic cation and anion resins, chelating resins, chromatographic columns, and inorganic sorbents have been used (Ryan, 1975; Myasoedov and Kremliakova, 1985; Bokelund *et al.*, 1989; Choppin, 1999).

A review in 1975 summarizes the work on ion exchange, with sections on cation, anion, and chelating resins as well as inorganic sorbents (Ryan, 1975). The trivalent actinides and lanthanides are strongly adsorbed from low concentrations of common monovalent acid solutions. Separation of lanthanides from actinides is accomplished by elution with a variety of organic complexants, such as α-hydroxyisobutyric acid, ethylenediaminetetracetic acid (EDTA), or DTPA. Such complexants can also be used to separate trivalent actinides from each other (Lebedev *et al.*, 1974; Ryan, 1975; Myasoedov and Kremliakova, 1985; Bokelund *et al.*, 1989). Extraction chromatography with Zn^{2+} and DTPA was used for separation of kilograms of curium from americium (Haug, 1974). Thiocyanate solutions are also useful in accomplishing similar separations.

Anion-exchange resins have been used with HCl, LiCl, and HNO_3 in both aqueous and aqueous–alcohol mixtures (Ryan, 1975; Myasoedov and Kremliakova, 1985; Bokelund *et al.*, 1989; Choppin, 1999). Solutions of LiCl have been used extensively (Ryan, 1975; Choppin, 1999). A time-resolved laser-induced fluorescence spectroscopic study of a $LiCl/H_2O/CH_3OH$ anion-exchange system suggested the primary Cm species in the solution phase (at 14 m LiCl) is $CmCl_4^-$, but the number of coordinated chloride ions is greater than 4 for the species sorbed to the anion-exchange resin (Arisaka *et al.*, 2002). Thiocyanate solutions have also been used for separation (Myasoedov and Kremliakova, 1985). Solvents that are a mixture of alcohols and acids have been widely used for curium separations (Ryan, 1975).

A variety of zirconium-based inorganic sorbents have been used for separation of Am(iii) and Cm(iii), either using solutions similar to those employed with organic cation-exchange resins, or by oxidizing Am(iii) to Am(v), which does not adsorb (Moore, 1971; Ryan, 1975).

Extraction chromatography with CMPO on an organic support allows ready separation of an americium and curium fraction (Cunningham and Wallmann, 1964; Fuger and Oetting, 1976; Oetting *et al.*, 1976). A commercially available resin based on CMPO has been used in studies (Kaye *et al.*, 1995; Maxwell, 1996).

Different chelate groups have been tried to increase selectivity of resins for curium (Ryan, 1975; Myasoedov and Kremliakova, 1985). A column containing the tertiary amine base, Aliquat-336, was used in combination with a column of HDEHP to obtain 6 g of pure ^{244}Cm (Bokelund *et al.*, 1989). Curium was first loaded onto the Aliquat column from $LiNO_3$, eluted, loaded onto the HDEHP column, and finally eluted with 1 M lactic acid containing DTPA. Other ion-exchange methods are described in Section 9.9.2.

9.5.3 Precipitation

Precipitation has been used for the separation of Cm(III) from americium in its higher valence states of V and VI. Separation at Savannah River was achieved by adjusting the solution to an Am(Cm) concentration of 10 g L^{-1} and 3.5 M K_2CO_3, oxidizing the Am(III) to Am(V) with hypochlorite, peroxydisulfate, or ozone, and precipitating the double carbonate $K_5AmO_2(CO_3)_3$ at 85°C (Groh *et al.*, 1965). Am(III) has also been oxidized to Am(V) electrochemically (Myasoedov and Kremliakova, 1985). A second precipitation is sometimes used to remove residual Am from the Cm solution. This process is based on the original work of Stephanou and Penneman (1952). After precipitation of Am(V) as the complex carbonate, Cm(III) can be precipitated with oxalate, hydroxide, or fluoride. It is noteworthy that the choice of cation is critical; if sodium is used in place of potassium, oxidation of americium proceeds past Am(V) to form the magenta-colored Am(VI) carbonate complex, which is soluble. Based on this observation, and utilizing the insolubility of $Cm(OH)_3$ in $NaHCO_3$, the americium content in the $Cm(OH)_3$ precipitate can be reduced to low levels (Coleman *et al.*, 1963).

9.6 THE METALLIC STATE

9.6.1 Physical properties

Curium is a lustrous, malleable, silvery metal with many properties comparable to those of the lighter actinide elements. The melting point of Cm (dhcp form) is 1345 ± 50°C (Fuger and Oetting, 1976; Oetting *et al.*, 1976), much higher than for the immediately preceding actinide elements, Np–Am (639–1173°C), but very similar to that of gadolinium (1312°C), its lanthanide analog (Cunningham and Wallmann, 1964; Reichlin *et al.*, 1981).

Curium metal exists in two modifications, a double hexagonal close-packed (dhcp) structure (α-lanthanum type) and a high-temperature cubic close-packed (fcc) structure. Using ^{244}Cm, the dhcp form was found to have lattice constants $a = 3.496(3)$ and $c = 11.331(5)$ Å, giving a calculated density of 13.5 g cm^{-3} and a metallic radius of 1.74 Å (Stevenson and Peterson, 1979; Reichlin *et al.*, 1981). Baybarz and Adair (1972) and Baybarz *et al.* (1976) reported the high-temperature fcc phase with $a = 5.039(2)$ Å, prepared by metal volatilization at 1650°C.

Using ^{248}Cm, Stevenson and Peterson (1979) also obtained this phase with $a = 5.065$ Å. Other preparations of Cm metal using ^{248}Cm have been reported. They exhibit the dhcp structure with $a = 3.500 \pm 0.003$ Å and $c = 11.34 \pm 0.01$ Å, and with $a = 3.490 \pm 0.006$ Å and $c = 11.308 \pm 0.018$ Å (Reichlin *et al.*, 1981). Other X-ray diffraction studies of ^{248}Cm metal have yielded evidence for an orthorhombic form as well as delocalization and compressibility data (Benedict *et al.*, 1985; Haire *et al.*, 1985).

The entropy of vaporization for Cm metal is similar to that of gadolinium; its vapor pressure is about double that of gadolinium over the measured range. The vapor pressure of triply distilled ^{244}Cm metal has been measured between 1300 and 2000 K and obeys the following relations (Ward *et al.*, 1975):

$$\log_{10}(p/(\text{atm})) = (6.082 \pm 0.129) - (19\,618 \pm 193)/T(\text{K}) \quad (\text{solid}, 1327\text{–}1639\ \text{K})$$

$$\log_{10}(p/(\text{atm})) = (5.586 \pm 0.157) - (18\,894 \pm 275)/T(\text{K}) \quad (\text{liquid}, 1640-1972\ \text{K})$$

From the latter equation the calculated boiling point of Cm is 3110°C. The derived heat of fusion, entropy of fusion, and average second-law entropy are 13.85 kJ mol^{-1}, 9.16 J K^{-1} mol^{-1}, and 106.7 ± 3.0 J K^{-1} mol^{-1}, respectively. Determination of low-temperature condensed-phase thermodynamic parameters awaits the availability of long-lived isotopes. For excellent discussions of thermodynamic, electronic, and magnetic effects in curium and other actinide and lanthanide metals, the reader is referred to articles by Ward and Hill (1975) and Ward *et al.* (1980). Konings (2001b) has reevaluated the thermodynamic data for curium metal in the solid, liquid, and gaseous states and has reported a set of recommended values that are similar to values by Ward *et al.* (1980).

Metallic curium obeys a Curie–Weiss magnetic susceptibility relationship between 100 and 550 K with a magnetic moment of 8.07 μ_B (Kanellakopulos *et al.*, 1976; Nave *et al.*, 1981; Reichlin *et al.*, 1981), comparable to earlier values of 7.85–8.15 μ_B (Marei and Cunningham, 1972), although a lower value of 6.0 μ_B was reported recently (Fujita *et al.*, 1976). However, the form of the metal was not identified by X-ray diffraction in the latter case. Schenkel (1977) performed electrical resistance measurements on ^{244}Cm metal, and showed that curium is the first reported magnetically ordered actinide metal, with a Néel temperature of 52.5 K. A neutron diffraction study of the dhcp (α-La) form indicated no structural change down to 5 K and also showed antiferromagnetic ordering below 52 K (Fournier *et al.*, 1977). A careful susceptibility study with ^{248}Cm metal confirmed an antiferromagnetic transition at about 65 K, but the fcc phase reveals a ferrimagnetic transition near 200 K (Eubanks and Thompson, 1969).

9.6.2 Preparation of curium metal

Curium metal can be prepared from CmF_3 by reduction with barium or lithium metal. Dry, oxygen-free CmF_3 is required and the temperatures used (>1600 K) are well above the melting point of the metal. One to ten micrograms of

Cm metal was made using tungsten coils and tantalum crucibles (tantalum is reported to dissolve slightly in Cm) (Cunningham and Wallmann, 1964; Stevenson and Peterson, 1979; Reichlin *et al.*, 1981). Gram quantities of the metal have been prepared in 75–90% yield by reduction with a magnesium–zinc alloy of CmO_2 suspended in a $MgF_2/MgCl_2$ melt (Eubanks and Thompson, 1969). When CmO_2 or Cm_2O_3 and pure hydrogen are heated to temperatures between 1200 and 1500°C in the presence of Pt, Ir, or Rh, alloy phases result with compositions of Pt_5Cm, Pt_2Cm, Ir_2Cm, Pd_3Cm, and Rh_3Cm (Erdmann and Keller, 1971, 1973). Similar alloys with Ni (Radchenko *et al.*, 1995), Al (Radchenko *et al.*, 1996), and Si (Radchenko *et al.*, 1998) have also been reported. Reports on CmPd alloys showed formation of a solid solution of Cm in Pd, with the fcc lattice parameter increasing linearly with at.% Cm (Radchenko *et al.*, 1985, 1989). The Cm–Pu phase diagram has been reported, which indicates that α-Cm (dhcp) predominates at lower wt% Pu and temperature, with β-Cm (fcc) forming as the Pu concentration and temperature increase, ultimately leading to γ-Cm (space group $Im3m$) (Okamoto, 2000). Pure curium metal has been prepared by decomposition of these intermetallic compounds (Müller *et al.*, 1972, 1977). The dhcp form of curium has also been prepared by reducing the dioxide or sesquioxide with thorium metal, followed by volatilization and condensation of the curium metal vapor on a tantalum condenser (Baybarz and Adair, 1972; Damian *et al.*, 1975; Baybarz *et al.*, 1976).

9.6.3 Chemical properties of the metallic state

Metallic curium appears to be even more susceptible to corrosion than the earlier actinide elements, a property due at least in part to radioactive self-heating. The metal dissolves rapidly in dilute acid solutions. The metal surface rapidly oxidizes in air to form a film that may begin as CmO (Cunningham and Wallmann, 1964; Burney, 1980; Reichlin *et al.*, 1981), progresses to Cm_2O_3 at room temperature, and further to CmO_2 at elevated temperatures. The metal is pyrophoric when finely divided.

The direct reactions of curium metal with non-metals such as Bi, P, As, Sb, S, and Se have been reported, and binary compounds with N, P, As, and Sb have been prepared by reactions using curium hydride (see Sections 9.7.5 and 9.7.6) (Charvillat *et al.*, 1975, 1976; Gibson and Haire, 1987; Zhu and Jiao, 1994).

9.7 CLASSES OF COMPOUNDS

9.7.1 General

Because curium is available in macro quantities, a number of Cm compounds have been synthesized and structurally characterized. Table 9.3 lists crystallographic data for Cm metal, alloys, and compounds.

The most important chemical characteristic that distinguishes curium from the lighter actinides is the great stability of the 3+ state with respect to oxidation or reduction. The stability of Cm(III) has been attributed to the relative stability of a half-filled ($5f^7$) configuration, and causes a chemical resemblance to lanthanides. All known Cm(IV) compounds are either fluorides or oxides.

In contrast to americium, the oxidation of Cm(III) to Cm(IV) is achieved only with the strongest oxidizing agents, and only two reports claim evidence for an oxidation state greater than IV (Peretrukhin *et al.*, 1978; Fargeas *et al.*, 1986). Transient divalent and tetravalent states have been observed in aqueous perchlorate media using pulse radiolysis techniques (Sullivan *et al.*, 1976). Attempts have been made to induce Cm(III)–Cm(IV) oxidation chemically (using ozone (Pages and Demichelis, 1966) and perxenate (Holcomb, 1967)) or electrochemically (Myasoedov *et al.*, 1973). These attempts have failed, an effect clearly not attributable solely to radiolytic reduction.

However, formation of a red Cm(IV) complex in phosphotungstate solution was achieved by the use of peroxydisulfate as the oxidant (Saprykin *et al.*, 1976). Kosyakov *et al.* (1977) demonstrated that, in such solutions, the Cm(IV) is reduced much more rapidly than can be accounted for by radiolytic effects, while Am(IV) in such solutions is much more stable, being reduced at a rate attributable to radiolytic effects alone. This behavior stands in contrast to the reduction of Cm(IV) in 15 M CsF, which does proceed at the slower radiolytic rate (Keenan, 1961). No value for the $E°$(Cm(IV)/Cm(III)) is known, but, from existing data, it is substantially more positive than $E°(Am^{4+}/Am^{3+})$ and probably about as positive as $E°(Pr^{4+}/Pr^{3+})$.

With the more common isotopes ^{242}Cm and ^{244}Cm, intense alpha self-irradiation and heating effects cause aqueous-solution instability (peroxide is always present) and solid-state instability (lattice changes and compound alteration). In some cases, these effects are sufficiently large that certain compounds may be identified in bulk only with the more stable isotopes, e.g. $^{244}CmF_4$ and $^{248}Cm(n\text{-}C_5H_5)_3$ (Asprey and Keenan, 1958; Laubereau and Burns, 1970b).

9.7.2 Hydrides

The hydrides of Cm are relatively little explored. The first Cm hydride was prepared by Bansal and Damien (1970) by reacting ^{244}Cm metal with hydrogen at 200–250°C. Based on its X-ray diffraction pattern, this hydride was characterized as the face-centered cubic (fcc) CmH_{2+x}, by analogy to NpH_{2+x}, PuH_{2+x}, and AmH_{2+x}. The existence of the dihydride was confirmed by Gibson and Haire (1985), who prepared the dihydride from ^{248}Cm metal. In the latter work, the hexagonal $CmH_{3-\delta}$ was also prepared. The trihydride was characterized from its x-ray diffraction pattern by analogy to those of known lanthanide and actinide trihydrides.

The dissociation enthalpy for CmH_2 has been reported to be 187 ± 14 kJ mol^{-1}, consistent with the trend in stability of the actinide dihydrides becoming more like that of the lanthanide dihydrides with increasing atomic number (Gibson and Haire, 1990). The order of stability of f-element dihydrides can be summarized as follows:

$$\text{Ln(most stable)} > \text{Cm} > \text{Am} > \text{Pu}$$

9.7.3 Halides

The halides represent by far the most extensively characterized class of curium compounds (see Table 9.3). The complete CmX_3 series (X = F, Cl, Br, I), as well as CmF_4 and several complex Cm(IV) fluorides, have been prepared and studied. Several reviews deal specifically with actinide halides; for further information (especially for cross-comparisons of Cm with other actinide halides) the reader is referred to these articles (Katz and Sheft, 1960; Bagnall, 1967; Brown, 1968; Penneman *et al.*, 1973).

Curium trifluoride is a white, sparingly soluble (~10 mg L^{-1}) compound (Cunningham, 1966) with the LaF_3 structure, which precipitates when fluoride ion is added to weakly acidic Cm(III) solutions, or HF to $Cm(OH)_3$. The anhydrous trifluoride is obtained by desiccation over P_2O_5 or by treatment with hot HF(g). The trifluoride melts at 1406 ± 20°C; its standard enthalpy and entropy of formation have been estimated to be 1660 kJ mol^{-1} (Ionova *et al.*, 1997) and 121 J K^{-1} mol^{-1} (Burnett, 1966; Cunningham, 1966) at 298 K, respectively. Curium has an irregular tricapped trigonal prismatic coordination in CmF_3 (Penneman *et al.*, 1973).

Curium trichloride is a white compound that can be obtained by treating curium oxides or CmOCl with anhydrous hydrogen chloride at 400–600°C (Wallmann *et al.*, 1967). The hydrate has been reported to be light green. A single-crystal study showed that $CmCl_3$ has the hexagonal UCl_3-type structure common among the actinide trichlorides. Based on the lattice constants for $CmCl_3$ (Table 9.3), a radius of 0.971 Å has been calculated for Cm(III) (Peterson and Burns, 1973). Curium has nine chloride neighbors in the form of a tricapped trigonal prism, with Cm–Cl lengths of 2.859 and 2.914 Å. A melting point of 695°C (Peterson and Burns, 1973) and an enthalpy of formation (298 K) of −974 ± 4 kJ mol^{-1} (Fuger *et al.*, 1975; Oetting *et al.*, 1976) have been reported. The entropy of formation of $CmCl_3$ at 298 K has been estimated to be 163 ± 6 J K^{-1} mol^{-1} (Konings, 2001a).

Curium tribromide has been prepared by heating the trichloride with NH_4Br at 400–450°C in a hydrogen atmosphere (Asprey *et al.*, 1965) and also by hydrogen bromide treatment of the calcined oxide at 600°C (Burns *et al.*, 1975). The compound melts at 625°C and has the $PuBr_3$ (orthorhombic) structure (Burns *et al.*, 1975). The metal ion is surrounded by eight bromide ions, two at 2.865 Å, four at 2.983 Å, and two at 3.137 Å. An analogous procedure ($CmCl_3+NH_4I$) has been used to prepare CmI_3, a colorless material having the BiI_3 structure (Asprey *et al.*, 1965). Preparation from elemental curium and iodine has also been reported (Seaborg *et al.*, 1949). The standard enthalpies of formation of $CmBr_3$ and CmI_3 are estimated to be 794 and 564kJ mol^{-1}, respectively, at 298 K (Ionova *et al.*, 1997).

The halides of tetravalent curium include the simple fluoride CmF_4 (Keenan and Asprey, 1969; Asprey and Haire, 1973; Haug and Baybarz, 1975), and a series of complex fluorides of the type $M_7Cm_6F_{31}$ (Keenan, 1966b, 1967a), M_2CmF_6 (Keenan, 1967b), and $MCmF_5$ (Keenan, 1966a), where M is an alkali metal. As with terbium, the only reported method for preparing the tetrafluoride is by fluorine oxidation of the trifluoride. CmF_4 is a brownish-tan solid with a monoclinic ZrF_4-type structure, in which curium has an antiprismatic eight coordination (Asprey and Haire, 1973; Penneman *et al.*, 1973; Haug and Baybarz, 1975). Magnetic susceptibility measurements suggest a fluoride-deficient structure, CmF_{4-x} (Haire *et al.*, 1982; Nave *et al.*, 1983).

Evidence for the existence of CmF_6 and $CmOF_3$ (as well as $NpOF_3$, NpF_7, PuO_3F, AmF_5, AmF_6, and EsF_4) has been reported using thermochromatographic techniques (Fargeas *et al.*, 1986). These fluorides were claimed to form in low yield when a deposit of Cm (chemical form not reported) on Ni metal was treated with a mixture of BF_3 and F_2 at 800°C. However, there has been no independent confirmation of these species.

A prominent series of isostructural complex actinide(IV) fluorides, $M_7An_6F_{31}$, with the $Na_7Zr_6F_{31}$ structure have been prepared (Keenan, 1966b, 1967a). With curium, the Na and K salts are known. The compounds were prepared by direct fluorination of evaporated salt mixtures of MX and CmX_3 at about 300°C. This 7:6 type of compound predominates with the larger alkali cations. The basic coordination polyhedron is a square antiprism (Penneman *et al.*, 1973). In tetragonal $LiCmF_5$, the curium coordination is tricapped trigonal prismatic (Penneman *et al.*, 1973). The compound Rb_2CmF_6 is orthorhombic with the Rb_2UF_6 structure, which consists of chains of fluoride dodecahedra (Penneman *et al.*, 1973). The oxychloride CmOCl has been synthesized by treatment of $CmCl_3$ (or Cm_2O_3) at 500–600°C, with the vapor in equilibrium with a 10 M HCl solution (Peterson, 1972):

$$CmCl_3 + H_2O \leftrightarrow CmOCl + 2HCl$$

From the equilibrium and known heats of formation, ΔH°_{f298} for CmOCl was calculated (Weigel *et al.*, 1977, Table 17.4). Marei and Cunningham (1972) found that the magnetic susceptibility of CmOCl follows the Curie–Weiss law over the temperature range 77–298 K, with $\mu_{eff} \sim 7.58\ \mu_B$ and a Curie temperature of approximately 22 K. The structure of CmOCl is of the PbClF-type (hexagonal), with each metal surrounded by four oxides and five chlorides (Peterson, 1972).

9.7.4 Oxides

Konings (2001a,b) has recently reviewed the thermochemical and thermophysical properties of Cm oxides. Crystallographic data for the various oxides are compiled in Table 9.3.

The white to faint tan sesquioxide Cm_2O_3 (m.p. 2270 ± 25°C) (Konings, 2001b) was prepared by thermal decomposition of $^{244}CmO_2$ at 600°C and 10^{-4} torr pressure (Asprey *et al.*, 1955). This material has the Mn_2O_3-type cubic-C lattice, which gradually changes at room temperature to a hexagonal A-form because of self-irradiation effects (Wallmann, 1964; Noé *et al.*, 1970). Haug (1967) prepared monoclinic B-type Cm_2O_3 by reduction of $^{244}CmO_2$ with hydrogen. This study showed that the cubic form described by Asprey *et al.* (1955) predominates at reaction temperatures below 800°C, changing to the monoclinic B-form at higher temperatures (Haug, 1967). These three crystal modifications correspond to the three types observed for lanthanide sesquioxides. Structural data, enthalpy of formation, and magnetic susceptibility were obtained by Morss *et al.* (1983) with B-form $^{248}Cm_2O_3$. The enthalpy of formation at 25°C has been estimated as –1684 ± 14 kJ mol^{-1} for the monoclinic Cm_2O_3 (Konings, 2001b), with the corresponding entropy of formation estimated to be 167 ± 5 J K^{-1} mol^{-1} (Konings, 2001a).

Preparation of the black curium dioxide by ignition in air was first claimed by Asprey *et al.* (1955). The product had a cubic (fcc) structure. The compound is also formed by thermal decomposition of ^{244}Cm(III)-loaded resin (Hale and Mosley, 1973) and by heating $^{244}Cm_2O_3$ to 650°C in 1 atm of oxygen, followed by cooling in oxygen (Noé and Fuger, 1971; Peterson and Fuger, 1971). Others have shown that the dioxide is the stable oxide form in an oxygen atmosphere at temperatures below 400°C (Chikalla and Eyring, 1969). At temperatures between 380 and 420°C, CmO_2 is reduced to $CmO_{1.95}$; above 430°C, rapid decomposition occurs via various intermediate oxides to Cm_2O_3 (Mosley, 1972). The enthalpy of formation at 25°C has been estimated as −912 ± 7 kJ mol^{-1} for CmO_2 (Konings, 2001b).

Curium oxalate, $Cm_2(C_2O_4)_3$, is routinely used for calcination to CmO_2. For example, oxalate precipitation has been used to process kilograms of ^{244}Cm, with subsequent metathesis with 0.5 M hydroxide to $Cm(OH)_3$ (Scherer and Fochler, 1968; Bibler, 1972).

Morss *et al.* (1989) reported a neutron diffraction and magnetic susceptibility study of CmO_2 prepared by calcination of Cm(III) oxalate at 775°C in flowing O_2, followed by annealing for 4 days at 350°C in flowing O_2. Based on the lattice parameter (a_0 = 5.359 ± 0.002 Å), the stoichiometry of this material was reported to be $CmO_{1.99 \pm 0.01}$, indicating that the material essentially contained only Cm(IV). Nevertheless, the effective paramagnetic moment was found to be $(3.36 \pm 0.06)\mu_B$, a value which had previously been attributed to the presence of Cm(III). Based on these data, it has been suggested that the electronic ground states in actinide dioxides may need to be reexamined.

The curium–oxygen phase diagram studies show a great similarity to analogous Pu, Pr, and Tb systems, and indicate the possible existence of two additional Cm_2O_3 phases which have not yet been isolated (Eyring, 1967; Stevenson and Peterson, 1975). Two intermediate oxides, $CmO_{1.72}$ and $CmO_{1.82}$, and two other non-stoichiometric phases close to the composition of CmO_2 and $CmO_{1.5}$, have also been detected (Chikalla and Eyring, 1969). A cubic (fcc) phase, CmO, was reported in an early preparation of the metal (Cunningham and Wallmann, 1964).

The ternary oxides $BaCmO_3$ (Fuger *et al.*, 1993) and Cm_2CuO_4 (Soderholm *et al.*, 1999) have recently been reported. The latter is of interest by its analogy to M_2CuO_4 (M= La, Pr–Eu), which are parent compounds for high-temperature superconductors. When doped with Th^{4+}, the M_2CuO_4 (M = Pr–Eu) materials become superconducting, with T_c of ~32 K. Although Cm_2CuO_4 is isostructural with the M_2CuO_4 (M = Pr–Gd) series, its Th-doped analog is not superconducting. This effect may be due to its high magnetic ordering temperature relative to other M_2CuO_4.

Hale and Mosley (1973) have reported the preparation of curium oxysulfate, $^{244}Cm_2O_2SO_4$, by heating Cm(III)-loaded resin (sulfonate form) in a stream of oxygen at 900°C. The thermogravimetric analysis indicated that heating to 1175°C under otherwise similar conditions yielded Cm_2O_3, which on cooling formed CmO_2. Haire and Fahey (1977) have prepared $Cm_2O_2SO_4$ by calcination of the hydrated sulfate in air at about 750°C. The brown $Cm_2O_2SO_4$ has a body-centered orthorhombic structure, similar to $Nd_2O_2SO_4$ and $Cf_2O_2SO_4$. The computed Cm(III) radius in $Cm_2O_2SO_4$, 0.980 Å, agrees with the value of 0.979 Å derived from Cm_2O_3. The oxysulfide Cm_2O_2S is formed when the sulfate is heated to about 800°C in H_2/Ar (Haire and Fahey, 1977). Cell constants for Cm_2O_2Sb and Cm_2O_2Bi have been reported (Charvillat and Zachariasen, 1977).

9.7.5 Chalcogenides

Damien *et al.* (1975) prepared $^{244}CmS_2$ and $^{244}CmSe_2$ by slow reaction of excess sulfur or selenium vapor with curium hydride in vacuum. The resulting solids gave powder patterns indicating the tetragonal Fe_2As-type cell (isostructural with AmS_2 and $AmSe_2$) with lattice parameters (Table 9.3) showing the materials to be non-stoichiometric.

The sesquisulfide Cm_2S_3 forms a defect body-centered cubic (bcc) phase of the Th_3P_4-type (Damien *et al.*, 1975). The sesquiselenide was obtained by thermal dissociation of $CmSe_2$ at 620°C, again yielding a Th_3P_4-type phase (Damien *et al.*, 1975). Unlike gadolinium or plutonium, no other sesquiselenide forms were observed, even after thermal treatment at various temperatures.

The monochalcogenides were prepared by heating stoichiometric mixtures of chalcogen and curium metal at 700–750°C for 15 h, followed by heating at 1250–1500°C under high vacuum (Damien *et al.*, 1979a). The monochalcogenides have fcc structures. In these preparations, accessory phases, possibly γ-Cm_2S_3, Cm_2O_2S, γ-Cm_2Se_3, and Cm_2O_2Te, were detected.

The oxysulfide Cm_2O_2S was prepared by partial oxidation of CmS_2 at 700°C (Damien *et al.*, 1975; Haire and Fahey, 1977). This compound has a hexagonal structure and is isostructural with the Np, Pu, and Cf analogs (Haire and Fahey, 1977).

Damien *et al.* (1976) have reported the preparation of $CmTe_3$ by the reaction of the hydride with tellurium at 400°C. At temperatures above 400°C, the tritelluride decomposes to form the successive lower tellurides $CmTe_2$ and Cm_2Te_3. At 1100°C in a quartz tube, the oxytelluride Cm_2O_2Te is formed.

9.7.6 Pnictides

The syntheses of the pnictide compounds CmX, where X = N, P, As, and Sb, have been reported (Charvillat *et al.*, 1975, 1976; Kanellakopulos *et al.*, 1976; Damien *et al.*, 1979a,b; Stevenson and Peterson, 1979; Nave *et al.*, 1981). The compounds were obtained by heating curium hydride or metal with the respective pnictide element in a sealed tube to temperatures of 350–950°C. The N, P, As, and Sb compounds all have the NaCl structure (Charvillat *et al.*, 1975, 1976; Kanellakopulos *et al.*, 1976; Damien *et al.*, 1979a,b; Nave *et al.*, 1981). Damien *et al.* (1979a,b) prepared the monopnictides (N, P, As, Sb) by directly heating stoichiometric mixtures of the elements. CmN and CmAs are ferromagnetic, with T_c of 109 and 88 K, respectively (Kanellakopulos *et al.*, 1976; Nave *et al.*, 1981). The calculated effective magnetic moments are 7.02 and 6.58 μ_B, lower than expected for a pure $5f^7$ configuration, probably because of strong spin–orbit coupling and crystal field effects (Kanellakopulos *et al.*, 1976; Nave *et al.*, 1981).

The possibility of using mixed nitride fuels for transmutation of minor actinides has gained recent attention because it is anticipated that the actinide nitrides are mutually miscible. The miscibility of CmN and PuN has been confirmed by the carbothermic synthesis of (Cm,Pu)N (Takano *et al.*, 2001). This was achieved by heating graphite and $(Cm_{0.4}Pu_{0.6})O_{2-x}$ at 1773 K in N_2. The lattice parameter of the resulting mixed nitride was close to that expected from the known lattice parameters for CmN and PuN.

9.7.7 Miscellaneous compounds

The trihydroxide, $Cm(OH)_3$, has been prepared from aqueous solution and crystallized by aging in water (Haire *et al.*, 1977). The compound has the lanthanide trihydroxide (hexagonal) structure. Although there have been no reports of Cm carbide, the silicides CmSi, $CmSi_2$, Cm_2Si_3, and Cm_5Si_3 have been reported (Weigel and Marquardt, 1983; Radchenko *et al.*, 2000).

The oxalate $Cm_2(C_2O_4)_3 \cdot 10H_2O$ forms when aqueous Cm(III) and oxalic acid are mixed. The compound dehydrates in a stepwise fashion when heated *in vacuo*, yielding the anhydrous oxalate at 280°C, which then converts to a carbonate above 360°C (Scherer and Fochler, 1968). A differential thermal analysis (DTA) investigation of the hydrated Cm oxalate under helium revealed endothermic events centered at 145 and 400°C, corresponding to the release of water and the formation of $Cm_2O_2CO_3$, respectively. Above 500°C, the $Cm_2O_2CO_3$ converts to Cm_2O_3 (Vasil'ev *et al.*, 1989). The hydrated oxalate dissolves readily in aqueous alkali-metal carbonate solutions (Bibler, 1972; Burney and Porter, 1967). The compound has a solubility (~0.8 mg Cm per liter at 23°C) lower than that of the americium analog in 0.1 M $H_2C_2O_4$/0.2 M HNO_3. The solubility increases rapidly with temperature.

Curium nitrate can be isolated by evaporation of solutions formed by dissolving curium oxide in nitric acid. DTA analysis of the freshly prepared $^{244}Cm(NO_3)_3$ indicated the decomposition pathway is the same under an oxygen atmosphere as it is under helium (Vasil'ev *et al.*, 1990). The thermal decomposition is characterized by endothermic events centered at 90, 180, 400, and 450°C. By analogy to the thermal decomposition of lanthanide nitrates, the first two endotherms have been assigned to melting of the crystalline hydrated nitrate and its dehydration, respectively. The last two endotherms (which overlap) are associated with the decomposition of the anhydrous Cm nitrate. The final product of the thermal decomposition is CmO_2, indicating the Cm is oxidized to Cm(IV) during the decomposition process. The enthalpy of formation of the anhydrous crystalline $Cm(NO_3)_3$ was estimated to be -700 kJ mol^{-1} from the DTA data.

Complex sulfates of the type $MAn(SO_4)_2 \cdot xH_2O$, where M = alkali metal, have been precipitated from solutions of M_2SO_4 and the appropriate trivalent actinide ion in dilute HCl or H_2SO_4 (Dedov *et al.*, 1965). Structural characterization is lacking for these compounds.

A series of actinide phosphates having the formulation $AnPO_4 \cdot 0.5H_2O$ has been prepared (An = Pu, Am, Cm) (Weigel and Haug, 1965; Kazantsev *et al.*, 1982). These compounds form when aqueous Cm(III) solutions are mixed with Na_2HPO_4 or $(NH_4)_2HPO_4$. The structures of the $AnPO_4 \cdot 0.5H_2O$ compound are unknown. The hydrated phosphate of Cm(III) dehydrates at 300°C to $CmPO_4$, which has the monazite structure (Weigel and Haug, 1965; Kazantsev *et al.*, 1982).

The compound $Cm[Fe(CN)_6]$ forms as a dark red precipitate when $K_3[Fe(CN)_6]$ is added to a solution of Cm nitrate in 0.2 M HNO_3 (Kulyako *et al.*, 1993). This contrasts to the lanthanides (Eu, Ce, Pr) that do not form precipitates under identical conditions, but is similar to the behavior of Am.

The compounds $CmNbO_4$ and $CmTaO_4$ are isotypic with the corresponding lanthanide compounds and are obtained by heating the precipitated, mixed hydroxide/hydrous oxides at 1200°C (Keller and Walter, 1965).

Heating mixtures of curium oxide and alumina affords $CmAlO_3$, which gives either a rhombohedral or a cubic product depending upon the quenching conditions (Mosley, 1971). The rhombohedral phase transforms to the cubic phase at room temperature. $BaCmO_3$ has also been reported (Haire, 1980; Nave *et al.*, 1983). The addition of K_2CO_3 to Cm(III) solution precipitates $Cm_2(CO_3)_3$ (Dedov *et al.*, 1965). The compound is soluble in 40% K_2CO_3.

The salt $CsCm(HFAA)_4 \cdot H_2O$, where HFAA = hexafluoroacetylacetone, has been studied in detail (Nugent *et al.*, 1969). This compound, as well as the Eu, Gd, Tb, Nd, Am, Bk, Cf, and Es analogs, forms readily when HFAA is added to ethanol solutions of Cm(III) in the presence of cesium ion. Of the actinides studied for possible laser properties, only Cm displayed UV-excited, sharp-line sensitized luminescence (Nugent *et al.*, 1969). Cm(III) was found to be a highly efficient emitter (resembling Eu(III)) in the crystalline state, in ethanol solution, and doped into a $CsGd(HFAA)_4$ crystal matrix; hence laser emission should be demonstrable. Strong luminescence has been observed from ^{244}Cm (III) on an anion-exchange resin and in solution (Gutmacher *et al.*, 1964; Beitz and Hessler, 1980).

A number of adducts of the type $CmL_3 \cdot n$Q have been prepared, where L is a fluorinated β-diketonate and Q is TBP or trioctylphosphine oxide (Davydov, 1978). The volatility, thermal, and radiation stabilities were studied with consideration of such compounds for gas chromatographic separation of Am and Cm.

9.7.8 Organometallics

Despite substantial recent advances in the organometallic chemistry of other actinide elements, progress with curium has been slow. This lack of progress apparently results from the radiolytic properties of the element rather than an inherent chemical instability of the organometallic compounds. For more detailed discussion of actinide organometallic compounds, the reader is directed to Chapters 25 and 26.

The synthesis and spectroscopic characterization of milligram quantities of white, crystalline tris(η^5-cyclopentadienyl)curium, $Cm(C_5H_5)_3$, has been reported from the reaction of $^{248}CmCl_3$ with $Be(C_5H_5)_2$ (Baumgärtner *et al.*, 1970; Laubereau and Burns, 1970b). The compound can be sublimed in vacuum at 180°C and is isostructural with the Pr, Pm, Sm, Gd, Tb, Bk, and Cf analogs (Laubereau and Burns, 1970a,b). Mass spectrometric evidence for volatile $Cm(C_5H_5)_3$ using microgram amounts of ^{244}Cm was obtained (Baumgärtner *et al.*, 1970).

In terms of structural properties, volatility, thermal stability, and solubility, $Cm(C_5H_5)_3$ closely resembles other actinide and lanthanide tris(cyclopentadienide) compounds and hence the bonding must be similar. Nugent *et al.* (1971) studied the optical spectrum of $^{248}Cm(C_5H_5)_3$ and found weak bands, typical for Cm(III). These workers derived a value for the nephelauxetic parameter $d\beta$ of 0.050 ± 0.004, corresponding to very weak covalency in the organometallic bond. Thus, like the lanthanide analogs, the bonding in $Cm(C_5H_5)_3$ appears to have rather little covalent character. The ^{248}Cm compound fluoresces bright red under 360 nm irradiation (Nugent *et al.*, 1971).

Gas-phase reactions of Cm^+ and CmO^+ ions with small organic compounds have been investigated (Gibson and Haire, 1998, 1999). The gas-phase Cm ions used in these studies were generated by laser ablation of Cm_7O_{12} and the reaction products were characterized by mass spectroscopy. Using this methodology, a number of Cm organometallic fragments have been identified, including Cm_2^+, CmC_2H^+, $CmCN^+$, and a series of $CmC_xH_y^+$ species. The relative ability of Cm^+ to activate C–H bonds is less than that for U^+ or Tb^+ ions.

9.8 AQUEOUS CHEMISTRY

9.8.1 Inorganic

The aqueous solution chemistry of curium is almost exclusively that of Cm(III). Relatively little non-aqueous solution chemistry has been reported with curium other than that related to separations and environmental applications. Dilute Cm(III) solutions are normally colorless, but Cm(III) in concentrated HCl appears greenish. Curium-242 solutions with concentrations of about 1 g l^{-1} will boil unless cooled. The hydration number for the Cm(III) ion is estimated to be 9, based on fluorescence lifetimes (Kimura and Choppin, 1994; Kimura *et al.*, 1996). In HCl solution, the hydration number for the Cm(III) ion remains 9 up until 5 M HCl, then decreases with increasing HCl concentration (Kimura *et al.*, 1998). At 11 M HCl, the hydration number is 7. In contrast, the hydration number for Cm(III) drops steadily with increasing HNO_3 concentration from 0 to 13 M, with the hydration number being 5 at 13 M HNO_3. The differences between the HCl and HNO_3 systems are presumably simply due to the stronger binding affinity of the nitrate ion compared to chloride.

For dissolution of dhcp Cm metal in 1 M HCl, the value of ΔH is -615 ± 4 kJ mol^{-1} at 298.2 K, which, with an estimated $S° = -194$ J mol^{-1} h^{-1} for the Cm^{3+} (aquo) ion, yields an estimated -2.06 ± 0.03 V for the Cm(III)/Cm(0) couple (Fuger *et al.*, 1975) (see Chapter 17). Raschella *et al.* (1981) found $\Delta H = -606.5 \pm 11.7$ kJ mol^{-1} for dissolution using ^{248}Cm metal. From electron-transfer spectra, the Cm(III)/Cm(II) couple was estimated at -4.4 V (Nugent *et al.*, 1973), but the results of the pulse radiolysis study and the potential of the hydrated electron place a lower value on this couple (Sullivan *et al.*, 1976). From studies in a melt, Mikheev (1983) obtained –2.8 V for $E°$(Cm(III)/Cm(II)). Fuger and Martinot (1985) report $E°$(Cm(III)/Cm(IV)) to be -3.1 V.

Solution reactions of Cm(III) resemble those of the trivalent lanthanides and other trivalent actinides. The fluoride, oxalate, phosphate, iodate, and hydroxide are essentially water-insoluble, and the chloride, iodide, perchlorate, nitrate, and sulfate are water-soluble. The first hydrolysis constant for Cm(III), i.e. for the reaction

$$\mathrm{Cm(III)} + H_2O \rightarrow CmOH^{2+} + H^+$$

is 1.2×10^{-6} ($\mu = 0.1$; 23°C), which is within experimental error of the value for Am^{3+} but ten times greater than that for Pu^{3+} (Désiré *et al.*, 1969; Korotkin, 1974). The formation constants for $[Cm(OH)]^{2+}$ and $[Cm(OH)_2]^+$ have been determined by time-resolved laser-induced fluorescence spectroscopy (Fanghänel *et al.*, 1994). The measurements were made under high ionic strength (up to 6 M NaCl). Extrapolation to zero ionic strength yielded values of $\log \beta_{11} = 6.44$ and $\log \beta_{12} = 12.3$. Ionic strength significantly affects the distribution of hydrolyzed species with the Cm(III) ion becoming more easily hydrolyzed as the ionic strength increases (Fig. 9.4).

Stability constants for Cm(III) complexes have been determined for a number of inorganic and organic liquids in aqueous solution (Table 9.4). Most recent stability constant measurements for Cm(III) have been performed using time-resolved laser-induced fluorescence spectroscopy; these studies provide the most self-consistent set of stability constant data for Cm(III). Cm(III) is a 'class A' or 'hard' metal ion, and thus complexes far more strongly to oxygen and fluoride donors than to more polarizable donors such as chloride or sulfur. This is reflected in the fact that β_1 for F^- is three orders-of-magnitude greater than that for Cl^-. The stability constants for oxygen donors (e.g. OH^- and CO_3^{2-}) are even higher than that for F^-.

Cm(III) forms complexes with a number of polytungstate and heteropolytungstate anions and the luminescence properties of these complexes have been extensively studied. Included in this class of compounds are $CmW_{10}O_{36}^{9-}$, $Cm(SiW_{11}O_{39})_2^{13-}$, $CmSiW_{11}O_{39}^{5-}$, $Cm(PW_{11}O_{39})_2^{11-}$, $CmPW_{11}O_{39}^{4-}$, $Cm(P_2W_{17}O_{61})_2^{17-}$, and $CmP_2W_{17}O_{61}^{7-}$ (Yusov and Fedoseev, 1989b, 1990). The polytungstate ligands quench the luminescence of Cm(III), evidently due to charge transfer between the excited Cm*(III) and W(VI). This effect is magnified when the solutions of these complexes are frozen, resulting in a sharp decrease in

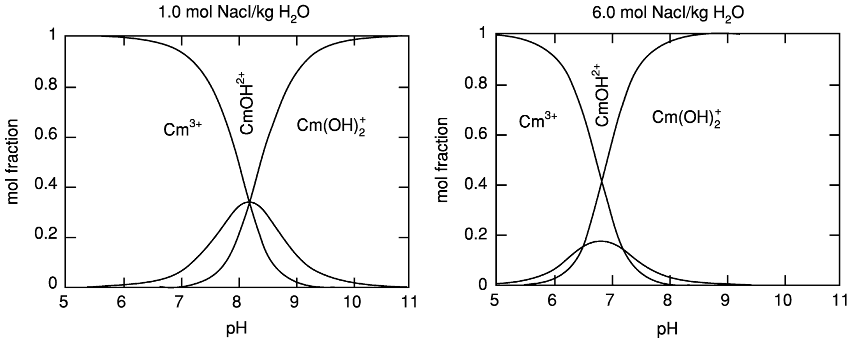

Fig. 9.4 *Comparison of Cm*(III) *species distribution as function of pH at two NaCl molalities. The speciation determination is based on Cm*(III) *fluorescence spectra. Used with permission from Fanghänel* et al. (1994).

the luminescence lifetimes. However, upon further cooling, the luminescence quenching decreases and sharp luminescence bands are observed for these complexes at 77 K. The luminescence quenching is severe in Cm(III) complexes with $P_2W_{17}O_{61}^{10-}$ as these complexes do not luminesce in solution at 293 K. In contrast, $CmW_{10}O_{36}^{9-}$, $CmPW_{11}O_{39}^{4-}$, $CmSiW_{11}O_{39}^{5-}$, $Cm(SiW_{11}O_{39})_2^{13-}$, and $Cm(PW_{11}O_{39})_2^{11-}$ all display luminescence in D_2O at 293 K. At 77 K, the luminescence spectra of the $P_2W_{17}O_{61}^{10-}$ complexes are very similar to the other Cm(III) polytungstate complexes. Addition of molybdate to solutions of the Cm(III) polytungstate or heteropolytungstate complexes results in rapid quenching of the Cm(III) luminescence (Yusov and Fedoseev, 1992a,b). This behavior is the opposite of what is observed for the analogous Eu, Nd, and Yb systems.

The trends for the complexation of carboxylate ligands to Cm(III) are somewhat difficult to interpret. The β_1 values at $\mu = 0.5$ can be compared for acetate, glycolate, lactate, and 2-hydroxyisobutyrate (Table 9.4). The β_1 value increases from 114 to 700 in going from acetate to glycolate, which could be due to interaction of the hydroxyl group in glycolate with the Cm(III) center. One would expect that the inductive effect of an added methyl group would lead to a further increase in β_1 for complexation of lactate ion, but the β_1 value drops to 550 for lactate. On the other hand, addition of yet another methyl group does result in a significant increase in β_1 for 2-hydroxyisobutyrate ($\beta_1 = 2700$). The anomaly for lactate may simply reflect the differing experimental conditions under which the measurements were made. As would be expected, the chelating carboxylate ligands display substantially stronger binding to Cm(III) than the monocarboxylate ligands.

There are a limited number of reports concerning Cm(IV) in aqueous media. A fluoride complex of Cm(IV) was obtained when CmF_4 was dissolved in concentrated (15 M) MF solution (M = alkali–metal ion) (Asprey and Keenan, 1958; Keenan, 1961) (see Fig. 9.2). Even under these conditions, and using ^{244}Cm, the self-reduction rate because of alpha decay is about 1% per minute. When CmF_4 is added to aqueous NH_4F, an immediate oxidation–reduction reaction occurs, with deposition of CmF_3. This is in sharp contrast to the stability of Am(IV) in NH_4F solution (Asprey and Penneman, 1962).

Other than the CmF_4/MF system, the only claims for chemically generated Cm(IV) in solution are the reports that red solutions result when aqueous Cm(III) solutions are mixed with potassium peroxydisulfate and heteropolyanions such as $[P_2W_{17}O_{61}]^{10-}$ (Saprykin *et al.*, 1976; Kosyakov *et al.*, 1977). Cm(IV), produced by persulfate oxidation of Cm(III) in phosphotungstate solution, converts back to Cm(III) at a rate that suggests that the reduction involves both radiolytic mechanisms and direct reduction by water (Kosyakov *et al.*, 1977). In contrast, reduction of Am(IV) to Am(III) under similar conditions is dominated by radiolytic processes. Electrochemical generation of Cm(IV) in phosphate solutions was unsuccessful, owing to the large Cm(IV)/Cm(III) potential, estimated to be greater than 2 V in these systems (Myasoedov *et al.*, 1973, 1974). Other attempts to prepare Cm(IV) by oxidation of Cm(III) in solution have failed. These attempts include electrochemical methods (Myasoedov *et al.*, 1973, 1974; Ionova and Spitsyn, 1978) and the use of sodium perxenate (Holcomb, 1967) and ozone (Pages and Demichelis, 1966), agents which readily oxidize Am(III) to Am(V) or Am(VI). $Cm(OH)_3$ in $NaHCO_3$ is not oxidized by ozone or $Na_2S_2O_8$, conditions which produce Am(VI) as a carbonate complex (Coleman *et al.*, 1963).

The polytungstate Cm(IV) complexes – $CmW_{10}O_{36}^{8-}$, $Cm(SiW_{11}O_{39})^{12-}$, and $Cm(PW_{11}O_{39})_2^{10-}$ – display chemiluminescence upon reduction to Cm(III) (Yusov *et al.*, 1986a,b). The brightest chemiluminescence was observed when the initial complexes were treated with 1–3 M alkali, in which case water in the system most probably served as reductant. Chemiluminescence has also been observed during dissolution of the Cm(IV) double oxide Li_xCmO_y in mineral acids (Yusov and Fedoseev, 1989a, 1991).

Despite the numerous unsuccessful attempts to oxidize Cm(III) and Cm(IV) compounds to higher oxidation states, some theoretical work suggests the possibility that Cm(VI) may be even more stable than Am(VI), and the lack of success in preparing Cm(VI) may result from the low stability of Cm(V) and the high Cm(IV)/Cm(III) potential (Ionova and Spitsyn, 1978; Spitsyn and Ionova, 1978). One report claims the synthesis of Cm(VI) by beta decay of $^{242}AmO_2^+$ (Peretrukhin *et al.*, 1978).

$$^{242}AmO_2^+ \xrightarrow[16h]{\beta^-} CmO_2^{2+}$$

The $K_3AmO_2(CO_3)_2$ starting material was aged 18–40 h and then dissolved in 0.1 M $NaHCO_3$ in the presence of ozone, followed by addition of $Na_4UO_2(CO_3)_3/K_2CO_3$ solution to precipitate MO_2^{2+} species as $K_4MO_2(CO_3)_3$. From the enhancement of Cm in the precipitate over that expected for Cm(III), it was concluded that a 30–60% conversion to Cm(VI) had occurred.

Cm(II) is unknown other than as a transient aqueous species and a species coprecipitated from melts, and possibly in CmO. Pulse radiolysis, producing OH radicals as oxidant and the aquo electron as reductant, produced changes in aqueous americium and curium perchlorate solutions. The new absorbances were attributed to transient formation of Cm(II), A_{max} 240 nm, and Cm(IV), A_{max} 260 nm (Sullivan *et al.*, 1976).

9.8.2 Organic

Studies of Cm chemistry in pure organic solvents are rare. The solvation of Cm(III) in non-aqueous and binary mixed solvents has been investigated by luminescence spectroscopy (Kimura *et al.*, 2001). This study revealed that the relative preference for solvation of Cm(III) ion is dimethylsulfoxide > dimethylformamide > H_2O > methanol.

Very few curium compounds containing organic ligands have actually been isolated (see Section 9.7.8), although it seems likely that efforts to isolate such compounds would prove fruitful. Because of the interest in extraction schemes for treating radioactive wastes, a substantial number of studies have determined stability constants and distribution coefficients for solutions containing curium and various organic ligating agents. However, these experiments have often involved tracer amounts of curium and have employed a variety of experimental conditions (ionic strength, temperature, concentrations, etc.); therefore, quantitative comparisons of the determined values are difficult. As with the inorganic anions, values, and in some cases even trends, can vary markedly under seemingly similar conditions. Most studies do not involve isolation or definitive formulation of the actual species in solution, and it is possible that complicated structures occur, e.g. $CmF_3 \cdot (HDEHP)_x$ (Aziz and Lyle, 1969).

Furthermore, crystal structure determinations for a number of pertinent lanthanide and actinide extractant complexes illustrate that surprises may be expected when more definitive structural information becomes available (Burns, 1982; Bowen *et al.*, 1984). Because of these complications, we have not tried to analyze the voluminous Cm extraction data that are available, but included in Table 9.4 the data for only a few of the more important extractants. The reader is referred to a more extensive compilation for additional data of this type (Jones and Choppin, 1969).

Keller and Schreck (1969) have shown that Cm(III), as well as Ac(III), Am(III), and Cf(III), are extracted with β-diketone ligands as 1:3 chelates only, with stability constants ($\log\beta_3$) decreasing in the series Cf > Cm ~ Am > Ac. Keller *et al.* (1966) have also shown that Am(III) and Cm(III) are extracted from aqueous solutions into chloroform solutions of 8-hydroxyquinoline ligands as AnL_2Y, where L is the 8-hydroxyquinolate anion and Y is probably OH^-, in contrast to the lanthanides, which are extracted as LnL_3 chelates.

Distribution ratios (chloroform–water) have been reported for curium complexes with 8-hydroxyquinoline, cupferron, and *N*-benzoylphenylhydroxylamine (Akatsu *et al.*, 1968). Only 1:3 complexes with Cm(III) and Am(III) were reported, and extraction into the organic phase appears to be very high at pH values above 5. Solution interaction of Cm(III) with bis(salicylidene)ethylenediimine and derivatives has also been studied (Stroński and Rekas, 1973). With the reagent arsenazo-III, both Cm(III) and Am(III) form 1:1 and 1:2 complexes (Myasoedov *et al.*, 1970).

During the last 20 years, the use of neutral bifunctional compounds as extractants for trivalent actinides has been extensively investigated. These compounds include carbamoylmethylphosphonates, CMPOs, and diamides. The mechanism by which these extractants operate is still open to debate. Slope analysis studies often give varied results. For example, Mincher (1992) has reported the extraction of trivalent actinides (including Cm) by CMPO to be due to formation of $M(NO_3)_3(CMPO)_4$ complexes, whereas most other studies indicate a stoichiometry of the type $M(NO_3)_3L_3$ (Horwitz *et al.*, 1981). Similar confusion can be cited for the diamide extractants, although mechanistic studies have not been performed specifically with Cm for this class of ligands.

9.9 ANALYTICAL CHEMISTRY

The analysis for curium has been done by the typical methods for metal ions and alpha-emitting actinides, such as alpha, gamma, and neutron spectroscopy, nuclear track detection, photon/electron-rejecting alpha liquid scintillation, mass spectrometry, spectrophotometry of highly colored complexes such as arsenazo, and time-resolved laser-induced fluorescence or luminescence spectroscopy (Buijs, 1973). In most cases, at least some separations are required before analysis of curium.

9.9.1 Analysis of curium

The curium isotopes, 242, 243, and 244, emit high-energy alpha particles (see Table 9.1) that are easily quantified in the presence of lower-energy α emitters without extensive separations. Curium isotopes 245–248 emit lower-energy alpha particles and generally require more extensive separations before alpha analysis. Alpha spectrometry is typically used for curium determination, although photon/electron-rejecting alpha liquid scintillation has been shown to have lower detection limits when combined with extractive scintillators (Metzger *et al.*, 1995; Dacheux and Aupais, 1998). One extractive scintillator was a combination of HDEHP and CMPO, allowing the separation and analysis to occur in one step (Metzger *et al.*, 1995). The key to alpha spectrometry is the preparation of counting plates with minimal solids to degrade the energy of the alpha particles. Various deposition techniques have been used, including electrodeposition, evaporation, and precipitation of insoluble compounds (Trautmann and Folger, 1989; Kaye *et al.*, 1995; Gascon *et al.*, 1996; Rameback and Skalberg, 1998; Diakov *et al.*, 2001). Precipitation can involve addition of a lanthanide ion to act as a carrier for curium (Kaye *et al.*, 1995). Nuclear track analysis has been shown to be useful for very low concentrations of curium, such as environmental samples and waste streams at nuclear power plants (Lancsarics *et al.*, 1988; Espinosa *et al.*, 1995). The alpha energies were determined by the size of the track after calibration with sources of known energy.

Spontaneous fission occurs for the even isotopes of curium, allowing neutron counting to be used for their determination, especially for ^{244}Cm and ^{248}Cm, but this method requires pure isotopes for quantification (Trautmann and Folger, 1989). Curium analyses have been done by inductively coupled mass spectrometry and isotope dilution thermal ionization mass spectrometry after separation to obtain a pure curium solution (Kinard *et al.*, 1995; Niese and Gleisberg, 1995; Chartier and Aubert, 1999).

As has been mentioned previously, time-resolved laser-induced fluorescence spectroscopy has been shown to be an especially valuable tool for investigating Cm solution chemistry, but it has also proved useful for quantitative determination of Cm (Elesin *et al.*, 1973; Dem'yanova *et al.*, 1986; Yusov *et al.*, 1986a,b; Decambox *et al.*, 1989; Kim *et al.*, 1991; Myasoedov and Lebedev, 1991; Myasoedov, 1994; Moulin *et al.*, 1997; Dacheux and Aupais, 1998). The Cm fluorescence emission signal is strong enough that no separations from other transuranium or lanthanide elements are required to use this technique to quantify Cm ion in solution. Sensitivity for curium detection is about 5×10^{-11} M in carbonate solution without separation from matrix elements (Radchenko *et al.*, 1999). An even lower detection limit of 5×10^{-13}M has been observed at 612 nm (Moulin *et al.*, 1997).

9.9.2 Separations for analysis

Separations are a primary component of most analytical procedures. Initial separation is from non-radioactive elements and the large quantity of uranium that may be present in the sample. Plutonium is often separated to allow determination without interference from the higher actinides. Separation of curium from americium and the lanthanides is possible, but may not be necessary, depending on the method of final analysis. A variety of separation methods have been reported, including ion exchange, extraction chromatography, and solvent extraction, or combinations of several of these methods. Early work was summarized in Gmelin (Buijs, 1973). A more recent review summarizes many of the methods for analytical separations (Myasoedov, 1994).

Anion-exchange resins have been used with HCl and HNO_3 in both aqueous and aqueous–alcohol mixtures (Trautmann and Folger, 1989; Gascon *et al.*, 1996; Diakov *et al.*, 2001). Anion exchange alone usually results in a product containing all trivalent actinides and lanthanides. Cation exchange from HCl solutions has been used to separate lanthanides from actinides, or with α-hydroxyisobutyric acid to separate both lanthanides and actinides (Myasoedov, 1994). Anion exchange from HCl has also been used to remove uranium and plutonium, followed by a rapid separation of curium from americium by high-pressure liquid chromatography (HPLC) using 2-hydroxy-2-methylbutyric acid as the eluent (Trautmann and Folger, 1989). Americium–curium separation was rapid, with no overlap between curium and americium peaks. Anion exchange has been combined with HDEHP to separate an americium–curium product (Gascon *et al.*, 1996).

Another method involves a combination of extraction of plutonium with trioctylphosphine oxide in cyclohexane from HNO_3, then absorbing the metal ions onto Dowex® 50 resin from an HCl solution containing oxalic acid.

Washing the column with 2 M HCl removed impurities, followed by americium–curium elution in 6 M HNO_3 (Niese and Gleisberg, 1995).

Extraction chromatography with CMPO on an organic support allows ready separation of an americium and a curium fraction. A commercially available resin based on CMPO has been used (Kaye *et al.*, 1995; Maxwell, 1996).

Separations by solvent extraction include extraction of all the actinides into HDEHP, with selective back-extraction of americium and curium into 5 M HNO_3 (Rameback and Skalberg, 1998). Another method used extraction of plutonium from HCl solution with triisooctylamine in xylene. Americium and curium were then extracted with dibutyl-*N*,*N*-diethylcarbamoyl phosphonate and stripped into dilute acid (Kimura *et al.*, 1996). CMPO has been used extensively for solvent extraction separations of americium and curium (Myasoedov and Lebedev, 1991). Other separation methods are given in the review by Myasoedov (1994).

ACKNOWLEDGMENT

This work was performed under the auspices of the U.S. Department of Energy. The authors gratefully acknowledge the excellent editorial support of Paula Ložar and helpful suggestions by Calvin Delegard (Pacific Northwest National Laboratory) and anonymous peer reviewers.

CHAPTER TEN

BERKELIUM

David E. Hobart and Joseph R. Peterson

10.1 HISTORICAL

As was the case for the previously discovered transuranium elements, element 97 was first produced via a nuclear bombardment reaction. In December 1949 ion-exchange separation of the products formed by the bombardment of ^{241}Am with accelerated alpha particles provided a new electron-capture activity eluting just ahead of curium (Thompson *et al.*, 1950a,b). This activity was assigned to an isotope (mass number 243) of element 97. The new element was named berkelium after Berkeley, California, USA, the city of its discovery, in a manner parallel to the naming of its lanthanide analog, terbium, after Ytterby, Sweden. The initial investigations of the chemical properties of berkelium were limited to tracer experiments (ion exchange and coprecipitation), and these were sufficient to establish the stability of Bk(III) and the accessibility of Bk(IV) in aqueous solution and to estimate the electrochemical potential of the Bk(IV)/Bk(III) couple (Thompson *et al.*, 1950b,c). Because a complete study of the chemistry of an element is not possible by tracer methods alone, a program for long-term neutron irradiation of about 8 g of ^{239}Pu was initiated in 1952 in the Materials Testing Reactor (Arco, Idaho, USA) to provide macroquantities of berkelium (Cunningham, 1959). In 1958 about 0.6 μg of ^{249}Bk was separated, purified, and used in experiments to determine the absorption spectrum of Bk(III) in aqueous solution and to measure the magnetic susceptibility of Bk(III) (Cunningham, 1959). No Bk(III) absorption was observed over the wavelength range 450–750 nm, but an upper limit of about 20 was set for the molar absorptivity of any

Bk(III) absorption in this wavelength region. The magnetic susceptibility, measured from 77 to 298 K with the Bk(III) ions sorbed in a single bead of cation-exchange resin, was found to conform to the Curie–Weiss law with an effective moment of 8.7 μ_B, suggesting a $5f^8$ electronic configuration for the Bk(III) ion. The first structure determination of a compound of berkelium, the dioxide, was carried out in 1962 (Cunningham, 1963). Four X-ray diffraction lines were obtained from 4 ng of BkO_2 and indexed on the basis of a face-centered cubic (fcc) structure with $a_0 = (0.533 \pm 0.001)$ nm. In the intervening years since this initial work to characterize element 97, considerable information about the physicochemical properties of berkelium has been obtained in spite of the rather limited availability and the short half-life (330 days) of ^{249}Bk, the only isotope available in bulk quantities.

The authors have focused this review of the chemistry of berkelium on open literature references in English or English translation, except where it was deemed necessary to cite a research institution report or technical memorandum or personal communication. References to theses, dissertations, and patents are minimal. The biologic and metabolic effects of exposure to and/or ingestion of berkelium on humans and animals have not been reviewed here (see Chapter 31). Also excluded are references dealing with the determination and/or use of the nuclear properties of the various isotopes of berkelium, with the notable exception of a few modern references dealing with the use of ^{249}Bk as a target material for the production of transactinide elements. The references cited herein are not necessarily inclusive or always the original ones, yet they should be adequate to permit the interested reader to access easily the broader literature beyond.

Earlier reviews of the physicochemical properties of berkelium are available in Keller (1971), in several new supplement series volumes of the *Gmelin Handbuch der Anorganischen Chemie* (e.g. Peterson, 1976), Peterson and Hobart (1984), and in Hobart and Peterson (1986).

10.2 NUCLEAR PROPERTIES, AVAILABILITY, AND APPLICATIONS

Selected nuclear properties of the 14 known isotopes of berkelium, ranging from mass numbers 238 to 251, are listed in Table 10.1 (Appendix II). Included in this list are two neutron-deficient isotopes that have been identified since the publication of the second edition of this text in 1986. These are ^{238}Bk with an electron-capture decay half-life of 2.4 min (Kreek *et al.*, 1994) and ^{241}Bk with an electron-capture decay half-life of 4.6 min (Asai *et al.*, 2003). Only ^{249}Bk is available in bulk quantities for chemical studies, as a result of prolonged neutron irradiation of Pu, Am, or Cm (Bigelow *et al.*, 1981). About 1 g of this isotope has been isolated from target rods irradiated in the High Flux Isotope Reactor (HFIR) at Oak Ridge National Laboratory (ORNL) in east Tennessee, USA, over the period 1967–2001 (Knauer, 2002). The relative atomic mass of

[b] Not known whether ground state nuclide or isomer.

^{249}Bk was given as 249.075 (Audi and Wapstra, 1995), and the most recent determination of its half-life yielded a value of (330 ± 4) days (Popov and Timofeev, 1999).

Besides the research use of ^{249}Bk for the characterization of the chemical and physical properties of element 97, its relatively rapid decay to ^{249}Cf (ca. 0.22% per day) makes it a valuable source of this important isotope of californium for chemical study. This genetic relationship has been exploited in studies of the chemical consequences of beta (β^-) decay in the bulk-phase solid state (Young *et al.*, 1980; Ensor *et al.*, 1981; Young *et al.*, 1984; Peterson *et al.*, 1986).

As a consequence of recent interest in nuclear power reactors to increase fuel burn-up and in the areas of nuclear waste transmutation, nuclear deterrence, and astrophysics, more accurate data on the nuclear characteristics of heavier actinides, including berkelium, are in demand. A recent compilation of the decay characteristics of actinides, including ^{249}Bk and ^{250}Bk, has been published (Popov and Timofeev, 1999). Fission fragment angular distributions for the compound nucleus ^{246}Bk have been measured (Behera *et al.*, 2001). ^{246}Bk was produced via two nuclear reaction pathways, lying on either side of the Businaro–Gallone critical asymmetry parameter.

By combining measured fission probabilities for reactions such as ^{248}Cm(^{3}He, d)^{249}Bk → fission (Gavron *et al.*, 1977) with calculated total neutron inelastic cross sections, empirical predictions for the neutron-induced fission cross sections for several actinides have been obtained (Britt and Wilhelmy, 1979). These predictions ignore differences in angular momentum distributions between the direct reaction products and the incident neutrons when populating the same energy levels in the compound nucleus. As demonstrated by Britt and Wilhelmy (1979), this assumption is reasonably good for equivalent neutron energies (energy of an incident neutron that would leave the identical residual nucleus at the same energy as is reached by the direct nuclear reaction) of greater than about 0.5 MeV. For Bk the equivalent (n,f) cross sections were extracted for the berkelium isotopes with mass numbers 244 to 248. Odd-mass-number Bk nuclei exhibit a strong reduction in the fission probability for excitation energies above the neutron-binding energy that is presumably caused by the opening of a large number of competing decay channels (Britt and Wilhelmy, 1979). Although no experimentally measured fission cross section for $^{248\mathrm{m}}$Bk has been determined, estimates of up to 1000 barns have been predicted based on correlations with other actinides having similar characteristics (Ronen, 1998).

The intrinsic single-particle states of ^{249}Bk have been studied by measuring the gamma radiations emitted after the alpha decay of ^{253}Es. The low spin states were studied by measuring gamma rays in the beta decay of ^{249}Cm. Levels in ^{249}Bk were also studied by the reaction ^{248}Cm(α,t)^{249}Bk. A diagram of the intrinsic states for ^{249}Bk, deduced from these decay studies, has been constructed. This well-established nuclear structure information, available only for the heaviest elements for which macro amounts are obtainable, can be used either to determine the parameters of a single-particle potential or to test the nuclear models of super-heavy elements (Ahmad, 2002).

Although currently there are no practical or commercial applications for any known berkelium isotopes, ^{249}Bk has been used extensively as a target material for the production of still heavier actinides such as lawrencium (Brüchle *et al.*, 1988; Scherer *et al.*, 1988) and transactinide elements such as element 104, rutherfordium, and element 107, bohrium (Gregorich *et al.*, 1988; Kratz *et al.*, 1992; Gobrecht *et al.*, 1999; Paulus *et al.*, 1999; Eichler *et al.*, 2000; Wilk *et al.*, 2000).

10.3 PRODUCTION

Methods of production for each of the isotopes of berkelium are listed in Table 10.1 (Appendix II). Only ^{249}Bk is available in bulk quantities for chemical studies, as a result of prolonged neutron irradiation of Pu, Am, or Cm (Bigelow *et al.*, 1981). About 0.73 g of this isotope was isolated from target rods irradiated with neutrons in the ORNL HFIR over the period 1967–1985 (Ferguson and Bigelow, 1969; King *et al.*, 1981; Bigelow, 1985). Toward the end of 1986, HFIR was shut down for an extended period of time for major maintenance and safety considerations. This action resulted from the nuclear reactor accident at Chernobyl (former USSR) earlier that year. After a 4+ year hiatus, HFIR was restarted with a power limit of 85 MW, down from the previous 100 MW level. Through the HFIR product campaign that started in late 2000, an additional 0.28 g of ^{249}Bk was recovered during the period 1986–2001. It is not known to the present authors how much ^{249}Bk has been produced elsewhere in the world, for instance, in the former USSR.

10.4 SEPARATION AND PURIFICATION

Berkelium may be purified by many methods that are also applicable to other actinide elements. Therefore, only those methods that apply specifically to berkelium separation and purification are treated here.

Because berkelium can be readily oxidized to Bk(IV), it can be separated from other, non-oxidizable transplutonium elements by combining oxidation–reduction (redox) methods with other separation techniques. The first application of this approach was performed by oxidizing Bk(III) with BrO_3^- in nitric acid solution (Peppard *et al.*, 1957). The resultant Bk(IV) was then extracted with bis(2-ethylhexyl)phosphoric acid (HDEHP) in heptane followed by back-extraction with nitric acid containing H_2O_2 as a reducing agent. In addition to other reports of the use of BrO_3^- as an oxidizing agent in berkelium purification procedures (Knauer and Weaver, 1968; Weaver, 1968; Fardy and Weaver, 1969; Overman, 1971; Erin *et al.*, 1979b), the use of CrO_4^{2-} (Knauer and Weaver, 1968; Milyukova *et al.*, 1980), $Cr_2O_7^{2-}$ (Moore, 1966; Shafiev *et al.*, 1974; Milyukova *et al.*, 1980), $Ag(I)/S_2O_8^{2-}$ (Milyukova *et al.*, 1978, 1980), PbO_2 (Myasoedov *et al.*, 1971; Myasoedov, 1974; Shafiev *et al.*, 1974), BiO_3^- (Shafiev *et al.*, 1974), O_3 (Myasoedov, 1974), and photochemical oxidation (Myasoedov, 1974) has also been reported.

Separation of the oxidized berkelium has been accomplished by the use of: (1) liquid–liquid extraction with HDEHP (Peppard *et al.*, 1957; Knauer and Weaver, 1968; Kosyakov *et al.*, 1977; Erin *et al.*, 1979b; Yakovlev and Kosyakov, 1983), trioctylphosphine oxide (Kosyakov and Yakovlev, 1983), alkylpyrocatechol (Karalova *et al.*, 1983), 2-thenoyltrifluoroacetone (TTA) (Moore 1966, 1969), primary, tertiary, or quaternary amines (Moore, 1969;

Milyukova and Myasoedov, 1978; Milyukova *et al.*, 1978, 1980; Malikov *et al.*, 1983), or tri(*n*-butyl)phosphate (TBP) (Milyukova *et al.*, 1981; Yakovlev *et al.*, 1982); (2) extraction chromatography with HDEHP (Kooi and Boden, 1964; Kooi *et al.*, 1964; Overman, 1971; Erin *et al.*, 1979a) or zirconium phosphate adsorbant (Myasoedov *et al.*, 1971; Shafiev and Efremov, 1972; Myasoedov, 1974; Shafiev *et al.*, 1974); (3) precipitation of the iodate (Weaver, 1968; Fardy and Weaver, 1969); or (4) ion-exchange methods (Moore, 1967; Overman, 1971; Shafiev and Efremov, 1972; Guseva and Stepushkina, 1987; Guseva *et al.*, 1987, 1991; Firsova *et al.*, 1996, 1998a,b). These techniques can be applied separately or in combination with one another.

The purification procedures outlined above provide separation of berkelium from all trivalent lanthanides and actinides with the notable exception of cerium. Because berkelium and cerium exhibit nearly identical redox behavior, most redox separation procedures include a Bk–Ce separation step (Moore, 1967; Horwitz *et al.*, 1969; Guseva *et al.*, 1971; Chudinov and Pirozhkov, 1972; Shafiev and Efremov, 1972; Shafiev *et al.*, 1974). Separation of Bk(III) from Ce(III) and other trivalent lanthanide and actinide elements can also be accomplished without the use of redox procedures (Moore and Jurriaanse, 1967; Farrar *et al.*, 1968; Horwitz *et al.*, 1969; Aly and Latimer, 1970; Guseva *et al.*, 1971; Chudinov and Pirozhkov, 1972; Harbour, 1972; Shafiev and Efremov, 1972; Horwitz and Bloomquist, 1973; Korpusov *et al.*, 1975; Khopkar and Mathur, 1980; Mathur and Khopkar, 1982; Ensor and Shah, 1984).

During the period 1967–2001, personnel at ORNL isolated and purified a total of about 1 g of ^{249}Bk (King *et al.*, 1981; Bigelow, 1985; Knauer, 2002) using the procedure outlined in Fig. 10.1.

The transcurium elements, partitioned by LiCl-based anion exchange, are precipitated as hydroxides, filtered, and dissolved in nitric acid. Initial isolation is accomplished by high-pressure elution from cation-exchange resins with α-hydroxyisobutyrate solution. The berkelium fraction is oxidized and extracted into HDEHP/dodecane from HNO_3–$NaBrO_3$ solution. The organic fraction containing Bk(IV) is treated with 2,5-di(*t*-butyl)hydroquinone (DBHQ) to reduce the Bk(IV) to Bk(III) before back-extracting (stripping) it into HNO_3–H_2O_2 solution. Then another oxidation/extraction, reduction/back-extraction cycle is carried out. The solution at this point is radiochemically pure except for the fission product cerium. After solvent cleanup and evaporation to dryness, the berkelium is dissolved in 0.1 M HCl for final ion-exchange purification steps including alcoholic HCl elution from cation-exchange resin and cation cleanup columns (Baybarz *et al.*, 1973).

Procedures for the rapid separation of berkelium from other actinides, lanthanides, and fission products have been developed in order to measure the decay properties of short-lived isotopes. Berkelium and cerium were separated from other elements using solvent extraction with HDEHP followed by cation-exchange high-pressure liquid chromatography (HPLC) using α-hydroxyisobutyrate as the eluant (Liu *et al.*, 1981). The elution curve, showing

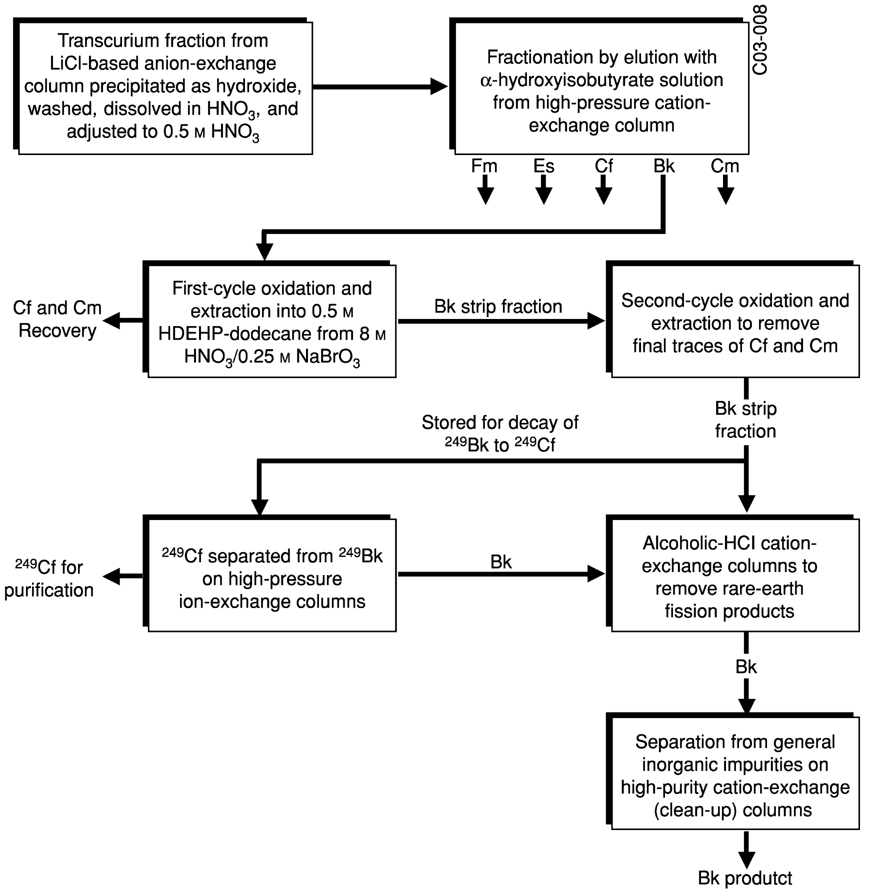

Fig. 10.1 *Schematic diagram of procedures used in the final isolation and purification of berkelium in the transuranium processing plant at the Oak Ridge National Laboratory.* (*Adapted from Baybarz* et al., 1973.)

a clean separation of Bk from Ce, is shown in Fig. 10.2. The total separation time was reported to be 8 min. (*Note*: A discrepancy exists in the drop number in the abscissa of Fig. 10.2; however, this figure is presented as it appeared in Liu *et al.* (1981).)

The fast separation of berkelium from beryllium foil targets and gold catcher foils has been published (Liu *et al.*, 1983). New, fast separation techniques, involving volatile mineral acid–alcohol solvent systems used to isolate very short-lived isotopes, have been reported (Maruyama *et al.*, 2002).

For additional discussion of berkelium separation procedures, the reader is referred to several reviews and comprehensive texts on the subject (Korkisch, 1966; Ulstrup, 1966; Müller, 1967; Bigelow, 1974; Myasoedov *et al.*, 1974;

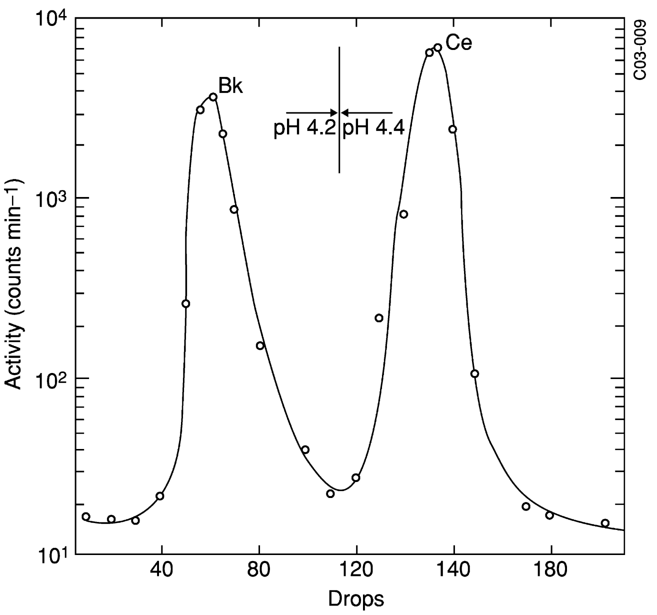

Fig. 10.2 *HPLC elution curve of Bk and Ce using* 0.5 M *ammonium α-hydroxyisobutyrate on a cation-exchange column* (*Liu* et al., 1981).

Campbell, 1981; Collins *et al.*, 1981; Myasoedov, 1987; Myasoedov and Lebedev, 1991).

10.5 PROPERTIES OF FREE ATOMS AND IONS

10.5.1 Thermochromatographic behavior of neutral atoms

The adsorption of ^{250}Bk atoms on niobium foils in a sapphire support tube has been studied (Hübener *et al.*, 2000). A deposition temperature of 1535 K was found in two separate experiments, and the enthalpy of adsorption was calculated to be –332 kJ mol^{-1}. A regular trend in the adsorption enthalpies of Bk–Fm and No is consistent with Bk adsorption on niobium in its trivalent $5f^86d^17s^2$ state (Taut *et al.*, 1998; Hübener *et al.*, 2000). In another approach by the same research group, the adsorption of elemental ^{248}Bk onto niobium was measured thermochromatographically (Taut *et al.*, 2000). The enthalpy of adsorption was determined to be –(349 ± 15) kJ mol^{-1}, in agreement with the above value, taking into account the experimental uncertainties.

10.5.2 Electronic energies

The ionization potential of neutral berkelium ($5f^97s^2$) was initially derived from spectroscopic data to be (6.229 ± 0.025) eV (Sugar, 1974). The changes in entropy associated with the stepwise ionization of gaseous berkelium atoms have also been calculated (Krestov, 1966). The energy interval between the ground level ($^7H_8$) and the first excited level ($^5H_7$) of singly ionized berkelium was determined from measurements done on plates using a high-resolution emission spectrograph and was found to be 1.48752×10^5 m^{-1} (Worden *et al.*, 1969). Several authors have calculated the energies of, and energy intervals between, the lowest-lying levels of the various electronic configurations of neutral berkelium (Nugent and Vander Sluis, 1971; Brewer, 1971a; Vander Sluis and Nugent, 1972, 1974) and of singly, doubly, and triply ionized berkelium (Brewer, 1971b; Vander Sluis and Nugent, 1974).

More recently, experimental determination of the first ionization potential of neutral berkelium was accomplished by resonance ionization mass spectroscopy (Erdmann *et al.*, 1998; Passler *et al.*, 1998; Waldek *et al.*, 2001). In this elegant approach (Kohler *et al.*, 1997) an atomic beam of Bk atoms was produced from heating a tantalum foil onto which Bk had been electrodeposited and then covered with a thin layer of titanium to reduce the Bk species to the metallic state. The Bk atoms were ionized in the presence of an electric field by multiple resonant laser excitation, and the Bk^+ ions were mass-selectively detected in a time-of-flight spectrometer. The first ionization potential was obtained by scanning the wavelength of the laser used for the last excitation step across the ionization threshold (indicated by a sudden increase in the Bk^+ count rate) at various electric field strengths. A linear plot of the ionization threshold against the square root of the electric field strength, extrapolated to zero field strength, yielded the first ionization potential of Bk to be (6.1979 ± 0.0002) eV. This value is just below the one derived from an extrapolation of spectral properties (Sugar, 1974). In addition the resonant excitation scheme used provided the energies of three of the excited energy levels of neutral Bk: 17666.0, 31541.3, and 32710.3 cm^{-1} (Kohler *et al.*, 1997; Erdmann *et al.*, 1998; Passler *et al.*, 1998).

From measurements of the energies of a number of internal conversion lines in ^{249}Bk (produced by the alpha decay of ^{253}Es), the atomic electron-binding energies in berkelium were calculated for the K through O shells (Hollander *et al.*, 1965). The K-series X-ray energies and intensities of berkelium were later measured, and the K-shell electron-binding energy was calculated (Dittner and Bemis, 1972). The measured energies and relative transition probabilities agreed well with theoretical predictions (Carlson *et al.*, 1969; Lu *et al.*, 1971). Also available are the results of relativistic relaxed-orbital *ab initio* calculations of L-shell Coster–Kronig transition energies for all possible transitions in berkelium atoms (Chen *et al.*, 1977), relativistic relaxed-orbital Hartree–Fock–Slater calculations of the neutral-atom electron binding energies in berkelium (Huang *et al.*, 1976), and calculations of the K- through O-shell binding energies and K and L X-ray energies for berkelium (Carlson and Nestor, 1977). Relativistic Hartree–Slater values of the X-ray emission rates for the filling of K- and L-shell vacancies in berkelium have been tabulated (Scofield, 1974). X-ray emission rates for the filling of all possible single inner-shell vacancies in berkelium by electric dipole transitions have been calculated using nonrelativistic Hartree–Slater wave functions (Manson and Kennedy, 1974).

10.5.3 Emission spectra

Twenty emission lines, produced from 0.2 μg of berkelium in a high-voltage spark, were reported by Gutmacher *et al.* (1965). In 1967 between 3000 and 5000 lines were recorded in the wavelength region 250–900 nm from 38 μg of ^{249}Bk in an electrodeless discharge lamp (Worden *et al.*, 1967). Many of the emission lines exhibited a well-resolved eight-component hyperfine structure, which established the nuclear spin of ^{249}Bk to be 7/2 (Worden *et al.*, 1967). This value is in agreement with that derived from nuclear decay systematics.

The ground state electronic configurations (levels) of neutral and singly ionized berkelium were identified as $5f^97s^2$ ($^6H_{15/2}$) and $5f^97s^1$ ($^7H_8$), respectively (Worden *et al.*, 1970). A nuclear magnetic dipole moment of 1.5 μ_N (Worden *et al.*, 1969) and a quadrupole moment of 4.7 barns (Conway, 1976) were determined for ^{249}Bk, based on analysis of the hyperfine structure in the berkelium emission spectrum.

The wavenumbers, wavelengths, and relative intensities of 1930 of the stronger emission lines from ^{249}Bk in the 254–980 nm wavelength region are available (Worden and Conway, 1978). The infrared emission spectrum of ^{249}Bk from 830 to 2700 nm has been recorded (Conway *et al.*, 1977). The emission profile of ^{249}Bk(III) in a silicate matrix has been studied as a function of excitation power and temperature (Assefa *et al.*, 1998). With both experimental parameters it was found that the two primary emission bands (believed to originate from f→f transitions) decreased in intensity at different rates with increasing excitation power or temperature, such that the higher-energy band became dominant over the lower-energy one. Thermal quenching and/or energy transfer between neighboring ions are possible factors responsible for this behavior (Assefa *et al.*, 1998).

A preliminary report on the self-luminescence of ^{249}Bk(III) in a $LaCl_3$ host lattice was published by Gutmacher *et al.* (1963), and the self-luminescence spectra of ^{249}Bk-doped BaF_2 and $SrCl_2$ were reported by Finch *et al.* (1978). The fluorescence and excitation spectra of Bk^{3+} ions (<0.001 mol fraction) in single-crystal $LaCl_3$ were determined using dye laser techniques (Hessler *et al.*, 1978). Selective laser excitation was used to excite specific Bk^{3+} levels, and then the subsequent fluorescence spectrum was recorded. Determining fluorescence lifetimes of all fluorescing levels and grouping the lines by lifetimes precluded confusion caused by transference of the excitation energy to a fluorescing level of another ion. The fluorescing manifolds of Bk^{3+} were found to be $J = 6$ at 1.540 μm^{-1} and $J = 4$ at 1.953 μm^{-1} (Hessler *et al.*, 1978). The absence of UV-excited sharp-line sensitized luminescence of ^{249}Bk-doped gadolinium hexafluoroacetyl acetonate has been observed (Nugent *et al.*, 1969, 1970). Such luminescence was absent also in cesium berkelium hexafluoroacetyl acetonate chelate in anhydrous ethanol (Nugent *et al.*, 1969). A study of Bk^{3+} fluorescence in H_2O and D_2O solutions has been reported, and a basis for assessing the use of fluorescence detection for transuranic ions established (Beitz *et al.*, 1981).

The first report of fluorescence from the Bk^{4+} ion included establishment of the total ground state splitting of this ion and probing the higher-lying electronic states of its $5f^7$ configuration (Jursich *et al.*, 1987). The Bk^{4+} ions were stabilized in CeF_4, where it is known that there are two distinct low-symmetry sites to accommodate them. Two Bk^{4+} bands were detected and assigned to transitions to the ground state. From laser excitation spectra taken at 4 K, a $5f^7$ energy-level diagram was proposed, which is consistent with the authors' assumption of a single average D_{4d} site symmetry. Mixing of higher lying states into the ground state caused the total ground state crystal-field splitting of Bk^{4+} in CeF_4 to be 58 cm^{-1} (Jursich *et al.*, 1987). The results of a detailed, systematic spectral analysis of these data, along with those obtained in additional site-selective laser excitation studies of another sample of Bk^{4+} in CeF_4, have been reported (Liu *et al.*, 1994a). A complete set of crystal-field parametric values was given and compared with those derived from the previous five tetravalent actinides. In addition an observed and calculated line list out to about 27 000 cm^{-1} was published (Liu *et al.*, 1994a). Another paper from the same research group focused on the use of fluorescence line narrowing spectra of 0.1 at% Bk^{4+} in CeF_4 to study emissions from the lowest energy component of $^6D_{7/2}$ at 16375 cm^{-1} to the four components of the $^8S_{7/2}$ ground multiplet (Liu *et al.*, 1994b). A linear relationship was observed between the excitation-laser photon energy and the energies of the Bk^{4+} emission lines. A subsequent study of the influence of the crystal field on the $^8S_{7/2}$ ground state splitting of Bk^{4+} ion in CeF_4, based on the 24 energy levels observed in their earlier work (Liu *et al.*, 1994a), was carried out (Brito and Liu, 2000). The parametric model used a set of nine nonzero parameters (corresponding to C_{2v} point symmetry) and yielded a good correlation between the experimental and calculated energy levels in Bk^{4+} ion. Compared with the isoelectronic Cm^{3+} ion, the large ground state splitting of Bk^{4+} ion in CeF_4 is attributed to the smaller energy gap between the ground state and the low-lying excited states (Brito and Liu, 2000). Subsequently, a model that included relativistic effects in an effective way was used to improve the theoretical reproduction of the splitting of the energy levels for such S-state f-electron ions (Smentek *et al.*, 2001). It was concluded in this work that the fitting procedure applied for the determination of the crystal-field parameters had to be done within the parametrization scheme that included the relativistic weights of the various parameters.

10.5.4 Solid-state absorption spectra

The absorption spectrum of Bk(iii) in a lanthanum chloride host matrix at 77 K was first obtained by Gutmacher (1964). A prediction of the energy-level structure of Bk(iii) was made by others the same year (Fields *et al.*, 1964). Extensive, low-temperature spectroscopic studies of $BkCl_3$ showed the absence of transitions to excited $J = 0$ and $J = 1$ states (Carnall *et al.*, 1972, 1973). This provided good evidence for a $\mu = 0$ ground level for Bk(iii), consistent with that of Tb(iii):$LaCl_3$ (Carnall and Fried, 1976). Experimental and theoretical studies of the crystal-field parameters of Bk(iii) in a $LaCl_3$ host lattice have also been reported (Carnall *et al.*, 1977).

Microscale spectrophotometric techniques, using 0.5–10 μg berkelium samples, have been applied for identification and characterization of berkelium halides and oxyhalides (Young *et al.*, 1978). The spectra of orthorhombic and hexagonal $BkCl_3$ have been recorded (Peterson *et al.*, 1986) and are shown in Fig. 10.3. Spectra of orthorhombic and monoclinic $BkBr_3$ (Peterson *et al.*, 1977a,b), trigonal and orthorhombic BkF_3 (Ensor *et al.*, 1981), and monoclinic BkF_4 (Ensor *et al.*, 1981) have been reported. This technique has also been applied to the study of the chemical consequences of radioactive decay in bulk-phase solid-state samples (Young *et al.*, 1980, 1981). It was found that the ^{249}Cf daughter growing into crystalline $^{249}BkBr_3$ exhibited the same oxidation state and crystal structure as its berkelium parent (Young *et al.*, 1980).

The absorption spectra of Bk(iii) and Bk(iv) hydroxides as suspensions in 1 m NaOH have been reported (Cohen, 1976). The solid-state absorption spectrum (Haire *et al.*, 1983) and Raman spectrum (Hobart *et al.*, 1983) of berkelium(iii) orthophosphate have been obtained, as well as those for berkelium(iii) oxalate decahydrate, $Bk_2(C_2O_4)_3 \cdot 10H_2O$ (Morris *et al.*, 2005). Line lists of the absorption bands of two organoberkelium compounds, $Bk(C_5H_5)_3$ (Laubereau and Burns, 1970) and $[Bk(C_5H_5)_2Cl]_2$ (Laubereau, 1970), have been published.

For additional information (Carnall, 1973) and discussion of the development of the theoretical treatment of berkelium spectra, the reader is referred to other sources (Carnall and Fried, 1976; Conway, 1976; Carnall *et al.*, 1984; Liu *et al.*, 1994a) and to Chapters 16 and 18.

10.5.5 Ion–molecule reactions in the gas phase

Organoberkelium ions have been produced by laser ablation of Bk_2O_3 dispersed in polyimide (Gibson and Haire, 2001a). Characterization of the resulting products via time-of-flight spectrometry identified the primary species as $BkCH_3^+$, BkC_2^+, BkC_2H^+, $BkCN^+$, BkC_4H^+, $Bk(OH)(CN)^+$, $BkOCN^+$, $BkOH^+$, $Bk(OH)_2^+$, and BkO^+, as shown in Fig. 10.4. The product ion compositions and abundance distributions were reasonably explained in the context of the electronic structure and energetics of the Bk^+ ion. Several of these organoberkelium species incorporate direct metal ion–carbon bonding via a single

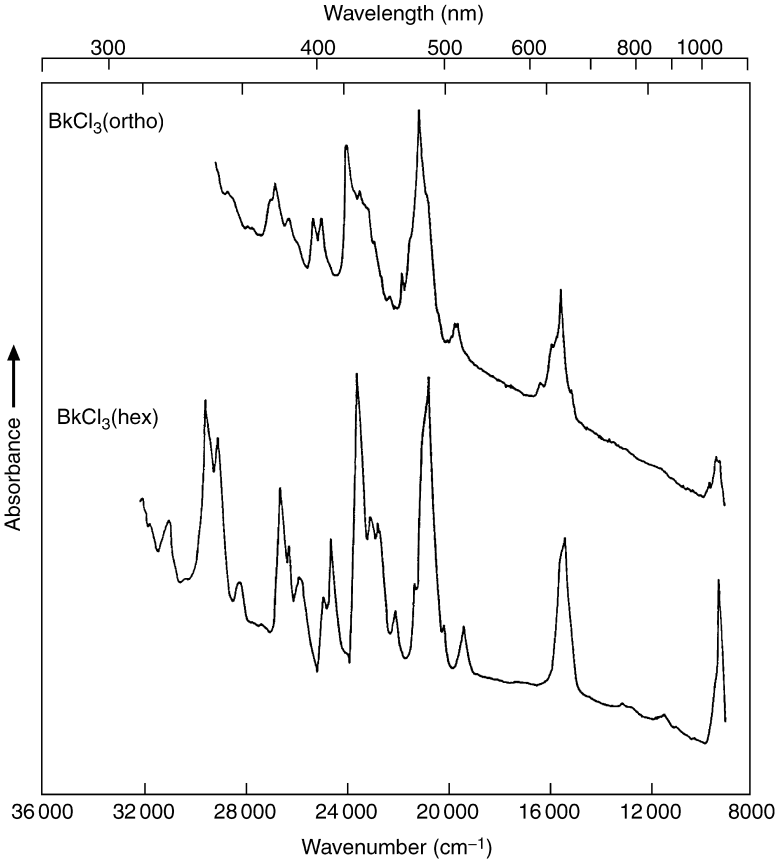

Fig. 10.3 *The solid-state absorption spectra of orthorhombic and hexagonal* $BkCl_3$ (*Peterson* et al., 1986).

σ-type covalent bond. Comparisons of the product ion compositions and abundance distributions of similarly produced organoactinide and lanthanide species provided correlations with the electronic promotion energies required to create a divalent or a monovalent state, capable of forming two or one covalent bonds, respectively (Gibson and Haire, 2001a). In an extension of the above work, gas-phase reactions of Bk^+ ion with several alkenes, butylamine, butyronitrile, and other reagents were studied in concert with similar reactions with Pu^+ ion or homologous Tb^+ ion to aid in the interpretation of the results in the context of the electronic structure and energetics of berkelium (Gibson and Haire, 2001b). A key result of this work was the finding that the efficiency of hydrocarbon, nitrile, and amine activation by Bk^+ ion directly reflected the energy required to excite the ion from its ground electronic state, $5f^97s^1$, to the lowest lying state with two spin-unpaired non-5f valence electrons, $5f^86d^17s^1$. Thus it appears that

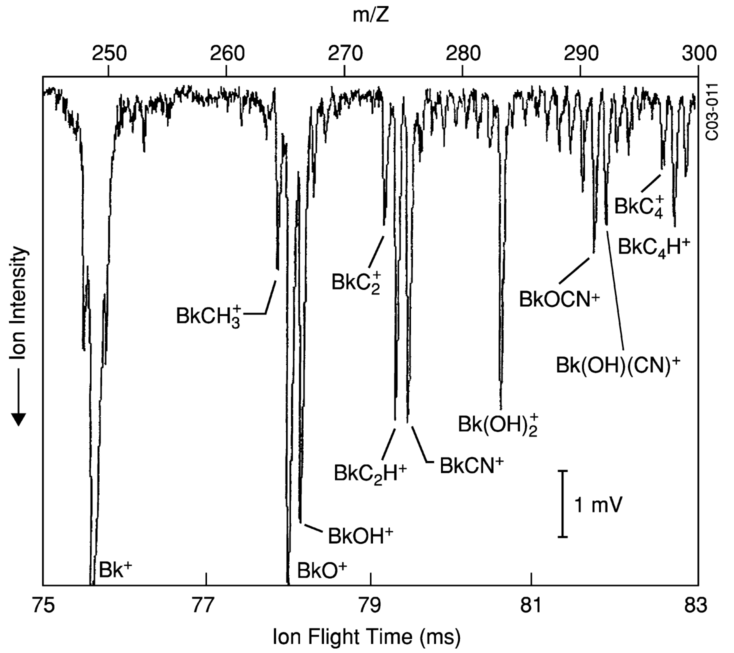

Fig. 10.4 *The mass spectrum of positive ions ablated from a Bk–polyimide target.* (*Reprinted figure with permission from Gibson and Haire* (2001*a*). *Copyright* 2001 *by Oldenbourg Verlag.*)

the 5f electrons in Bk^+ ions do not participate in organometallic bond activation. A variety of organoberkelium species were identified, as well as a few inorganic ones, e.g. BkF^+. A covalent bonding model was used to estimate the Bk^+–O bonding energy as (610 ± 40) kJ mol^{-1} (Gibson and Haire, 2001b).

10.6 THE METALLIC STATE

10.6.1 Pure metal

(a) Preparation

The first bulk (>1 μg) samples of berkelium metal were prepared in early 1969 by the reduction of BkF_3 with lithium metal vapor at about 1300 K (Peterson *et al.*, 1971). The BkF_3 samples were suspended in a tungsten wire spiral above a charge of Li metal in a tantalum crucible. Berkelium metal samples up to 0.5 mg each have been prepared via the same chemical procedure (Fuger *et al.*, 1975). Elemental berkelium can also be prepared by reduction of BkF_4 with lithium metal and by reduction of BkO_2 with either thorium or lanthanum metal

(Spirlet *et al.*, 1987). The latter reduction process is better suited to the preparation of thin metal foils unless multi-milligram quantities of berkelium are available.

(b) Physical properties

Berkelium metal exhibits two crystallographic modifications: double hexagonal close-packed (dhcp) and fcc. Thus, it is isostructural with the two preceding actinide elements, both of which also exhibit the fcc structure at high temperature. The room-temperature lattice constants of the dhcp (α) form are $a_0 = (0.3416 \pm 0.0003)$ nm and $c_0 = (1.1069 \pm 0.0007)$ nm, yielding a calculated density of 14.78 g cm^{-3} and a metallic radius (coordination number, CN 12) of 0.170 nm (Peterson *et al.*, 1971). The room-temperature metastable fcc (β) lattice parameter is $a_0 = (0.4997 \pm 0.0004)$ nm, from which the X-ray density and metallic radius (CN 12) are calculated to be 13.25 g cm^{-3} and 0.177 nm, respectively (Peterson *et al.*, 1971). The metallic radius of berkelium, assuming a metallic valence of 3- and 12-fold coordination, has been calculated to be 0.1739 nm (Sarkisov, 1966). On the other hand, the radii (CN 12) of berkelium were predicted to be 0.184 nm for a trivalent metal and 0.1704 nm for a tetravalent metal; so it was proposed that the observed dhcp form corresponds to tetravalent metal, while the fcc form represents a metallic valence of ~3.5 (Zachariasen, 1973).

Although berkelium metal is dimorphic, the transformation temperature is not known with certainty. A change in the appearance of Bk metal samples at (1203 ± 30) K during the course of two melting point determinations might correspond to the dhcp→fcc phase transformation, which should be accompanied by a 12% change in the volume of the sample (Fahey *et al.*, 1972). By analogy with the behavior of neodymium, a phase-transition temperature of (1250 ± 50) K was assigned by Ward *et al.* (1982), in agreement with the Fahey *et al.* (1972) observation. The melting point of berkelium metal was first determined to be (1259 ± 25) K from measurements on two samples (Fahey *et al.*, 1972). The melting and boiling points of elemental berkelium have been reported to be (1323 ± 50) K and (2900 ± 50) K, respectively (Ward *et al.*, 1982). These two melting-point determinations are in agreement, considering their experimental uncertainties.

The first studies of berkelium metal under pressure were performed with a diamond anvil pressure cell using energy-dispersive X-ray powder diffraction analysis (Haire *et al.*, 1984). Three different metallic phases were observed as the pressure was increased to 57 GPa. The normal-pressure dhcp form changed to an fcc form at about 8 GPa. Above 22 GPa (reported to be at about 32 GPa in later reports; Itié *et al.*, 1985; Peterson *et al.*, 1987), the fcc form was transformed to the alpha-uranium-type orthorhombic structure (Haire *et al.*, 1984). A 12% shrinkage in volume accompanied the latter transition. This collapse was associated with delocalization of the 5f electrons (Benedict *et al.*, 1984).

Below 22 GPa, a bulk modulus (compressibility) of (30 ± 10) GPa was estimated for berkelium metal (Haire *et al.*, 1984). This bulk modulus only for the normal-pressure dhcp phase of Bk metal was reported later to be 52 GPa (Itié *et al.*, 1985). Berkelium metal under pressure behaves similarly to americium, curium, and some light lanthanide metals and does not appear to undergo an isostructural phase transition corresponding to a change in metallic valence before delocalization of the 5f electrons (Johansson *et al.*, 1981).

Retention of the fcc phase in Bk metal after release of pressure (pressure quenched) allows comparison of the atomic volume of this cubic phase at room temperature and pressure (RTP) with the atomic volume of the same phase produced via thermal treatment and quenching to RTP (temperature quenched) (Haire *et al.*, 1986). The values obtained were 2.80×10^{-2} nm^3 for the pressure-quenched fcc phase and 3.12×10^{-2} nm^3 (Peterson *et al.*, 1971) for the temperature-quenched fcc phase. Similar results were found in the cases of Cm and Cf metals. In fact, for the three metals, the atomic volumes of their temperature-quenched fcc phases are all larger than those of their RTP dhcp phases. In contrast, the atomic volumes of their pressure-quenched fcc phases at RTP are in good agreement with those of their RTP dhcp phases (Haire *et al.*, 1986). The argument is made that the lattice parameter of the pressure-quenched fcc phase of these metals is preferred to that of the temperature-quenched fcc phase, in that it provides consistency with the atomic volumes of their RTP dhcp phases and the known trend in lattice parameters of their corresponding mononitrides (Haire *et al.*, 1986).

In the first experiments to measure the vapor pressure of metallic berkelium using Knudsen effusion target-collection techniques, the preliminary data were fitted with a least-squares line to give a provisional vaporization equation for the temperature range 1326–1582 K and $\Delta_{\mathrm{v}}H^0_{298} = (382 \pm 18)$ kJ mol^{-1} (Ward *et al.*, 1980). Later measurements of the vapor pressure of Bk metal over the temperature range 1100–1500 K, using combined Knudsen effusion mass-spectrometric and target-collection techniques (Ward *et al.*, 1982), led to the vaporization equations:

$$\log p(\mathrm{atm}) = (5.78 \pm 0.21) - (15718 \pm 253)/T(\mathrm{K})$$

for solid Bk between 1107 and 1319 K, and

$$\log p(\mathrm{atm}) = (5.14 \pm 0.17) - (14902 \pm 244)/T(\mathrm{K})$$

for liquid Bk between 1345 and 1528 K. The enthalpy of fusion was calculated to be 7.92 kJ mol^{-1}, and the enthalpy associated with the dhcp→fcc transition was calculated to be 3.66 kJ mol^{-1} (Ward *et al.*, 1982). The crystal entropy, S^0_{298}, of berkelium was estimated to be (76.2 ± 1.3) J K^{-1} mol^{-1} (Ward and Hill, 1976) and then later to be (78.2 ± 1.3) J K^{-1} mol^{-1}, and the average of data according to the second and third law data analysis yielded (310 ± 6) kJ mol^{-1} for its enthalpy of vaporization, $\Delta_{\mathrm{v}}H^0_{298}$ (Ward *et al.*, 1982). Earlier correlation systematics had suggested that the standard enthalpy of sublimation of berkelium metal, $\Delta_f H^0$(Bk(g)), is 280 kJ mol^{-1}, and that the standard enthalpy of formation of aqueous Bk(III), $\Delta_f H^0$ (Bk^{3+}(aq)), is −615 kJ mol^{-1} (Nugent *et al.*, 1973a; Johansson and Rosengren, 1975). A later modification of the systematics (Nugent *et al.*, 1973a) led to values of (320 ± 8) kJ mol^{-1} and −(590 ± 21) kJ mol^{-1} for $\Delta_f H^0$ (Bk(g)) and $\Delta_f H^0$ (Bk^{3+}(aq)), respectively (David *et al.*, 1976). There is very good agreement between the value of (320 ± 8) kJ mol^{-1} for $\Delta_f H^0$ (Bk(g)) derived from systematics and the value of (310 ± 6) kJ mol^{-1} for $\Delta_v H^0_{298}$, which is the same thermodynamic quantity, derived from experiment.

The enthalpy of solution of Bk metal (dhcp) to Bk^{3+}(aq) in 1 M HCl at 298 K was determined from five measurements to be −(576 ± 25) kJ mol^{-1} (Fuger *et al.*, 1975). The error limits reported did not reflect the precision of the calorimetric measurements but rather the uncertainties in the purity of the berkelium metal. A new determination of the enthalpy of solution of Bk metal (dhcp) in 1 M HCl at (298.15 ± 0.05) K has yielded a value of −(600.2 ± 5.1) kJ mol^{-1} (Fuger *et al.*, 1981). From this value $\Delta_f H^0$ (Bk^{3+}(aq)) was derived to be −(601± 5) kJ mol^{-1}, in good agreement with the value from systematics (David *et al.*, 1976), and, using reasonable entropy estimates, the standard potential of the Bk(III)/Bk(0) couple was calculated to be −(2.01 ± 0.03) V (Fuger *et al.*, 1981).

Studies of the magnetic susceptibility of berkelium metal have been hampered by the difficulty in obtaining well-characterized, single-phase bulk samples containing minimal amounts of daughter californium. Recent results obtained from a 21 μg sample of dhcp Bk metal (~12 at% Cf) indicated a transition to antiferromagnetic behavior at about 34 K and paramagnetic behavior between 70 and 250 K (Nave *et al.*, 1980). Applying the Curie–Weiss susceptibility relationship to the berkelium data obtained at fields greater than 0.08 T (where the field dependency was saturated) yielded $\mu_{\text{eff}} = 9.69\ \mu_B$ and $\theta = 101.6$ K. The agreement of this value with the theoretical free-ion effective moment (9.72 μ_B) calculated for trivalent berkelium with LS coupling suggests that dhcp Bk metal exhibits high-temperature magnetic behavior like its lanthanide homolog, terbium. The results of earlier magnetic measurements on smaller samples of berkelium metal exhibiting mixed phases were reported by others (Fujita, 1969; Peterson *et al.*, 1970).

(c) Chemical properties

During the handling of microgram-sized samples of berkelium metal, it was observed that the rate of oxidation in air at room temperature is not extremely rapid, possibly due to the formation of a ‘protective’ oxide film on the metal surface (Peterson *et al.*, 1970). Berkelium is a chemically reactive metal, and berkelium hydride (Fahey *et al.*, 1972), some chalcogenides (Fahey *et al.*, 1972; Damien *et al.*, 1979, 1981), and pnictides (Stevenson and Peterson, 1979; Damien *et al.*, 1980) have been prepared directly from the reaction of Bk metal with the appropriate nonmetallic element. Berkelium metal dissolves rapidly in aqueous mineral acids, liberating hydrogen gas and forming Bk(III) in solution.

(d) Theoretical treatment

A hybridized nondegenerate 6d and 5f virtual-bound-states model has been used to describe the properties of the actinide metals, including berkelium (Jullien *et al.*, 1972). It accounted for the occurrence of localized magnetism in Bk metal. A review of the understanding of the electronic properties of berkelium metal as derived from electronic band theory was published shortly thereafter (Freeman and Koelling, 1974). Included was the relativistic energy band structure of fcc Bk metal ($5f^86d^17s^2$), and the conclusion was that berkelium is a rare earth-like metal with localized (ionic) 5f electrons resulting from less hybridization with the 6d and 7s itinerant bands than occurs in the lighter actinides.

A phenomenological model based on crystal structure, metallic radius, melting point, and enthalpy of sublimation has been used to arrive at the electronic configuration of berkelium metal (Fournier, 1976). An energy difference of 0.92 eV was calculated between the $5f^97s^2$ ground state and the $5f^86d^17s^2$ first excited state. The enthalpy of vaporization of trivalent Bk metal was calculated to be 2.99 eV (288 kJ mol^{-1}), reflecting the fact that berkelium metal is more volatile than curium metal. It was also concluded that the metallic valence of the fcc form of berkelium metal is less than that of its dhcp modification (Fournier, 1976).

A relativistic Hartree–Fock–Wigner–Seitz band calculation has been performed for Bk metal in order to estimate the Coulomb term U (the energy required for a 5f electron to hop from one atomic site to an adjacent one) and the 5f electron excitation energies (Herbst *et al.*, 1976). The results for berkelium, in comparison to those for the lighter actinides, show increasing localization of the 5f states, i.e. the magnitude of the Coulomb term U increases through the first half of the actinide series with a concomitant decrease in the width of the 5f level.

10.6.2 Intermetallics

There have been no reports of berkelium intermetallics. Bk–Cf alloys formed from the natural decay of ^{249}Bk metal samples have been studied and are discussed in Section 10.6.3.

10.6.3 Alloys

^{249}Bk ($t_{1/2}$ = 330 days) decays by β^- emission to ^{249}Cf, and because this transition occurs on an atomic scale at randomly distributed lattice sites, truly homogeneous solid solutions (alloys) result. Two such alloys, one Bk-rich (65%)

and the other Cf-rich (60%), have been studied under pressure via energy-dispersive X-ray powder diffraction (Itié *et al.*, 1985; Peterson *et al.*, 1987). The Bk-rich alloy exhibited the same phases with increasing pressure as did pure Bk metal, and the Cf-rich alloy exhibited the same phases with increasing pressure as did pure Cf metal (Peterson *et al.*, 1987). Continuity was observed between the values for pure Bk and Cf metals in the phase-transition pressures, the relative volume and volume decrease upon delocalization (point at which the α-uranium structure is first exhibited), and the bulk modulus. Thus one can consider these alloys as actinide metals with nonintegral atomic numbers (Itié *et al.*, 1985).

Two ^{248}Cm–Bk alloys have been prepared by reduction of their mixed anhydrous trifluorides (precipitated from aqueous solution and treated with fluorine) with lithium metal (Heathman and Haire, 1998). One alloy contained 30% Bk and the other contained 54% Bk. The stated goal of this work was to understand the phase and relative volume behavior of both alloys in terms of chemical bonding, each element's electronic configuration, and the alloys' pressure behavior relative to that reported for the pure Am–Cf metals (Heathman and Haire, 1998). The structural behavior of these two alloys was monitored by energy-dispersive X-ray powder diffraction. Both exhibited the expected RTP dhcp phase that transformed to the fcc phase at 12 GPa (30% Bk) or 8 GPa (54% Bk). The fcc phase changed to a third, unidentified phase at 35 GPa (30% Bk) or at 24 GPa (54% Bk), which was retained up to the maximum pressure studied (53 GPa) (Heathman and Haire, 1998). These results are consistent with the phase-transition pressures in pure Cm and Bk metals, i.e. the greater the concentration of Bk in the alloy, the lower the corresponding phase transition pressure.

10.7 COMPOUNDS

10.7.1 General summary

The trivalent oxidation state of berkelium prevails in the known berkelium compounds, although the tetravalent state is exhibited in BkO_2, BkF_4, Cs_2BkCl_6, and $[N(CH_3)_4]_2BkCl_6$. Selected crystallographic data for a number of berkelium compounds are collected in Table 10.2. In cases where there have been multiple reports of lattice parameters for a particular compound, the ones considered more reliable by the present authors are given in Table 10.2. The interested reader is encouraged to refer to the citations given in the table and text for complete details. An inherent difficulty, not addressed here, in the determination of lattice constants of 'pure' ^{249}Bk compounds concerns the ingrowth of daughter ^{249}Cf at the rate of about 0.22% per day. Two experimental methods to address this problem are: (1) the determination of the lattice parameters of berkelium compounds as a function of californium content and then extrapolation to zero californium content; and (2) the utilization of Vegard's law to correct measured berkelium lattice parameters for the presence of a known amount of californium (assuming, of course, that the lattice parameters of the isostructural 'pure' californium compound are known).

A summary and discussion of the structural aspects of solid-state actinide chemistry are presented in Chapter 22, so no attempt is made to do so here for the compounds of berkelium. Estimated thermochemical values for many compounds of berkelium can be found in Chapter 19. Only those values determined by direct experiment are discussed here.

An empirical set of 'effective' ionic radii in oxides and fluorides, taking into account the electronic spin state and coordination of both the cation and the anion, have been calculated (Shannon and Prewitt, 1969). For six-coordinate Bk(III), the radii values are 0.096 nm, based on a six-coordinate oxide ion radius of 0.140 nm, and 0.110 nm, based on a six-coordinate fluoride ion radius of 0.119 nm. For eight-coordinate Bk(IV), the corresponding values are 0.093 and 0.107 nm, respectively, based on the same anion radii (Shannon and Prewitt, 1969). Other self-consistent sets of trivalent and tetravalent lanthanide and actinide ionic radii, based on isomorphous series of oxides (Peterson and Cunningham, 1967a; Shannon, 1976) and fluorides (Peterson and Cunningham, 1968b; Shannon, 1976), have been published. Based on a crystal radius for Cf(III), the ionic radius of isoelectronic Bk(II) was calculated to be 0.114 nm (Ionova *et al.*, 1977). It is important to note, however, that meaningful comparisons of ionic radii can only be made if the values compared are calculated in like fashion from the same type of compound, with respect to both composition and crystal structure (Shannon, 1976).

The thermal decomposition of $Bk(NO_3)_3 \cdot 4H_2O$, $BkCl_3 \cdot 6H_2O$, $Bk_2(SO_4)_3 \cdot 12H_2O$, and $Bk_2(C_2O_4)_3 \cdot 4H_2O$ has been studied in air, argon, and H_2–Ar atmospheres and compared to that of the corresponding hydrates of cerium, gadolinium, and terbium (Haire, 1973). In air or Ar the final berkelium product was BkO_2; in H_2–Ar it was Bk_2O_3.

10.7.2 Hydrides

The preparation of berkelium hydride has been accomplished by treatment of berkelium metal at 500 K with H_2 gas derived from thermal decomposition of UH_3 (Fahey *et al.*, 1972). The product exhibited an fcc structure with lattice parameter $a_0 = (0.523 \pm 0.001)$ nm determined from nine observed X-ray diffraction lines. By analogy with the behavior of the lanthanide hydrides (Holley *et al.*, 1955), the stoichiometry BkH_{2+x} $(0 < x < 1)$ was assigned. Later studies of the berkelium–hydrogen system resulted in products with either fcc symmetry, identified as the dihydride, or hexagonal symmetry, which was taken to be berkelium trihydride, BkH_{3-x} $(0 < x < 1)$ (Gibson and Haire, 1985). Additional work is required to characterize fully the berkelium–hydrogen system.

10.7.3 Oxides

The first compound of berkelium identified on the basis of its characteristic X-ray powder diffraction pattern was BkO_2 (Cunningham, 1963). Other researchers have since confirmed its CaF_2-type fcc structure with $a_0 = 0.533$ nm (Peterson and Cunningham, 1967a; Baybarz, 1968, 1973; Fahey *et al.*, 1974; Sudakov *et al.*, 1977). The thermal expansion of BkO_2 in 1 atm of oxygen was determined and shown to be reversible with temperature (Fahey *et al.*, 1974). The data were fitted by the expression

$$a_0(t) = 5.3304 + (4.32 \times 10^{-5})t + (15.00 \times 10^{-9})t^2,$$

where $a_0(t)$ is the unit cell edge (in Å) at temperature t (in °C). In addition, the instantaneous expansion coefficients at 25 and 900°C were calculated to be $8.25 \times 10^{-6}\ °C^{-1}$ and $13.2 \times 10^{-6}\ °C^{-1}$, respectively (Fahey *et al.*, 1974).

The results of a preliminary study of a sample of berkelium oxide (BkO_2, Bk_2O_3, or a mixture of the two) via X-ray photoelectron spectroscopy (XPS) included measured core- and valence-electron-binding energies (Veal *et al.*, 1977). The valence-band XPS spectrum, which was limited in resolution by phonon broadening, was dominated by 5f electron emission. The photoelectron spectrum of the 4f lines of Bk in BkO_2 was recorded, and the binding energies of the $4f_{5/2}$ electrons determined to be 515.6(4) eV, and those of the $4f_{7/2}$ electrons, 499.6(4) eV (Krause *et al.*, 1988). These values were reported to be slightly lower than theoretical estimates, but the spin–orbit splitting of the 4f levels, 16.0 (3) eV, was in good agreement with the results of relativistic Hartree–Slater calculations (Krause *et al.*, 1988).

A capacitance manometer system was used to measure the equilibrium oxygen decomposition pressures over non-stoichiometric BkO_x $(1.5\ x < 2.0)$ (Turcotte *et al.*, 1971). Three broad non-stoichiometric phases were defined: $BkO_{1.5–1.77}$; $BkO_{1.81–1.91}$; and BkO_{2-x} $(x \leq 0.07)$. Later, an X-ray diffraction investigation of this BkO_x system under equilibrium conditions was undertaken to correlate the above data with structural behavior (Turcotte *et al.*, 1980). A phase diagram was suggested, showing above 673 K two widely non-stoichiometric phases: body-centered cubic (bcc) for $1.5 < O/Bk \leq 1.70$ and fcc for $1.78 \leq O/Bk < 2.00$. Interestingly, no evidence was found for the formation of Bk_7O_{12}, expected to exhibit a rhombohedral structure based on its common presence in other MO_x $(1.5 < x < 2.0)$ systems. Using the data from the work of others (Peterson and Cunningham, 1967a; Baybarz, 1968, 1973; Turcotte *et al.*, 1980), a berkelium–oxygen phase diagram was constructed over the range from 59 to 67 at% oxygen and from 200 to 900°C (Okamoto, 1999). Also provided is a summary of Bk–O crystal structure data.

The stable room-temperature form of berkelium sesquioxide exhibits the bixbyite-type bcc structure with $a_0 = 1.0887$ nm (Peterson and Cunningham, 1967a). This has been corroborated by an independent study (Baybarz, 1968, 1973). The cubic sesquioxide has also been analyzed by electron diffraction

(Haire and Baybarz, 1973). The high-temperature behavior of Bk_2O_3 has been studied, with the finding that the cubic-to-monoclinic transition at (1473 ± 50) K is irreversible, while the monoclinic-to-hexagonal transition at about 2025 K is reversible (Baybarz, 1973). In addition, the melting point of Bk_2O_3 was determined to be (2193 ± 25) K. Thus berkelium continues the trend of actinide sesquioxides exhibiting trimorphism; with increasing temperature, the structure of Bk_2O_3 changes from bcc (C-form) to monoclinic (B-form) to hexagonal (A-form).

The possibility of the existence of BkO has been considered (Fahey *et al.*, 1972). The true identity of the brittle, gray material exhibiting an fcc structure with $a_0 = 0.4964$ nm is still in doubt. This phase might represent a nitride or an oxide nitride.

A preliminary report of the synthesis and structural characterization of polycrystalline $Bk_2M_2O_7$ and solid solutions of $(Bk,M)O_2$, where M = Zr or Hf, has been given, but no specifics were provided (Haire and Raison, 2000). In a later report the lattice parameter for $Bk_2Zr_2O_7$ was presented to be 1.058 nm in a graph (Haire *et al.*, 2002).

As part of an investigation of the fundamental chemistry and materials science of the 4f and several 5f elements in glass matrices, berkelium was put into two high-temperature (850 and 1450°C), silicate-based glasses and into one sol–gel glass (formed by the hydrolysis of a silicate ester) (Haire *et al.*, 1998). Berkelium (along with cerium and americium) provided an exception to the general observation that the oxidation state of the f element in the high-temperature glasses correlated with that in the element's usual binary oxide produced in air. The same correlation also applied to the f elements in the sol–gel glasses after they had been heated to 200–400°C. The authors only observed Bk(III) in the three glasses and reasoned that without the added stability afforded by the fluorite lattice in BkO_2, Bk(III) was the more stable oxidation state in these glasses (Haire *et al.*, 1998). The anomalous dependence on excitation power of the emission profile of Bk(III) in the 850°C silicate-based glass (Assefa *et al.*, 1998) has been discussed in Section 10.5.3.

10.7.4 Halides

The only reported binary Bk(IV) halide is BkF_4 (Asprey and Keenan, 1968; Keenan and Asprey, 1969; Asprey and Haire, 1973; Haug and Baybarz, 1975), prepared by fluorination of BkO_2 or BkF_3. Although these researchers agree that it exhibits the UF_4-type monoclinic structure, there is some variance in the reported lattice parameters. This could result from the complexity of the X-ray powder diffraction pattern of BkF_4. A molecular volume of 7.07×10^7 pm^3 is calculated from the lattice constants given in Table 10.2, in contrast to those of 7.148×10^7 pm^3 (Asprey and Haire, 1973) and 7.28×10^7 pm^3 (Asprey and Keenan, 1968; Keenan and Asprey, 1969) derived from the other reported lattice parameters. The solid-state absorption spectrum of BkF_4 was obtained by Ensor *et al.* (1981). Mixed alkali metal (M)–Bk(IV) fluoride compounds of the types $MBkF_5$, M_2BkF_6, M_3BkF_7, and $M_7Bk_6F_{31}$, although at present unreported, should be readily prepared. The structural systematics of such actinide fluoride complexes have been discussed elsewhere (Thoma, 1962; Penneman *et al.*, 1973).

In addition to $[N(CH_3)_4]_2BkCl_6$ (discussed in Section 10.7.7), one other Bk(IV) halide compound, Cs_2BkCl_6, has been characterized by its crystallographic properties (Morss and Fuger, 1969). This orange compound precipitated upon dissolution of Bk(IV) hydroxide in chilled, concentrated HCl solution containing CsCl, and was found to crystallize in the Rb_2MnF_6-type hexagonal structure with $a_0 = 0.7451$ nm and $c_0 = 1.2097$ nm. Using a separated halogen atom model, the lattice energy of this compound has been calculated to be 1295 kJ mol^{-1} and the average radius of the $BkCl_6^{2-}$ ion to be 0.270 nm (Jenkins and Pratt, 1979).

The trihalides of berkelium can be prepared by hydrohalogenation of BkO_2, Bk_2O_3, or a lighter berkelium halide. BkF_3 (Peterson and Cunningham, 1968b; Ensor *et al.*, 1981), $BkCl_3$ (Peterson and Cunningham, 1968a; Young *et al.*, 1978; Peterson *et al.*, 1981, 1986), and $BkBr_3$ (Burns *et al.*, 1975; Peterson *et al.*, 1977b) have been shown by X-ray powder diffraction and absorption spectrophotometric studies to be dimorphic. Berkelium is the lightest actinide whose trifluoride exhibits the YF_3-type orthorhombic structure as the room-temperature alpha phase and the LaF_3-type trigonal structure as the high-temperature phase (Peterson and Cunningham, 1968b).

In the case of dimorphic $BkCl_3$, the UCl_3-type hexagonal structure (Peterson and Cunningham, 1968a) represents the low-temperature form, while the $PuBr_3$-type orthorhombic structure is exhibited by the high-temperature modification (Peterson *et al.*, 1981, 1986). The phase-transition temperature appears to be close (Peterson *et al.*, 1981, 1986) to the $BkCl_3$ melting point (876 K) (Peterson and Burns, 1973). The volatilization behavior of many of the binary actinide chlorides including $BkCl_3$ has been studied and correlated with the oxidation state and atomic number ($Z < 92$ or $Z \geq 92$) of the actinide (Merinis *et al.*, 1970). More recent thermochromatographic studies of berkelium chloride using ^{250}Bk confirmed these early results, in that under non-oxidizing conditions, only one deposition peak was observed, corresponding to $BkCl_3$ (Yakushev *et al.*, 2003). With oxidizing conditions (Cl_2 or $Cl_2/SOCl_2$), however, a lower temperature deposition peak grows slowly over time and was assigned to more volatile $BkCl_4$. The adsorption enthalpies were calculated via a Monte Carlo simulation method (Zvara, 1985) and found to be $-(201 \pm 6)$ and $-(154 \pm 6)$ kJ mol^{-1} for $BkCl_3$ and $BkCl_4$, respectively (Yakushev *et al.*, 2003). White $Cs_2NaBkCl_6$ was crystallized from aqueous CsCl–HCl solution by increasing the HCl concentration and cooling to −23°C, and it was found to exhibit an fcc structure in which the Bk(III) ions (O_h site symmetry) are octahedrally coordinated by chloride ions (Morss and Fuger, 1969). The unique properties of such compounds stimulated the synthesis and study of an isostructural set of Cs_2NaMCl_6 compounds containing trivalent cations (including M = U, Np, Pu, Am, and Cf) whose ionic radii ranged from 0.065 to 0.106 nm (Morss *et al.*, 1970; Schoebrechts *et al.*, 1989).

X-ray diffraction from a powder sample of $BkCl_3 \cdot 6H_2O$ showed that it is isostructural with $AmCl_3 \cdot 6H_2O$, whose structure was refined by single-crystal diffraction methods (Burns and Peterson, 1971). By analogy, the basic units of the berkelium structure are $BkCl_2(OH_2)_6^+$ cations and Cl^- anions, the latter being octahedrally coordinated by water molecules.

From X-ray powder diffraction patterns of $BkBr_3$ obtained as a function of the sample's thermal treatment, it was concluded that the $PuBr_3$-type orthorhombic structure is the low-temperature form of $BkBr_3$, and the $AlCl_3$-type monoclinic structure is the high-temperature form (Burns *et al.*, 1975). Because these two crystallographic modifications differ by 2 in the Bk(III) CN, absorption spectrophotometric analysis easily distinguishes between them (Peterson *et al.*, 1977b). The possibility of a third polymorph of $BkBr_3$ has been suggested on the basis of eight lines of low intensity in one powder pattern (Burns *et al.*, 1975). If it does exist, it would be the form intermediate between the $PuBr_3$- and $AlCl_3$-type structures and would exhibit the $FeCl_3$-type rhombohedral structure with $a_0 = 0.766$ nm and $\alpha = 56.6°$ (Burns *et al.*, 1975). There is one additional report (Cohen *et al.*, 1968) with lattice parameters for the orthorhombic form of $BkBr_3$ and for BiI_3-type hexagonal BkI_3.

Samples of berkelium trifluoride, trichloride, tribromide, and triiodide have been studied over time to ascertain the physicochemical effects of beta decay in the bulk-phase solid state (Young *et al.*, 1984). In each case Bk^{3+} was found to transform to Cf^{3+}, and the crystal structure of the solid remained unchanged. Maintenance of oxidation state would seem to be a chemical effect of this transformation, whereas maintenance of crystal structure is more of a physical effect, the structure of the progeny being controlled by its environment. Details of the characterization and study of dimorphic $BkCl_3$, via X-ray powder diffraction and absorption spectrophotometry, have been published (Peterson *et al.*, 1986). The results of monitoring each of the crystal forms of $BkCl_3$ over a period of almost 3 years are included. Justification (and some limitations) for the use of electronic f→f absorption peaks in the spectra of berkelium (and other actinide) compounds for the elucidation of the crystal structures of these compounds (crystal-field effects) has been published (Peterson *et al.*, 1990). In addition to absorption spectrophotometry, phonon Raman spectroscopy has been shown to be an effective way to elucidate the structure of a solid-state compound. Each crystal type possesses a unique set of fundamental crystal vibrations resulting from the positions, coordinations, bonding, and masses of its atoms. A catalog of phonon Raman spectral data for selected actinide compounds, including both crystallographic and spectroscopic parameters for each individual crystal structure exhibited, is available (Wilmarth and Peterson, 1991). A discussion of the comparative science of the lanthanide and actinide halides, mainly focusing on the trivalent chlorides and bromides, provides the systematics into which berkelium fits as expected (Peterson, 1995).

10.7.5 Chalcogenides and pnictides

The only other crystallographic result reported for a berkelium chalcogenide besides those summarized in Table 10.2 is a cubic lattice parameter of 0.844 nm for Bk_2S_3 (Cohen *et al.*, 1968). The microscale synthesis of the brownish-black sesquisulfide was carried out by treatment of berkelium oxide at 1400 K with a mixture of H_2S and CS_2 vapors. In a later work (Damien *et al.*, 1979, 1981), the higher chalcogenides were prepared on the 20–30 μg scale in quartz capillaries by direct combination of the elements. These were then thermally decomposed *in situ* to yield the lower chalcogenides. The stoichiometries of these compounds have not been determined directly.

The berkelium monopnictides have been prepared on the multi-microgram scale by direct combination of the elements (Damien *et al.*, 1980). In all cases the lattice constants of the NaCl-type cubic structures were smaller than those of the corresponding curium monopnictides but comparable to those of the corresponding terbium compounds. This supports the semimetallic classification for these compounds. One additional report of BkN has appeared (Stevenson and Peterson, 1979). The lattice parameter derived from the sample exhibiting a single phase was (0.5010 ± 0.0004) nm, whereas that extracted from the mixed-phase sample of BkN resulting from incomplete conversion of a hydride was (0.4948 ± 0.0003) nm. Additional samples of BkN should be prepared to establish more firmly its lattice constant.

10.7.6 Other inorganic compounds

BkOCl (Peterson and Cunningham, 1967b), BkOBr (Cohen *et al.*, 1968), and BkOI (Cohen *et al.*, 1968; Fellows *et al.*, 1977) have been synthesized and are found to exhibit the PbFCl-type tetragonal structure. Although presently unreported, BkOF certainly can be prepared and probably exhibits polymorphism.

Both the oxysulfate (body-centered orthorhombic) and the oxysulfide (trigonal) of Bk(III) have been studied by X-ray powder diffraction (Haire and Fahey, 1977). $Bk_2O_2SO_4$ resulted from the decomposition of $Bk_2(SO_4)_3 \cdot nH_2O$ in an argon atmosphere (to prevent oxidation to BkO_2) at about 875 K, whereas Bk_2O_2S was formed upon thermal decomposition of the sulfate hydrate in a 4% H_2/96% Ar atmosphere. No decomposition of the oxysulfide was observed up to 1300 K in the H_2/Ar gas mixture (Haire and Fahey, 1977). Both $Bk_2O_2SO_4$ and Bk_2O_2S are isostructural with the corresponding lanthanide and actinide compounds.

Berkelium(III) orthophosphate has been prepared and characterized by X-ray powder diffraction and solid-state absorption and Raman spectroscopies (Haire *et al.*, 1983; Hobart *et al.*, 1983). Analysis of the X-ray data has shown this compound to be isostructural with samarium and europium orthophosphates and to exhibit similar lattice parameters (Haire *et al.*, 1983). The structure type was confirmed by the direct correlation of the Raman spectrum of $BkPO_4$ with those of the isostructural lanthanide orthophosphates (Hobart *et al.*, 1983).

The preparation of berkelium(III) sesquioxalate decahydrate has been reported, along with its monoclinic unit cell parameters and its absorption and Raman spectra. It was observed that the Bk(III) compound underwent oxidation in about 24 h to a non-stoichiometric Bk(IV) oxalate complex, presumably the result of its self-irradiation (Morris *et al.*, 2005).

10.7.7 Coordination compounds

A β-diketonate compound of Bk(III) has been prepared and reported to be stable when volatilized. The possibility of using this volatile compound in transport and subsequent separation of berkelium from other actinides has been proposed (Fedoseev *et al.*, 1983).

More recently $[N(CH_3)_4]_2BkCl_6$ samples were prepared from cold, concentrated HCl(aq) on the milligram scale and studied via X-ray powder diffraction and optical spectroscopy in KBr and KCl pellets (Morss *et al.*, 1991). The powder patterns were indexed on fcc symmetry, with $a_0 = 1.308(2)$ nm, although from systematics a smaller lattice parameter was expected. No fluorescence attributable to Bk^{4+} was found under several modes of excitation. Strong f-center absorptions, due to radiation damage, and several very weak absorptions, presumably due to transitions to the first excited state of Bk^{4+}, were noted (Morss *et al.*, 1991).

10.7.8 Organometallic compounds

Two cyclopentadienylberkelium(III) compounds have been reported, but only one of them, $Bk(C_5H_5)_3$, has been characterized crystallographically (Laubereau and Burns, 1970). In addition to the data given in Table 10.2, the formula volume of this compound is 2.98×10^8 pm^3. The amber-colored tris(cyclopentadienyl)berkelium(III) was isolated from a reaction mixture of $BkCl_3$ and molten $Be(C_5H_5)_2$ by sublimation in vacuum at 475–495 K. It decomposes to an orange melt at 610 K (Laubereau and Burns, 1970).

During vacuum sublimation from a mixture of $BkCl_3$ and molten $Be(C_5H_5)_2$ at temperatures above 500 K (up to 600 K), a second berkelium fraction was obtained (Laubereau, 1970). Its identity was established to be bis(cyclopentadienyl)berkelium(III) chloride dimer, $[Bk(C_5H_5)_2Cl]_2$, based on the similarities of its X-ray powder diffraction pattern and sublimation behavior to those of known $[Sm(C_5H_5)_2Cl]_2$. The solid-state absorption spectrum of $[Bk(C_5H_5)_2Cl]_2$ was obtained and noted to be very similar to that of $Bk(C_5H_5)_3$ (Laubereau, 1970).

10.7.9 Magnetic behavior of berkelium ions

In order to improve upon the precision (±10%) of the initial measurements of the magnetic susceptibility of Bk(III) ions (Cunningham, 1959) and to extend the range of measurements to lower temperatures, single beads of cation-exchange resin were saturated with Bk(III) and subjected to susceptibility measurements over the temperature range 9–298 K (Fujita, 1969). The magnetic behavior of Bk(III) over the entire temperature range was described well by the Curie–Weiss relationship with $\mu_{\mathrm{eff}} = (9.40 \pm 0.06)\ \mu_{\mathrm{B}}$ and $\Theta = (11.0 \pm 1.9)$ K. The magnetic susceptibility of Bk(III) in an octahedral environment of host matrix $Cs_2NaLuCl_6$ was measured; temperature-independent paramagnetism was observed over the temperature range 10–40 K, with the lowest level of Bk(III) determined to be Γ_1 and with a Γ_1–Γ_4 separation of $8.5 \times 10^3\ \mathrm{m}^{-1}$ (Hendricks *et al.*, 1974).

Results of electron paramagnetic resonance (Boatner *et al.*, 1972) and magnetic susceptibility (Karraker, 1975) studies of Bk(IV) in ThO_2 have been reported. The eight-line hyperfine pattern confirmed that the nuclear spin of ^{249}Bk is 7/2; the estimated nuclear moment was $(2.2 \pm 0.4)\ \mu_{\mathrm{N}}$ (Boatner *et al.*, 1972). Two regions of temperature-dependent paramagnetism of BkO_2 in ThO_2 were observed over the temperature range 10–220 K; the possibility of an antiferromagnetic transition at 3 K was noted (Karraker, 1975).

The first measurements of the magnetic susceptibilities of bulk-phase samples of some berkelium compounds (BkO_2, BkF_3, BkF_4, and BkN) were made in 1981. The effective moments were found to agree with the calculated free-ion values, assuming Bk(IV) or Bk(III) cores and LS coupling (Nave *et al.*, 1981). The paramagnetic effective moments for BkF_4 and BkO_2 were determined from a Curie–Weiss fit to the data displayed in Fig. 10.5. The experimentally determined μ_{eff} values for BkF_4 and BkO_2 of $(7.93 \pm 0.03)\ \mu_{\mathrm{B}}$ and $(7.92 \pm 0.1)\ \mu_{\mathrm{B}}$, respectively, are in good agreement with a localized $5f^7$ ionic model where μ_{eff} (theory) $= 7.94\ \mu_{\mathrm{B}}$ (Nave *et al.*, 1983).

10.8 IONS IN SOLUTION

10.8.1 Oxidation states

Berkelium exhibits both III and IV oxidation states in solution, as would be expected from the oxidation states displayed by its lanthanide counterpart, terbium. Evidence has been offered for the existence of Bk(II), but there is only speculation on the possible existence of Bk(V). Bk(III) is the most stable oxidation state in non-complexing aqueous solutions. Bk(IV) is reasonably stable in solution in the absence of reducing agents because of the stabilizing influence of the half-filled $5f^7$ subshell. Bk(III) and Bk(IV) exist in aqueous solution as simple hydrated ions, Bk^{3+}(aq) and Bk^{4+}(aq), respectively, unless complexed by ligands. Bk(III) is green in most mineral acid solutions. Bk(IV) is yellow in HCl solution and orange-yellow in H_2SO_4 solution.

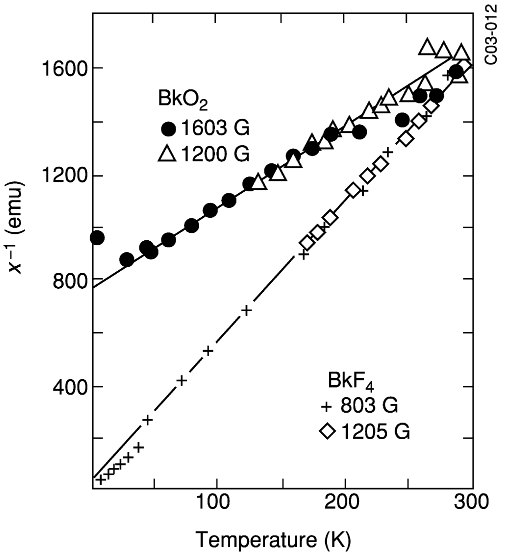

Fig. 10.5 *Inverse magnetic susceptibility of* BkF_4 *at* 803 *and* 1205 G *and* BkO_2 *at* 1200 *and* 1603 G *as a function of temperature.* (*The solid lines are least-squares fits of the data to the Curie–Weiss law.*) (*Reprinted figure with permission from Nave* et al. (1983). *Copyright* 1983 *by the American Physical Society.*)

The possible existence of divalent berkelium was studied by polarography in acetonitrile solution. Because of high background currents, caused by radiolysis products obscuring the polarographic wave, evidence for Bk(ii) was not obtained (Friedman and Stokely, 1976). Divalent berkelium has been reported to exist in mixed lanthanide chloride–strontium chloride melts. The claim is based on the results of the distribution of trace amounts of berkelium between the melt and a solid crystalline phase (co-crystallization technique) (Mikheev *et al.*, 1979; D'yachkova *et al.*, 1980). As discussed in Section 10.8.2, additional evidence for the transient existence of Bk(ii), generated via pulse radiolysis of an aqueous bicarbonate–ethanol solution, has been reported (Sullivan *et al.*, 1988).

10.8.2 Spectra in solution

The first attempts to measure the absorption spectrum of Bk(iii) involved the use of a single ion-exchange resin bead (Cunningham, 1959). Later the spectrum of a 3.6×10^{-3} M Bk(iii) solution was recorded in a microcell (Gutmacher *et al.*, 1967). Sixteen absorption bands of Bk(iii) were identified in the solution spectrum recorded in a 'suspended-drop' microcell over the wavelength range 320–680 nm (Peterson, 1967, 1980). The results of additional observations identified a total of 23 absorption bands in the 280–1500 nm wavelength region (Fujita, 1969).

The first attempts to record the Bk(IV) solution absorption spectrum were hindered by the presence of cerium impurities (Gutmacher *et al.*, 1967). The positions of the Bk(IV) absorption bands, superimposed on the strong Ce(IV) bands, suggested the assignment of $5f^7$ for the electronic configuration of Bk(IV), which is in agreement with the actinide hypothesis.

The absorption spectra of Bk(III) and Bk(IV) have been recorded in a variety of solutions (Baybarz *et al.*, 1972). New absorption bands were reported as the result of using larger quantities of ^{249}Bk of higher purity. Observations of the spectrum of Bk(III) were extended further into the UV wavelength region (to 200 nm), and nine new absorption bands were reported (Gutmacher *et al.*, 1973). An interpretation of the low-energy bands in the solution absorption spectra of Bk(III) and Bk(IV) was published (Carnall *et al.*, 1971). Later experimental work using larger quantities of berkelium than had been available previously, coupled with a new technique for rapidly separating small quantities of daughter ^{249}Cf, has resulted in a Bk(III) solution absorption spectrum with minimal interference from radiolysis products and significantly higher resolution than those of previously published spectra (Carnall *et al.*, 1984). A parametric fit of the data was performed in order to obtain the energy-level structure of the Bk^{3+} aquo ion. The band intensities were analyzed using the Judd–Ofelt theory, and fluorescent branching ratios were computed from theoretical parameters (Carnall *et al.*, 1984).

The spectra of Bk(III) and Bk(IV) in complexing, concentrated aqueous carbonate solutions have been reported (Hobart *et al.*, 1990). Bk(III) rapidly oxidizes in strongly basic carbonate solutions, and thus the Bk(III) spectrum could only be obtained by electrochemically reducing Bk(IV) in such solutions in a semi-micro cell. The stable Bk(IV) carbonate solution spectrum exhibited a strong charge transfer band peaking at 282 nm in 2 M carbonate solution and at 274 nm in 5 M carbonate solution. The Bk(III) carbonate spectrum showed characteristic f–f transitions superimposed on remnants of the Bk(IV) spectrum. The spectra of Bk(III) in 0.1 M citrate solution at pH values of 1 and 4 have also been reported (Hobart *et al.*, 1990).

The solution absorption spectra of 1×10^{-4} M solutions of yellow Bk(IV) nitrate- and brown Bk(IV) perchlorate–triphenylarsine oxide adducts in acetonitrile were recorded as a result of ozonolysis of initial Bk(III) adduct solutions. Both Bk(IV) spectra exhibited a charge transfer UV cutoff around 300 nm (Payne and Peterson, 1987).

Fluorescence X-ray absorption near-edge spectra (XANES) and the L_3-edge fluorescence X-ray absorption fine structure (XAFS), and their Fourier transforms, of Bk(III) and Bk(IV) aquo ions have been published (Antonio *et al.*, 2002).

Although there have been a number of elegant solid-state studies that provided indirect evidence for the existence of the divalent state of berkelium (e.g. Young *et al.*, 1981), an attempt was made to generate Bk(II) in an aqueous bicarbonate–ethanol solution via pulse radiolysis (Sullivan *et al.*, 1988). The absorption

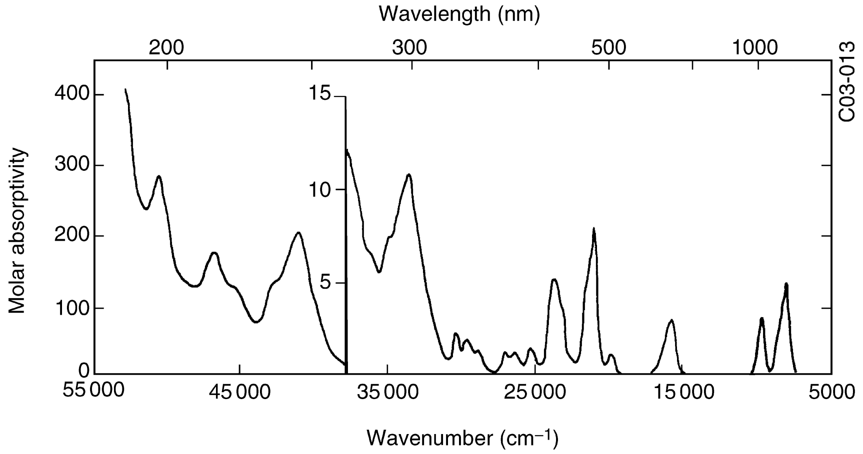

Fig. 10.6 *Solution absorption spectrum of Bk(*III*) in* 0.2 M *$HClO_4$ (DCl solutions were used for portions of the infrared spectrum) (Carnall* et al., 1984).

spectrum of Bk(II), obtained by subtracting out the contributions of the ethanol radical, yielded a peak with a maximum at 310 nm and a molar absorptivity of $(2.3 \pm 0.2) \times 10^3$ cm^{-1} M^{-1}. Bk(II) is unstable in this medium, and the rate of its disappearance was reported to be $(1.53 \pm 0.25) \times 10^5$ s^{-1} (Sullivan *et al.*, 1988).

The solution absorption spectrum of non-complexed Bk(III) is shown in Fig. 10.6. This spectrum is characterized by sharp absorption bands of low molar absorptivity attributed to 'Laporte-forbidden' f–f transitions and by intense absorption bands in the UV region attributed to f–d transitions (Gutmacher *et al.*, 1973). The spectra of Bk(IV) shown in Fig. 10.7 are dominated by a strong absorption band at 250–290 nm, the peak position of which is strongly dependent on the degree of complexation of Bk(IV) by the solvent medium. This dominant band is attributed to a charge transfer mechanism (Gutmacher *et al.*, 1973).

Electronic spectra of Bk(III) (Varga *et al.*, 1973b; Carnall *et al.*, 1984) and Bk(IV) (Varga *et al.*, 1973c) and a prediction of the electronic spectrum of Bk(II) (Varga *et al.*, 1973a) have been published. Spin–orbit coupling diagrams for these berkelium ions, based on a free-ion interpretation of the f–f spectra, were proposed. Further discussion of the absorption spectra of berkelium ions in solution can be found in Chapter 18.

10.8.3 Hydrolysis and complexation behavior

Although Bk(IV) is well known in solution, only stability constants of complexes with Bk(III) have been reported, most of which were determined during investigations of separation procedures. A compilation of the stability constants of Bk(III) complexes with various anions is given in Table 10.3. In most cases the

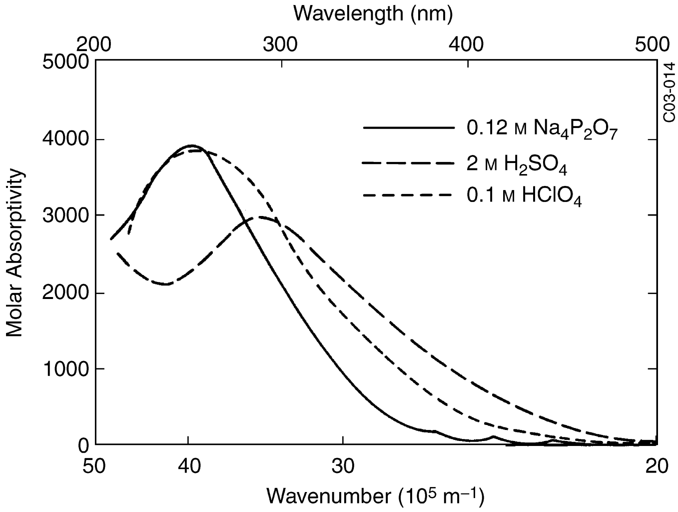

Fig. 10.7 *Solution absorption spectra of Bk*(IV) *in various media* (*Gutmacher* et al., 1973).

lack of replicate results precludes an assessment of the accuracy of the reported values. The reader should consult the original sources for any information regarding the precision of the stability constant values. Although the number of directly measured stability constants for complexes of Bk(III) is rather small, a number of additional, reasonably accurate values for other complexes of Bk(III) can be obtained by interpolation of the stability constant data for the corresponding complexes of Am(III), Cm(III), and Cf(III).

Attempts to obtain thermodynamic data for solvent extraction of Bk(III) by thenoyltrifluoroacetone (TTA) in benzene and for complexation of Bk(III) by hydroxide and citrate ions were unsuccessful (Hubert *et al.*, 1976). The high extractibility and complexibility of the easily accessible tetravalent state of berkelium probably accounts for the difficulty encountered in this study. However, TTA was used successfully to determine the first hydrolysis constant (Désiré *et al.*, 1969; Hussonnois *et al.*, 1973) and citrate complexation constants (Aly and Latimer, 1970; Stepanov, 1971) of Bk(III).

Although no complexation constant values have been reported for Bk(IV), one study is worth noting (Makarova *et al.*, 1979). The electromigration behavior of Bk(IV), Ce(IV), and other actinide(IV) ions was studied in perchloric and nitric acid solutions and mixtures of these acids. In pure 6 M $HClO_4$ both Bk(IV) and Ce(IV) have equal mobilities of $(13.0 \pm 1.0) \times 10^{-5}$ cm^2 V^{-1} s^{-1} and behave as free hydrated ions. As HNO_3 is added to $HClO_4$ solution, keeping the total acid concentration constant at 6 M, the mobility of both ions decreases, with the Bk(IV) mobility decreasing more sharply and then remaining constant (4×10^{-5} cm^2 V^{-1} s^{-1}) between 3 and 6 M HNO_3 (Makarova *et al.*, 1979). The decreased mobility is attributed to changes in the charge of the berkelium species, possibly

forming $[Bk(H_2O)_x(NO_3)_3]^+$ between 3 and 6 M HNO_3. It was also reported that Bk(IV) does not form negatively charged species up to 10 M HNO_3. This study provides an explanation for the differences observed in the ion-exchange and solvent extraction behavior of Bk(IV) as compared to that of Ce(IV), Th(IV), Np(IV), and Pu(IV) (Makarova *et al.*, 1979).

The extraction of Bk(III) by organophosphorus acids has been studied, and activity coefficients for Bk(III) in nitric acid solution were estimated (Chudinov *et al.*, 1976). In addition a mechanism for the extraction of Bk(IV) by HDEHP from nitric acid solution was proposed. The self-diffusion coefficients (D) of Bk(III) ion in perchloric acid media were measured using the open-end capillary method (Latrous and Oliver, 1999). The limiting value, D_0, at zero ionic strength was reported to be 5.95×10^{-6} cm^2 s^{-1}. This value is in good agreement with $D_0 = 5.81 \times 10^{-6}$ cm^2 s^{-1}, calculated by using a microscopic version of the Stokes–Einstein law (Mauerhofer *et al.*, 2003). Both reported values correlate well with experimentally determined values for neighboring trivalent actinide and analog lanthanide ions.

The kinetics of exchange of Bk(III) with $EuEDTA^-$ (EDTA = ethylenediaminetetraacetic acid) in aqueous acetate solutions of 0.1 M ionic strength has been studied (Williams and Choppin, 1974). The exchange was found to be first order with both acid-dependent and acid-independent rate terms. Rate values were calculated and compared to other actinide reaction rates.

The aqueous solubilities of Bk(III) oxalate and Bk(IV) iodate have been reported to be 1.5 and 10 mg L^{-1}, respectively (Erin *et al.*, 1977).

10.8.4 Redox behavior and potentials

Berkelium(III) in solution can be oxidized by strong oxidizing agents such as BrO_3^- (Knauer and Weaver, 1968; Weaver, 1968; Fardy and Weaver, 1969; Overman, 1971; Erin *et al.*, 1979b; Malikov *et al.*, 1980), AgO (Erin *et al.*, 1976), $Ag(I)S_2O_8^{2-}$ (Milyukova *et al.*, 1977, 1978, 1980), perxenate (Lebedev *et al.*, 1975), and ozone (Myasoedov *et al.*, 1973, 1974, 1975; Myasoedov, 1974).

Oxidation of green Bk(III) hydroxide as a suspension in 1 M NaOH to yellow Bk(IV) hydroxide was performed by bubbling ozone through the slurry (Cohen, 1976). In hydroxide solution, Bk(III) is unstable toward oxidation by radiolytically produced peroxide (Cohen, 1976). This 'self-oxidation' has also been observed in carbonate solutions (Baybarz *et al.*, 1972; Timofeev *et al.*, 1987; Hobart *et al.*, 1990; Morris *et al.*, 1990). Bk(III) can be stabilized in these solutions, however, by the presence of a reducing agent such as hydrazine hydrate (Cohen, 1976).

$BkCl_3$ is reported to be soluble in acetonitrile saturated with tetraethylammonium chloride (Nugent *et al.*, 1971). A colorless 7.6×10^{-4} M $BkCl_6^{3-}$ solution was formed that could be completely oxidized to red-orange $BkCl_6^{2-}$ by treatment with chlorine gas. The color of this Bk(IV) solution was quite similar to that observed for crystalline Cs_2BkCl_6 (Morss and Fuger, 1969).

Investigation of the amalgamation behavior of actinides in aqueous acetate and citrate solutions by treatment with sodium amalgam showed that berkelium and the lighter actinides do not readily form the amalgam. Those lanthanides that are known to exist only in the trivalent or the tetravalent state in solution also do not readily amalgamate. This behavior is in contrast to that of the heavier actinides californium, einsteinium, fermium, and mendelevium, and those lanthanides that exhibit stable divalent states, all of which readily amalgamate (Malý, 1967, 1969). This has been extensively studied as a basis for lanthanide/actinide and actinide/actinide separations and for determining redox reactions, kinetics, potentials, and other thermodynamic parameters (David *et al.*, 1990).

Bk(IV) is a strong oxidizing agent, comparable to Ce(IV) (Weaver and Stevenson, 1971). It can be coprecipitated with cerium iodate (Weaver, 1968) or zirconium phosphate (Cunningham, 1959). The stability of Bk(IV) solutions is a function of the degree of complexation of Bk(IV) by the solvent medium (Baybarz *et al.*, 1972). Bk(IV) is reduced by radiolytically generated peroxide in acidic and neutral solutions. The rate of reduction of Bk(IV) can be accelerated by the introduction of a reducing agent such as hydrogen peroxide (Peppard *et al.*, 1957; Kazakova *et al.*, 1975), hydroxylamine hydrochloride (Kazakova *et al.*, 1975), or ascorbic acid (Kazakova *et al.*, 1975).

Potentials of berkelium redox couples are summarized in Table 10.4. Replicate values for the Bk(IV)/Bk(III) couple under various conditions are in reasonable agreement with one another. The first estimate of the Bk(IV)/Bk(III) potential was made in 1950, only a short time after the discovery of the element. A value of 1.6 V was reported, based on tracer experiments (Thompson *et al.*, 1950a). Later, a refined value of (1.62 ± 0.01) V was reported for the couple, based on the results of experiments with microgram quantities of berkelium (Cunningham, 1959). The potential of the Bk(IV)/Bk(III) couple has subsequently been determined by several workers using direct potentiometry (Stokely *et al.*, 1969; Propst and Hyder, 1970; Nugent *et al.*, 1973b; Simakin *et al.*, 1977a; Kulyako *et al.*, 1981) or indirect methods (Musikas and Berger, 1967; Weaver and Fardy, 1969; Weaver and Stevenson, 1971). A recent, novel determination of the Bk(IV)/Bk(III) potential in $HClO_4$ solution, using *in situ* X-ray absorption spectroelectrochemistry, was reported to be (1.595 ± 0.005) V (Antonio *et al.*, 2002), in close agreement with some of the other values in perchloric acid solution listed in Table 10.4.

All of the above-mentioned determinations were performed in media of relatively low complexing capability. The potential of the Bk(IV)/Bk(III) couple is significantly shifted to less positive values in media containing anions that strongly complex Bk(IV). Values of 1.36 V (Stokely *et al.*, 1969; Kulyako *et al.*, 1981) and 1.12 V (Stokely *et al.*, 1972) have been reported for the couple in sulfuric and phosphoric acid solutions, respectively. Carbonate ions, apparently forming the strongest complex with Bk(IV) of the anions listed in Table 10.4, provide conditions for the least positive potential, 0.26 V (Stokely *et al.*, 1972), as compared to the potential of 1.6 V for the couple in non-complexing

perchlorate solutions (Stokely *et al.*, 1972; Simakin *et al.*, 1977a). Other studies of the Bk(IV)/Bk(III) couple in complexing concentrated carbonate solutions also yielded potential values significantly shifted from those in non-complexing perchloric acid media (Timofeev *et al.*, 1987; Hobart *et al.*, 1990; Morris *et al.*, 1990). This behavior closely parallels that of the Ce(IV)/Ce(III) couple. In fact the

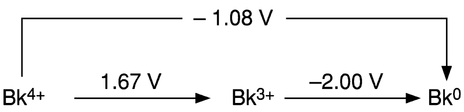

Fig. 10.8 *Standard reduction potential diagram for berkelium ions in acid solution* (*Chapter* 19).

Bk(iv)/Bk(iii) couple markedly resembles the Ce(iv)/Ce(iii) couple in its redox chemistry.

The overall thermodynamic and electrochemical data support a value of (1.67 ± 0.07) V for the standard potential (E°) of the Bk(iv)/Bk(iii) couple (Fuger and Oetting, 1976; Martinot and Fuger, 1985), which is 0.05 V less positive than the accepted value of (1.72 ± 0.02) V for the corresponding cerium couple (Morss, 1985), though within the stated uncertainties.

The potential of the Bk(iii)/Bk(0) couple has been investigated using radiopolarography (Samhoun and David, 1976, 1979) and theoretical calculations (Krestov, 1965), as well as by correlation with data concerning enthalpy of formation (David *et al.*, 1976; Fuger *et al.*, 1981). Estimates of the potentials of berkelium redox couples have also been made from correlation plots of electron-transfer and f–d absorption band energies versus redox potential and by theoretical calculations (Nugent *et al.*, 1971, 1973b, 1976; Nugent, 1975). The overall data support a value of –(2.00 ± 0.02) V for the standard potential of the Bk(iii)/Bk(0) couple.

Theoretical estimates of the potentials of the Bk(v)/Bk(0) and Bk(v)/Bk(iv) couples have been reported as 0.2 and 3.5 V, respectively (David *et al.*, 1976). These estimates suggest that Bk(v) would be very unstable in aqueous solution.

The scatter in the potential values of the Bk(iii)/Bk(ii) and Bk(iii)/Bk(0) couples in Table 10.4 reflects the necessary requirement of making estimates of thermodynamic quantities that have not been directly determined. A standard reduction potential diagram for berkelium ions is shown in Fig. 10.8. Additional information on the redox behavior of berkelium can be found in reviews by Martinot (1978) and Martinot and Fuger (1985).

10.8.5 Thermodynamic properties

Values of thermodynamic properties for the formation of berkelium ions in solution, according to the reactions:

$$\mathrm{Bk(cr,dhcp)} + 3\mathrm{H}^+(\mathrm{aq}) \rightarrow \mathrm{Bk}^{3+}(\mathrm{aq}) + 3/2\,\mathrm{H}_2(\mathrm{g})$$

and

$$\mathrm{Bk(cr,dhcp)} + 4\mathrm{H}^+(\mathrm{aq}) \rightarrow \mathrm{Bk}^{4+}(\mathrm{aq}) + 2\mathrm{H}_2(\mathrm{g}),$$

are summarized in Table 10.5. These values result from the evaluation of experimental measurements on the enthalpy of formation of Bk^{3+}(aq)

Table 10.5 *Thermodynamic quantities for simple aqueous berkelium ions at* 298 K.[a]

Bk ion	$\Delta_f H^o$ (kJ mol^{-1})	$\Delta_f G^o$ (kJ mol^{-1})	S° (J K^{-1} mol^{-1})

[a] Chapter 19.

(Fuger *et al.*, 1981), on the temperature dependence of the Bk(IV)/Bk(III) couple (Simakin *et al.*, 1977b), and on estimated entropies. These values are discussed in more detail in Chapter 19.

An electrostatic hydration model has been applied to the trivalent lanthanide and actinide ions in order to predict the standard Gibbs energy ($\Delta_{\text{hydr}}G_t^0$) and enthalpy ($\Delta_{\text{hydr}}H_t^0$) of hydration for these series. Assuming crystallographic and gas-phase radii for Bk(III) to be 0.096 and 0.1534 nm, respectively, and using 6.1 as the primary hydration number, $\Delta_{\text{hydr}}G_{298}^0$ was calculated to be –3357 kJ mol^{-1} and $\Delta_{\text{hydr}}H_{298}^0$ to be –3503 kJ mol^{-1} (Goldman and Morss, 1975). Later efforts to calculate semi-empirically entropy and enthalpy effects associated with hydration (David, 1986a,b), as well as an effort to intercorrelate non-complexed di-, tri-, and tetravalent actinide aquo ions based on crystallographic radii, have been published (David, 1986c). More recently the hydration enthalpy of Bk(III) has been derived by interpolation from data for the neighboring actinides attained by combining previously published thermodynamic and structural data with new data on high-symmetry elpasolites ($Cs_2NaAnCl_6$) using Born–Haber cycles (Schoebrechts *et al.*, 1989). The value obtained for Bk(III), $\Delta_{\text{hydr}}H_{298}^0 = -3501$ kJ mol^{-1}, is in excellent agreement with that calculated by Goldman and Morss (1975). A more comprehensive treatment of the thermodynamic properties of berkelium, including correlations of berkelium hydration enthalpies and Gibbs hydration energies with those of other actinides, can be found in Chapter 19.

Activity coefficients for Bk(III) in aqueous $NaNO_3$ solutions have been calculated from distribution data for the ion between the aqueous phase and a tertiary alkylamine organic phase (Chudinov and Pirozhkov, 1973). The activity coefficient values were reported as a function of the $NaNO_3$ concentration. Additional discussion of, and derived thermochemical properties for, a number of compounds of berkelium can be found in Chapter 19.

10.9 ANALYTICAL CHEMISTRY

The analytical determination of berkelium is dominated by radioanalytical methods, usually after separation from other radionuclides by procedures outlined in Section 10.4. ^{249}Bk, the most common isotope available, emits primarily (>99%) beta (β^-) particles up to a maximum energy of 125 keV. A proportional flow or liquid scintillation counter is used to measure this radiation. The use of scintillators for this determination is complicated by the fact that most substances quench the weak scintillations induced by the beta particles; however, a detection limit of ~0.1 Bq can be attained with an error of about 0.1% (Myasoedov, 1987). The beta decay of ^{249}Bk results in the ingrowth of daughter ^{249}Cf ($t_{1/2} = 351$ years) at about 0.22% per day. This has been utilized for an analytical determination of the parent berkelium. After an initial Bk/Cf separation, the ingrowth decay product is measured over time (Propst and Hyder, 1970) to determine the original berkelium amount.

Methods other than radioanalytical techniques have been developed for berkelium determination. Coulometric determinations of berkelium utilizing the Bk(IV)/Bk(III) couple have been reported (Propst and Hyder, 1970; Timofeev *et al.*, 1986). A spectrophotometric titration method for determination of microgram amounts of berkelium has been proposed (Frolova *et al.*, 1986). Berkelium is electrolytically oxidized to Bk(IV) in nitric acid solution and titrated with H_2O_2 or $NaNO_2$ solution with the equivalence point determined by the disappearance of the high molar absorptivity peak of Bk(IV) at 350 nm. The error in the determination of >70 mg of Bk is reported to be 3–5% (Frolova *et al.*, 1986).

Mass spectrometric techniques that provide increased sensitivity for detection of lanthanides and other actinides in berkelium samples have been developed. In 0.1 μg of berkelium, californium can be determined at the 0.03% level with an error of 10–20% (Tikhomirov *et al.*, 1981). The ionization efficiency of ^{250}Bk has been investigated utilizing an on-line isotope separator, which may have valuable applications in analytical determinations (Asai *et al.*, 2002).

A sensitive neutron-activation method for Bk determination in mixtures of curium and californium has been developed (Ivanov *et al.*, 1979). Thermal neutron irradiation of ^{249}Bk produces ^{250}Bk ($t_{1/2} = 3.217$ h) which emits intense gamma radiation at 989 keV that can be measured using a semiconductor detector. The absolute measurement error for Bk in a 2 μg sample was 1.8×10^{-4} %, and a detection limit for Bk of 4 pg was observed (Ivanov *et al.*, 1979).

The emission spectrum of berkelium over the range from 250 to 336 nm excited by an alternating current arc has been investigated in an effort to develop a semi-quantitative analysis method for berkelium in solutions containing large amounts of curium, cerium, and other elements. The reported detection limit for berkelium is 30 ng over the concentration range 1–100 μg of total metal per milliliter (Myasoedov, 1987).

10.10 CONCLUDING REMARKS

Berkelium is the first member of the second half of the actinide series of elements. Extended knowledge of the stability and accessibility of the various oxidation states of berkelium is important to the understanding and predictability of its physicochemical behavior. In addition such information would enable more accurate extrapolations to the physicochemical behavior of the transberkelium elements for which experimental studies are severely limited by lack of material and/or by intense radioactivity.

Although berkelium oxidation states 0, III, and IV are known in bulk phase, further work is required to characterize more completely the solid-state and solution chemistries of this element. The synthesis of divalent berkelium in bulk should be possible via the metallothermic reduction of its trihalides, e.g.

$$\mathrm{Bk} + 2\mathrm{BkBr}_3 \rightarrow 3\mathrm{BkBr}_2,$$

in an inert reaction vessel. It is quite possible that nature accomplishes this synthesis through alpha decay of the dihalides of ^{253}Es. A direct synthesis, however, would allow both absorption spectrophotometric and X-ray powder diffraction analyses, the results of which would aid in the identification of Bk(II) species in aged einsteinium dihalide samples that also contain Cf(II) (Peterson *et al.*, 1979; Young *et al.*, 1981).

Intermetallic compounds, various alloys, and additional semimetallic compounds of berkelium should be prepared and characterized to extend the knowledge of the physicochemical behavior of berkelium in these kinds of solids. Studies of such materials under pressure would be of interest in determining the effects of the non-berkelium component on physical properties such as bulk modulus (compressibility), pressure for the onset of 5f electron delocalization, and possible volume collapse associated with a change in the metallic valence of berkelium from three to four.

The range of oxidation states accessible to berkelium in solution should be further examined by using strong complexing agents in an effort to stabilize Bk(II), Bk(IV), and possibly Bk(V), produced chemically or electrochemically in nonaqueous or molten salt media. The complexation of Bk(III) with additional organic ligands should be studied to improve solvent extraction separation procedures. Also lacking to date, but experimentally obtainable, are stability constants of any complexes of Bk(IV). With an estimated potential of 3.5 V for the Bk(V)/Bk(IV) couple, it may be possible to prepare Bk(V) in a noncomplexing molten salt solution.

In the intervening years since the 1986 publication of the second edition of this work, a surprisingly large number of berkelium research reports have been published. This is significant because berkelium is quite rare and its longest-lived isotope has a half-life of a little less than 1 year. This continued interest must be attributed, in part, to the extensive use of ^{249}Bk as a nuclear target for creating still heavier elements. New research on this fascinating element will continue to contribute to the knowledge of the physicochemical properties of berkelium and will aid in elucidating the intricacies of the structure of the atom and in extending the limits of the periodic table.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of Ms Kathy Garduno at the Los Alamos National Laboratory for gathering some of the references included herein and of Ms Annie Loweere and Mr Josh Smith for graphics support. The cooperation of numerous colleagues in supplying and/or verifying information, identifying oversights, and in commenting on the manuscript is greatly appreciated. J.R.P. acknowledges with gratitude Professor B. B. Cunningham (University of California, Berkeley; deceased), whose guidance, inspiration, and personal interest during the first systematic study of the physicochemical properties of berkelium are still fondly remembered. D.E.H. acknowledges with sincere appreciation his coauthor, Professor Emeritus J.R.P., for his dedication in the early education and mentoring of his young protégé and in his continued rewarding collaborations in the exciting area of actinide chemistry.

The preparation of this chapter was sponsored by the Division of Chemical Sciences, Geosciences, and Biosciences, Office of Basic Energy Sciences, U.S. Department of Energy, under contracts W-7405-ENG-36 with Los Alamos National Laboratory, operated by the University of California, and DE-ACO5-00OR22725 with Oak Ridge National Laboratory, managed and operated by UT-Battelle, LLC.

CHAPTER ELEVEN

CALIFORNIUM

Richard G. Haire

11.1 INTRODUCTION

The discovery of californium came in the era of the syntheses and identifications of other transplutonium elements, following the end of World War II. The discovery of the element californium, like many of the other actinide elements, hinged on the development of new experimental techniques in conjunction with predictions based on nuclear systematics. Californium was named after the University and State of California where many of the transuranium elements were first identified. This element was discovered by Thompson, Street, Ghiorso, and Seaborg (Hyde *et al.*, 1971; Seaborg and Loveland, 1990) in February, 1950. The discovery of californium came only 2 months after the preparation and identification of the first isotope of berkelium, element 97 (see Chapter 10). An account of the discovery and reminiscences about the early work on californium has been given by Ghiorso (1983).

The first preparative method for californium was to bombard microgram targets of ^{242}Cm with 35 MeV helium ions in a 60 in. cyclotron. This produced ^{244}Cf by a (α,2n), reaction which decayed primarily by alpha emission ($t_{1/2}$ = 19.4 min, with two different alpha energies having a 75% and 25% branching ratios; see Table 11.1). This isotope also has a small decay branch that proceeds via electron capture. Since element 98 ('eka-dysprosium') was expected to have a stable tripositive oxidation state in aqueous solution, its elution behavior in chromatographic separation schemes was predicted and this was used as a guide to estimate which collection fractions should be examined for the new element. In addition to acquire a high degree of decontamination

* See Appendix II.

** The existence of these isotopes has been questioned but included for completeness.

from other radionuclides, it was also necessary that the chemical separations be completed rapidly (within about 1 h) due to the short half-life projected for this isotope of californium.

Californium, element 98, is in the second half of the actinide series, where its 5f electrons are further removed from the valence electrons than in the lighter actinide elements. It is this effect that makes californium more 'lanthanide-like' in many compounds and in solutions. However, in progressing across this half of the actinide series, there is also an increasing tendency for a divalent metallic state and the formation of a divalent state in compounds, and several compounds containing Cf(II) are known. Thus, its comparison to the lanthanide elements has limitations, as seen from topics discussed throughout this chapter. Unlike members of the second half of the lanthanide series, which may exhibit either a divalent or tetravalent oxidation state in addition to their more common trivalent state, californium is known to exhibit a divalent, trivalent, and tetravalent state in compounds. In solution, the trivalent state is dominant, although the II, IV states, and a potential V state have been reported. In its elemental state, californium properties differ from those exhibited by its lanthanide homolog, dysprosium.

When the existence of californium was established, scientific interests and efforts progressed to prepare other isotopes of this element, to determine their nuclear properties, and to investigate the chemistry of the element. These initial studies were performed using only small numbers of atoms, but it is to the credit of the early investigators that considerable amounts of chemical and nuclear data were accumulated in their work. Tracer experiments were sufficient to establish the stability of Cf(III) in solution, as well as some of the element's basic chemistry. Additional information on the chemistry of californium was generated as microgram quantities became available, which also permitted the preparation and study of solid compounds. The first compound of californium of a definitive structure (the oxychloride by Cunningham and Wallmann) was determined a decade after the discovery of the element (Seaborg and Loveland, 1990).

Larger quantities of the transplutonium elements, including californium, subsequently became available by the development of a reactor irradiation program that was initiated in the mid-1960s by the former U.S. Atomic Energy Commission. The U.S. Department of Energy retains the ability to produce these transplutonium elements, including sub-gram amounts of the different californium isotopes yearly in the High-Flux Isotope Reactor (HFIR) at Oak Ridge National Laboratory, Oak Ridge, Tennessee. The continued production at HFIR may be limited in the future. Transplutonium elements are also produced in high-flux reactors at Dimitrovgrad in the Russian Federation, and potentially in other reactors. Smaller amounts of californium can be generated by irradiation of special targets in accelerators, but in the best case these smaller quantities only serve for chemical tracer studies or for determining their nuclear properties.

Reactor-produced californium consists of californium isotopes from ^{249}Cf through ^{254}Cf, with the major isotope produced being ^{252}Cf. Californium isotopes produced in accelerators normally have lower atomic masses and obtained in much smaller quantities. Considering these production schemes and the californium daughters formed as daughter products of other decaying isotopes, californium isotopes with masses as small as 237 and as large as 256 have been reported. An example of accelerator-produced californium is the generation of ^{242}Cf reported by Sikkeland and Ghiorso (1967), in the time frame when HFIR was producing californium isotopes through successive neutron capture processes.

This chapter focuses on the chemistry and physical properties of californium that are available in the open literature, and supplementing/evaluating this information when appropriate. An effort was made to minimize the number of references to technical reports, unpublished information, etc., except for cases when such a citation was warranted. The number of publications dealing with technological and medical applications of neutrons from ^{252}Cf is very large. There are numerous references to work done with californium covering biological studies, radiotherapy, neutron radiography, neutron activation analyses, dosimetry, etc. Some 70% of the work published during the last decade concerns efforts in these arenas using the ^{252}Cf isotope. The remaining reports deal with chemical studies and separation work, which normally employ the longer-lived ^{249}Cf isotope.

A significant amount of the basic chemical work on californium has been reported in different publications, but this should not be construed to interpret that additional chemical or physical studies are not needed! Indeed, given some of the recent advances in scientific techniques (i.e. those involving synchrotron sources, such as extended X-ray absorption fine structure (EXAFS), X-ray absorption near edge structure (XANES), photoelectron scattering, etc.), new studies should be pursued with californium and its compounds, and such investigations would be expected to yield even further insights into this element's science. Some of the more recent thrusts in the chemistry and physics of californium have involved its gas-phase chemistry, high-pressure studies of the metal and compounds, and new separation science. These topics are covered in the different sections of this chapter.

11.2 PREPARATION AND NUCLEAR PROPERTIES

It is unlikely that, nor have there been reports or evidence of, primordial californium in nature. Thus, isotopes of californium with mass numbers between 237 and 256 have been prepared as man-made isotopes. A summary of methods for the preparation of and nuclear data for these isotopes is given in Table 11.1, and in Appendix II. The lighter masses (neutron deficient) are produced by accelerator methods, (e.g. the helium bombardment of curium isotopes) which was the initial technique used to generate and discover californium. But californium isotopes can also be prepared by heavy-ion bombardment of elements other than curium. Examples of the latter are bombarding thorium with oxygen ions, and uranium with carbon or nitrogen ions. These preparations involve high-energy accelerators and produce only limited numbers of atoms of the product nucleus, and therefore are not useful for producing weighable quantities (i.e. even micrograms quantities) of californium needed for the preparation of pure solid compounds. An excellent discussion on the history, preparation, and nuclear properties of californium isotopes is given by Hyde *et al.* (1971) and Seaborg and Loveland (1990).

Californium isotopes with larger neutron contents (higher mass numbers) are usually prepared by irradiation of targets (plutonium through curium) in nuclear reactors that have a high neutron flux ($>10^{15}$ neutrons cm^{-2} s^{-1}). These and even heavier californium isotopes are also generated in nuclear explosions, where for short periods of time the neutron flux is even higher (fluence $> 10^{29}$ neutrons cm^{-2}). In the latter case, the formation of higher-Z elements and heavier isotopes is favored due to the high density of neutrons and in time spans that are short relative to the various decay half-lives of the materials formed. In principle, the objective would be to favor the significant neutron capture by the uranium to plutonium atoms present in such devices over the decay process of the products formed. This builds very rapidly by capture beyond the particularly short-lived isotopes before they can decay appreciably. Although transplutonium elements have been intentionally produced in underground nuclear explosions, processing of large amounts of 'ore material' (rock debris) in reasonable time periods makes this preparation procedure for these elements impracticable. Thus, weighable quantities of californium are best obtained as direct or indirect products from irradiation of materials in nuclear reactors.

Since the mid-1960s californium has been produced in special nuclear reactors (i.e. the HFIR at Oak Ridge National Laboratory). Most recently the intial targets consist mainly of curium isotopes (^{244}Cm through ^{248}Cm isotopes), which are irradiated in the reactor by neutrons to produce californium isotopes from ^{249}Cf through ^{255}Cf with the major isotope being ^{252}Cf. The HFIR located at Oak Ridge National Laboratory can produce currently up to 0.5 g of ^{252}Cf (together with other californium isotopes) per year. By using larger reactors, this quantity could be conceivably be increased to produce several grams of ^{252}Cf per year, and at one time this was planned in the U.S. but the greater need for this isotope never materialized.

The ^{252}Cf isotope has a 2.6 year alpha decay half-life, and a 85 year spontaneous fission branching half-life, which is the source of the neutrons it emits. Neutrons from its fission offer the main use for this isotope (i.e. neutron activation analysis, medical treatments, neutron radiography, etc.), but it is also useful for chemical tracer work, given its high specific alpha activity and greater availability. However, the neutron field (3×10^{6} neutrons s^{-1} $\mu\text{g}^{-1}$and the gamma radiation accompanying fission and/or the alpha decay of ^{252}Cf (up to 7 MeV gammas)) normally precludes its use for basic chemical/physical studies, as considerable shielding is required to protect personnel and equipment from even microgram amounts of it (gloved box limits are normally only a few micrograms). As a result, the mixture of californium isotopes obtained directly from reactors (which contains ^{252}Cf as the primary isotope) is not generally considered when multiple micrograms or more of californium are needed for studies without extensive shielding. Instead, the ^{249}Cf isotope is used.

Although in principle, ^{251}Cf has the most desirable radiation characteristics with regard to performing research studies, and it could be isolated from mixed californium isotopes using a mass separator, the cost and low yields (10%) makes this process unattractive. This isotope is only formed at low concentrations, as a result of its high-neutron capture and fission cross sections.

Another isotope, ^{253}Cf, is important as a parent for obtaining isotopically pure ^{253}Es (see Chapter 12). If a chemically pure (i.e. free of einsteinium) fraction of mixed californium isotopes from a reactor is obtained, and the ^{253}Cf present is allowed to decay, then a subsequent chemical separation of this californium fraction allows recovery of its pure ^{253}Es daughter.

For the majority of basic studies, especially those requiring weighable quantities of californium, the ^{249}Cf isotope is desired. Its alpha half-life of 351 years makes it suitable for chemical/physical experiments in gloved boxes, although there is still significant gamma radiation associated with its decay, which may require some shielding for protection. Typically, gloved box studies are rather limited to less than 10 mg because of radiation levels.

Isotopically pure ^{249}Cf is best obtained form the decay of ^{249}Bk (beta emitter, half-life of 330 days; see Appendix II). This latter isotope is the major berkelium isotope obtained from reactor irradiations (^{250}Bk is also formed in reactors but it has a 3.217 h half-life and rapidly decays; see appendix II). Thus, to obtain ^{249}Cf free of other californium isotopes for research studies, it is necessary to generate berkelium in a reactor and then separate it chemically from the other transplutonium elements present. After sufficient decay of the ^{249}Bk to ^{249}Cf, the latter can be subsequently separated chemically from the berkelium fraction. It is possible to obtain multi-milligrams (up to 60 mg at the HFIR at Oak Ridge National Laboratory) per year in this manner. And, as the half-life of ^{249}Cf is 351 years, it is possible to accumulate larger amounts of it over time by recovery operations. The only other known production source of ^{249}Bk in significant quantities, and hence a source of isotopically pure ^{249}Cf by its decay, is in Russia but the quantity available there is often smaller. It is then possible to provide in relatively short time frames multi-milligram amounts of ^{249}Cf.

The half-life of ^{250}Cf (13.08 years), which is produced along with other californium isotopes in reactors, has been determined recently (Popov *et al.*, 1996). The ^{238}Cf nuclide had been reported from bombardment of lead isotopes (^{207}Pb and ^{208}Pb) with ^{34}S and ^{36}S ions (Lazarev *et al.*, 1995). Its mode of decay is suggested to occur by spontaneous fission.

The K series of X-rays generated form californium has been discussed by Dittner and Bemis (1972), and can be used for the identification of californium during its decay processes. The vibration states in californium nuclei have been discussed by Ahmad (1980).

11.3 APPLICATIONS

As mentioned in Section 11.2, californium produced in nuclear reactors is mainly comprised of ^{252}Cf, and only a small quantity of this isotope mixture can be employed for chemical/physical studies outside of heavy shielding or hot cells. Thus, the applications for this ^{252}Cf isotope are for: (1) neutron emissions; (2) a target material for producing transcalifornium elements; (3) a californium tracer, using its higher specific alpha activity; and/or (4) a parent for obtaining ^{248}Cm (^{248}Cm is the alpha-decay product of ^{252}Cf; see Chapter 9). This long-lived isotope of curium is very useful for basic studies of curium. In practice, a mixture of ^{246}Cm, ^{248}Cm, and small amounts of other curium isotopes are obtained from the decayed californium reactor products (~97% ^{248}Cm and 3% ^{246}Cm from the alpha decays of ^{252}Cf and ^{250}Cf isotopes present).

Although it is beyond the scope of this work to review such applications of ^{252}Cf fully, or mixtures where this is the main californium isotope, its potential usefulness warrants some coverage here. The reader is also referred to: the ^{252}Cf Information Center at the Savannah River Laboratory (USAEC Rept, 1969) , Georgia, U.S.A. or the ^{252}Cf User Facility located at Oak Ridge National Laboratory. More extensive information is also given by Martin *et al.* (1997, 2000) and by Osborne-Lee and Alexander (1995). When ^{252}Cf is used as a neutron source, the data listed in Table 11.2 may be useful. Martin *et al.* (1998; 2004) have discussed applications of ^{252}Cf.

Considering the spontaneous fission half-lives, ^{252}Cf has the shortest one (85 years), a 3.09% fission fraction and yields 3.767 neutrons per fission. One observes a range from 2 to 3.8 neutrons per event for other fissioning actinide isotopes. The calculated neutron emission rate for ^{252}Cf is 2.3×10^{12} neutrons s^{-1} g^{-1}, although one would rarely expect to have a gram. In contrast, high-flux reactors have fluxes of three orders of magnitude higher. But, this rate for ^{252}Cf is lower than that for ^{254}Cf (1.2×10^{15} neutrons s^{-1} g^{-1}) due to its 99.7% fission fraction and 3.83 neutrons per fission event. But, this later isotope is not readily available in any significant quantities. For comparison, the neutron emission for ^{248}Cm, which also undergoes spontaneous fission, is only 4.2×10^{7} neutrons s^{-1} g^{-1}. It has a long alpha decay having a half-life of 3×10^{5} years, 8.39% fission fraction, and 3.2 neutrons per fission event. Data are summarized in Table 11.2.

Applications of ^{252}Cf can be broadly classified as medical, analyses, and biological studies, where the majority of the work involves in one way or the other the spontaneous-fission neutrons emitted from ^{252}Cf (Karelin *et al.*, 1997). These sources have been useful in such areas as neutron activation analysis, neutron radiography (a technique that complements X-ray radiography), and medical therapy for treatment of cancer. They are most useful where access to nuclear reactors is not possible, or convenient, and/or where a lower neutron flux is adequate for the need at hand. An important application for ^{252}Cf is to

Table 11.2 *Data for ^{252}Cf and other selected neutron sources*.*

Isotope	*Half Life* (yrs)	*Specific Activity* (Ci g^{-1})	*Spontaneous Fission Half-Life* (yrs)	*Fission Fraction* (%)	*Neutrons per Fission*	*Neutron Rate* (n $s^{-1}g^{-1}$)

**Sources*: The Health Physics and Radiological Health Handbook (1998); Osborne-Lee and Alexander (1995).

provide neutrons for the initial start-up of nuclear reactors (Osborne-Lee and Alexander, 1995).

Portable neutron activation analysis systems using ^{252}Cf have been designed for use in deep-sea exploration for minerals, or for space probes (Senftle *et al.*, 1969; Wiggins *et al.*, 1969; Filippov, 1979; Bakiev *et al.*, 1991).

Various sizes and forms of ^{252}Cf sources have been designed for medical applications, both for external irradiation and for internal implantation. How extensive the practical applications of ^{252}Cf can be determined by the success of experiments using this nuclide. The more extensive shielding hinders medical applications needed for the neutrons (greater thickness of paraffin for neutrons versus that of lead for shielding X-rays). Remote operation/delivery of the californium sources to the application site aids in this respect. A large number of such applications have been reported (Castro *et al.*, 1973; Poda and Hall, 1975; Zech *et al.*, 1976a,b; Maruyama *et al.*, 1978, 1980, 1991; Belenkll *et al.*, 1991; Yanch *et al.*, 1993; Patchell *et al.*, 1997; Knapp *et al.*, 1999; Rivard, 1999a,b, 2000a–c; Rivard *et al.*, 1999, 2002, 2004; Wanwilairat *et al.*, 2000; Tacev *et al.*, 2003a,b, 2004a,b).

Studies involving the injection of ^{252}Cf into beagles (Lloyd *et al.*, 1972a,b, 1976; Taylor *et al.*, 1972) and into swine (Mahony *et al.*, 1973; Beamer *et al.*, 1974) have also been reported. Investigations involving mouse mammary-carcinoma and bone were also reported (Fu and Phillips, 1973).

Several biological studies have used ^{252}Cf to examine the effects of neutron radiation. Work on DNA (Tacev *et al.*, 1998; Florjan *et al.*, 1999) has been done, as well as work on its bioefficiency (Cebulska-Wasilewska *et al.*, 1999). The biokinetics of it in marine isopods (Carvalho and Fowler, 1985) and the survival of human cells under irradiation (Todd *et al.*, 1984) have also been published. A solvent extraction/liquid scintillation counting method for determining ^{252}Cf in biological samples has been discussed (Miglio, 1978).

There is an extensive list of reports and publications dealing with the applications. The reader is referred to these for more extensive information. One useful source in this regard is an ORNL Report (Osborne-Lee and Alexander, 1995). Other sources of information involve the use of ^{252}Cf: for cervical carcinoma treatment (a 12 year review by Tacev *et al.*, 2004a,b); a review of other clinical applications (Mignano and Rivard, 2004); and advances in neutron radiographic techniques (Berger, 2004). Dullmann *et al.* (2003) also discuss fission fragment sources using ^{252}Cf.

11.4 SEPARATION AND PURIFICATION

The choice of a separation and purification scheme for californium depends on the nature of its source, the particular isotopes of californium involved, the amount of material, the impurities present, as well as several other factors. In short, the best procedure needs to be customized to the particular situation at hand. Usually, ion exchange is involved either as the main separation technique, or at least in some secondary capacity. Since californium in aqueous solutions is normally stable only in its tripositive state, oxidation–reduction cycles are not useful for separation. Due to the very similar chemical behavior of the tripositive transplutonium elements, as well as lanthanide ions of comparable ionic radii (i.e. Sm–Tb), the separation chemistry for californium employed must often rely on small differences in chemical behaviors for the different materials to be separated.

The separation procedure most suitable for californium isotopes generated in accelerators may not be the same as that used for californium produced in reactor targets. In some accelerator experiments, the desired californium isotopes generated may be physically separated via recoil mechanisms from the targets, which simplifies the separations and shortens the time required for the shorter-lived isotopes. The need for nuclear or radioactive purity, as opposed to chemical purity, will also affect the particular separation processes to be used. A considerable amount of information on californium chemistry was determined using tracer levels of californium, usually using ^{252}Cf isotope. The major purification schemes for californium at tracer levels have frequently involved ion-exchange techniques to separate californium from other transcurium elements.

For purposes of separation, the transplutonium elements can be placed into two groups: (1) americium and curium and (2) the group of the next several transcurium elements, which includes californium. The separation of californium from its neighbors, especially einsteinium, is therefore more difficult than separating it from americium/curium or from the lighter actinides. Separation of californium from berkelium is simplified by the ability to oxidize berkelium in an aqueous medium, which then permits the solvent extraction of Bk(IV) away from Cf(III).

A number of procedures have been used for the separation/purification of californium. One of the early ion-exchange methods involved the use of cation-exchange resin (Dowex 50) and ammonium citrate or ammonium lactate as eluants. A superior eluant, ammonium α-hydroxyisobutyrate (α-HIBA), was first used over 30 years ago (Choppin *et al.*, 1956), and this reagent is still in use today for the separation of californium from other actinides. Thompson *et al.*, (1954). A very useful group separation between the lanthanides and actinides can be accomplished using concentrated hydrochloric acid as an eluant for the transcurium elements sorbed on cation resin; the separation is improved by using an ethanol–hydrochloric acid mixture as an eluant (Street and Seaborg, 1950). Another method for separation elements from the two groups, especially with smaller quantities has been the use of TEVA™ columns (Horwitz *et al.*, 1992, 1993, 1995; Porter *et al.*, 1997). These resin columns are available commercially (Eichrom Industries) and employ thiocyanate and formic acid solutions. The greater complexing ability of the transplutonium elements is evident as they desorb ahead of the lanthanide elements when using these separation approaches. The separation of californium from its actinide neighbors, using cation- or anion-exchange resins, or elution with either hydrochloric or ethanol–hydrochloric acid mixture, alone is not feasible.

Anion-exchange separation procedures using slightly acidic $LiNO_3$ or $Al(NO_3)_3$ solutions (Surls and Choppin, 1957; Adar *et al.*, 1963; Marcus *et al.*, 1963) or ethylenediaminetetraacetic acid (EDTA; Baybarz, 1966a,b) as eluants have also been reported. Several extraction procedures have been used, such as the extraction of trivalent actinides from concentrated LiCl or $LiNO_3$ (slightly acidic) solutions and the use of trilaurylamine or other trialkylamines (Baybarz *et al.*, 1963) or quaternary ammonium salts (Moore, 1964, 1966; Horwitz *et al.*, 1966). Extraction chromatography using quaternary ammonium salts or bis(2-ethylhexyl)phosphoric acid (HDEHP) as a stationary phase has also been employed (Gavrilov *et al.*, 1966; Horwitz *et al.*, 1967, 1969a,b). Inorganic ion exchangers such as zirconium phosphate materials have limited applications for californium separations due to their lower selectivity as compared to organic-type extractant materials.

Several summaries of separation procedures have been discussed and can be found in: Miller (1967), Keller (1971), Myasoedov *et al.* (1974), Bigelow (1974), Ishimori (1980), King *et al.* (1981), Collins *et al.* (1981), Benker *et al.* (1981), and Campbell (1981).

Most extraction procedures are useful for separating californium from americium/curium or from lighter actinides, but are limited for separating it from other transcurium elements. For example, HDEHP dissolved in an aromatic diluent has been used to separate Cf and Cm providing a separation factor of about 50, but it is not useful for californium–einsteinium separations. Efforts continue to find new and better extractants with the aim of improving separation factors and selectivity. It is unlikely that a specific extractant for californium alone will be developed but new materials may provide improved separation factors over methods presently used or known. Reviews that discuss californium extraction chemistry are available (Bigelow *et al.*, 1980, 1981; Myasoedov *et al.*, 1980; Shoun and McDowell, 1980).

One application of HDEHP on an inert support material, such as porous glass (i.e. Bioglass), is worth noting. An excellent separation between curium and californium can be achieved using this approach, which is important process for recovering $^{248}Cm/^{246}Cm$ from their $^{252}Cf/^{250}Cf$ parents. In this procedure, the actinides are loaded onto a column with the agent, and then eluted with 0.1 M HNO_3. As the californium is retained more strongly due to complexation, the curium is eluted first.

It is also useful to note that berkelium and californium can be readily separated by solvent extraction of Bk(IV) away from Cf(III). This separation is important since isotopically pure ^{249}Cf is obtained from the beta decay of ^{249}Bk. The berkelium can be readily oxidized to Bk(IV) in aqueous solution with a strong oxidant (i.e. bromate ion) in nitric acid solution.

Since the majority of californium is produced in nuclear reactors, or obtained as a by-product from reactor-produced ^{249}Bk, it is appropriate to discuss briefly a flowsheet for the separation techniques employed in recovering californium for reactor targets. If uranium or plutonium is present as the main target material, then these elements must also be separated from the transplutonium element group (containing the californium) in addition to fission products (lanthanide elements, transition metals, etc.) and other products (aluminum from target assemblies, etc.). If americium and curium, or pure curium, is the main starting material, then only small amounts (if any) of the lighter actinides may be present, which simplifies the situation.

The general separation scheme, Scheme A in Fig. 11.1, is for separating and purifying californium from the HFIR products containing uranium and plutonium at the Oak Ridge National Laboratory. Reports on different aspects of these purification processes are available (Baybarz *et al.*, 1973; King *et al.*, 1981; Bigelow *et al.*, 1981). The procedure begins with alkali dissolution of the aluminum target holders used for the reactor. This leaves the insoluble actinide oxides, which are subsequently dissolved in hydrochloric or nitric acid to generate a solution of the elements to be separated.

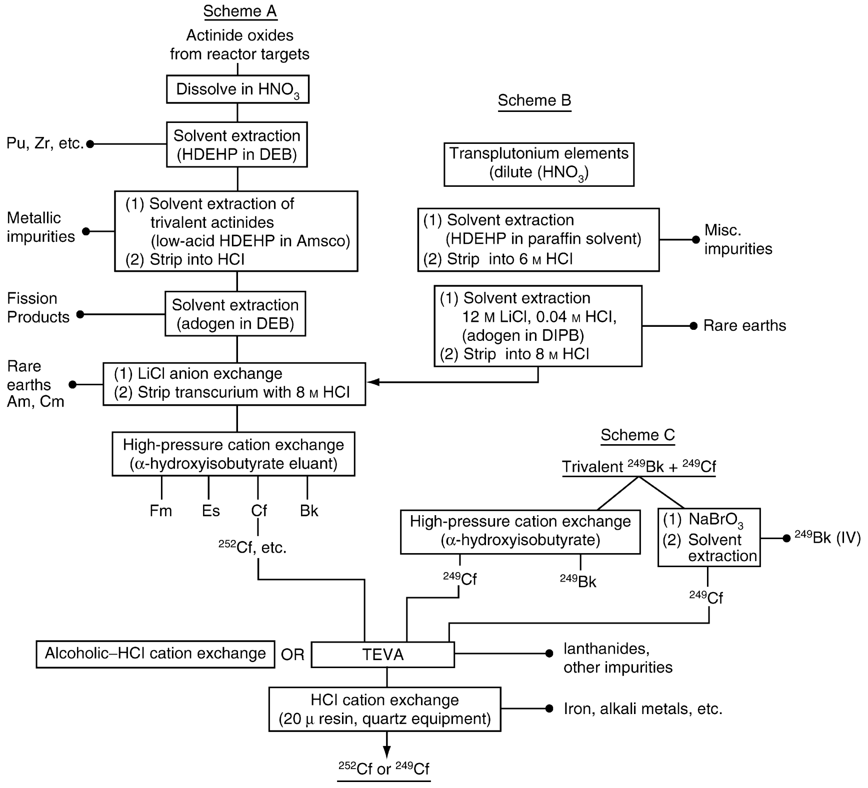

Fig. 11.1 *Separation and purification scheme for californium.*

Solvent extraction (HDEHP in an aromatic diluent as diethylbenzene) (DEB) removes plutonium and zirconium from the system. Scheme B is given for the situation where only the transplutonium elements are present (i.e. starting with americium and curium targets rather than plutonium).

In both cases, the transplutonium elements are then extracted with HDEHP in an aliphatic solvent, and a subsequent amine extraction (adogen) of these actinides removes them from most of the fission products. At this point, the product contains the transplutonium elements and any lanthanides present (fission products). A LiCl anion-exchange process partitions the transcurium elements from americium, curium, and the lanthanides, leaving the transcurium elements as a separate fraction. Scheme B in the figure considers only mixtures of the transplutonium elements.

The transcurium elements (Bk, Cf, Es, and some Fm) are then separated on high-pressure cation-exchange columns. Using a buffered α-hydroxyisobutyric acid solution as an eluant, californium is obtained as a separate fraction using a high-pressure ion-exchange process (very small resin particles, elevated temperature, at 80°C). The subsequent treatment of the different fractions obtained from this process depends on several factors, which include the final use of the material. The purification requirements for the californium isotopes produced directly in the reactor are based on whether Es or Cm daughters will be recovered, or the medical/industrial uses of the californium isotopes.

The californium fraction is further treated to remove residual lanthanide elements; this is especially important for nuclear studies where traces of radioactive lanthanide isotopes are detrimental, or for target materials, where unwanted reaction products may be generated from any impurities present. An ethanol–hydrochloric column is shown in Fig. 11.1, but it could also be replaced by a TEVA™ column. Horwitz *et al.*, (1992, 1993, 1995); Porter *et al.*, (1997).

Since most basic research studies involving milligram quantities of californium make use of ^{249}Cf obtained from the decay of ^{249}Bk, the purification requirements and processes for the californium produced in this manner is different, and shown in Scheme C in Fig. 11.1. Here, the material normally consists of only ^{249}Bk and ^{249}Cf isotopes plus any non-actinide impurities (i.e. accumulated from berkelium used in research studies). The objective is then to separate californium from its berkelium parent and any other impurities that may be present. To achieve the very high chemical purity desired for basic research work on californium, different things must be considered and the necessary separation processes must be addressed on an individual basis. The easiest situation is when the ^{249}Bk precursor for ^{249}Cf is already available in a highly pure state, and the separation of the californium involves only its separation from a relatively pure parent material. It this case, Scheme C in the figure could apply. For separating berkelium and californium, either a cation-exchange column (with α-hydroxyisobutyrate as the complexing agent) or the solvent extraction of berkelium as Bk(IV) away from trivalent californium (several different extracts schemes can be used). In the latter process, the berkelium is first oxidized to Bk(IV) in solution with bromate ions, and the californium remains trivalent. An advantage with the ion-exchange process is that it avoids generating higher acid solutions and does not add bromide or bromate ions to the californium fraction.

In general, the purification of ^{249}Cf normally involves multiple pressurized cation-exchange columns with 0.25 M α-hydroxyisobutyric acid as an eluant (using solutions of variable pH from 3.8 to 4.2 at 80°C) to separate californium from other transplutonium elements, which also provides a general purification from other impurities than actinides. Then, a cation-exchange column with an ethanol–hydrochloric acid as an eluant, or a TEVA column, can remove lanthanide elements, alkaline earths, alkali metals, iron, nickel, etc. The columns, especially the final column and product receiver, are often constructed of acid-leached quartz. Special alpha detectors are used to determine the fractions that contain the californium. Using this process, a very pure californium chloride product is obtained, which can then be used for preparing compounds or the metal of californium for research.

Additional separation approaches have been reported in more recent publications. Firsova *et al.* (1998) have used bis(1-phenyl-3-methyl-4-acylpyrazolol-5-one) and its derivatives for solvent extraction, and other chromatographic separation methods (Firsova *et al.*, 1996) for separating berkelium and californium. Extractions using 4-benzoyl-2, 4-dichloro-5-methyl-2-phenyl-3H-pyrozol-3-thione, and tri-*n*-octylphosphine oxide (TOPO) have also been tested (Hannink *et al.*, 1992). Separation exclusion chromatography techniques have also been applied for separating californium from americium, curium, and lanthanides (Firsova *et al.*, 1990). The transplutonium elements have also been extracted from carbonate solutions using oligomers and alkylphenol derivatives (Karalova *et al.*, 1990), and extraction chromatography results with *DHDECMP* in nitric acid and characterization of DHDECMP/XAD-4 resins have been tested in the purification process (Kimura and Akatsu, 1991).

Extractions approaches for Cf(III) have also been done with aqueous pyrophosphates and lithium polyphosphate solutions with HDEHP (Chakravortty *et al.*, 1989). Extractions have also used HDEHP in nitric acid solutions (Kasimov and Skobelev, 1987). A modified ion-exchange procedure using α-hydroxyl-2-methyl butyrate was reported by Vobecky (1989). The separation of einsteinium from californium irradiation targets by ion exchange has been discussed by Elesin *et al.* (1986). The separation of californium using different salts of HDEHP was published by Dedov *et al.* (1986a,b). The extraction of magnesium and its influence on californium extraction via HDEHP for citric acid–magnesium nitrate systems has also been discussed (Kovantseva *et al.*, 1986). The effect of cations on exchange chromatography of curium and californium has been reported (Erin *et al.*, 1981) and the complexation of Cf(III) in perchlorates was also reported (Lebedev and Mazur, 1981). A simple separation approach for special applications has been suggested by Guseva *et al.* (1973), and a curium–californium extraction chromatography approach was published by Aly and Abdelras (1972). The use of 8-hydroxyquinoline and 5,7-dichloro-8-hydroxyquinoline for extraction of californium was suggested by Feinauser and Keller (1969).

Three extraction studies involving californium were reported by Horwitz and coworkers. One study involved bis(2-ethyl)orthophosphoric acid (Horwitz *et al.*, 1969a); a second report was made on the same system (Horwitz *et al.*, 1969b); and the third effort was an extraction using high molecular weight quaternary amines in ammonium nitrate solutions (Horwitz *et al.*, 1967). The chelating and extraction of Cf(III) by acetylacetone and derivatives of it were also reported by Keller and Schreck (1969). Fused salt, molten metal processes have also been examined for separating californium (Knighton and Steunenberg, 1966; Mailen and Ferris, 1971). The analytical chemistry of the actinides has been reviewed by Myasoedov and Lebedev (1991), and several aspects of separation chemistry are also discussed in this work.

In principle, an alternative procedure for the separation of californium in special circumstances may be to reduce a mixture of actinide oxides with thorium metal under vacuum, and distill away the more volatile californium metal and then condense it on a suitable receiver (Haire, 1982). The separation of californium oxide from curium oxide using a vacuum sublimation procedure was also suggested (Aleksandrov *et al.*, 1972).

11.5 ELECTRONIC PROPERTIES AND STRUCTURE

A considerable amount of spectroscopic data has been obtained for californium and a number of theoretical calculations have been made concerning its energy levels. The californium neutral atom's ground state is assigned as $5f^{10}7s^2$ ($^5I_8$) and the Cf^+ ground state as $5f^{10}7s$ ($^6I_{17/2}$) (Worden and Conway, 1970; Martin *et al.*, 1974; Blaise and Wyart, 1992; for further details see Chapter 16). The ionization energy for the neutral californium atom has been calculated from spectroscopic data and were found to be 6.298 eV or 50800 (200) cm^{-1} (Sugar, 1973), respectively, but it now has been determined experimentally and found to be 6.2817(2) eV or 50665(200) cm^{-1}, respectively (Erdmann *et al.*, 1996, 1998) using resonance ionization mass spectrometry. Some of the lowest energy levels and the representative configurations are given in Tables 11.3 and 11.4, and experimental F^k(ff) and Hartree–Fock values are listed in Table 11.5. These values were determined using the ^{249}Cf isotope. Ionova *et al.* (1977) have also discussed the electronic levels of californium.

From limited absorption and self-luminescence spectra for californium, an early partial energy-level scheme was published for the $5f^9$ configuration (Conway *et al.*, 1962a,b). Predictions of the energy-level structure for Cf(III) appeared in 1964 (Fields *et al.*, 1964), and work on the triply ionized form of californium has also been published (Carnall *et al.*, 1973; Varga *et al.*, 1973a,b).

Blaise and Wyart (1992) and Wyart *et al.* (2005) have more recently reported a comprehensive list of electron energy levels for californium, which are recommended values. Additional information is given in Chapter 15.

Absorption spectra of Cf(III) are mainly characteristic of f–f transitions (Laporte forbidden) within the $5f^{10}$ configuration. Spectra of Cf(III) in $DClO_4$–D_2O have been used to make term assignments and energy levels for californium (Varga *et al.*, 1973a). The electronic spectrum and estimated energies of the electronic configurations of Cf(IV) has also been predicted from spin–orbit coupling (Varga *et al.*, 1973b). Estimated energies of the electronic configurations for californium had appeared earlier (Brewer, 1971a,b), where values were given for singly, doubly, and triply charged californium ions.

A detailed theoretical interpretation of solid-state absorption spectra of $CfCl_3$ has also been published (Carnall *et al.*, 1973), and energy level assignments made for several californium absorption bands. The observed and calculated free-ion energy levels for Cf(III) have also been compared to the lower energy levels in californium's analog, Dy(III) (Carnall *et al.*, 1973). An attempt to correlate the electronic excitation energies for 4f and 5f elements suggested that the $f^ns^2 \rightarrow f^{n-1}ds^2$ excitation values for californium compare best with the lighter lanthanide elements (Mikheev *et al.*, 1979). A valence-band approach for high-coordination bonding in the californium compounds has also been suggested by Carter (1979); this approach implies d- and f-orbital splitting into bonding hybrids. From quantum chemistry considerations, the monopositive ion of californium should be more stable than monopositive lanthanide or lighter actinide ion, based on its lower calculated excitation energy. Calculations have also shown that, from berkelium to nobelium, the excitation (promotion) energies for the $f^ns^2 \rightarrow f^{n-1}ds^2$ configuration, which is taken as a measure of the stability of the divalent state, increases with the atomic number up to element 103 (Spitsyn, 1977). Thus, Cf(II) should be more stable than Bk(II) but less stable than Es(II). These promotion energies are discussed throughout this chapter and play an important role in the californium chemistry.

Predictions for excitation energies for $7s^2 \rightarrow 7s7p$ and $7s^26d$ levels have also been given (Carnall *et al.*, 1977). Experimental data were obtained and crystal field calculations have been made for Cf(III) in different crystal hosts (Carnall *et al.*, 1977). Relativistic Hartree–Fock–Slater calculations have yielded neutral-atom electron binding energies for californium (Haung *et al.*, 1976), and relativistic relaxed-orbital calculations of L-shell Coster–Kronig transition energies have been reported for californium (Chen *et al.*, 1977). An interpolation scheme for cohesive energies provides binding energies for electrons, which can correlate and compare the divalent nature of transplutonium elements; this approach has predicted a divalent metallic state for einsteinium rather than for californium (Johansson and Rosengren, 1975a,b). The divalent metallic state for einsteinium has been verified (see Chapter 12) but this state is less likely for bulk forms of californium (see Section 11.6).

Photoelectron spectrometry of californium has been performed on Cf_2O_3 and Cf_7O_{12}, using an MgKα excitation source (Krause *et al.*, 1988). Values for the

4f doublet ($4f_{5/2}$ and $4f_{7/2}$) of californium were determined in that work. The spin–orbit splitting for californium was estimated to be 17.5 eV.

The energy spectrum of electrons in ^{252}Cf has been given (Rykov and Yudin, 1998) and the energy levels of ^{249}Cf, both neutral Cf(I) and singly ionized Cf(Ii), are also available (Blaise and Wyart, 1992; Conway *et al.*, 1995; and Chapter 16). Ionova *et al.* (1989a,b) has reported computational results for the electronic structure of californium. Also see subsequent sections of this chapter regarding discussions of the absorption spectra of Cf(II) in solids and Cf(III) in solution, and californium's electronic behavior in the gas-phase studies (see Section 11.9). The nuclear magnetic moment of ^{249}Cf has been determined and found to be –0.28 nuclear magnetons, and its nuclear spin is accepted as being 9/2 (see Ahmad, Appendix I).

11.5.1 Emission spectra

The first emission spectrum for californium was reported by Conway *et al.* (1962a,b) and obtained via the copper-spark method. The majority of subsequent work on californium has been carried out using electrodeless lamps, where multi-microgram amounts of material are sealed in quartz envelopes and the californium is excited by external radiation. Emission spectra of californium have been observed from 2400 to 2.5 μm, with approximately 25000 lines having been recorded and accurately measured (Conway, 1976; Conway *et al.*, 1977). Fourier transform analyses of data obtained from californium lamps have been carried out with the goal of resolving the hyperfine structure (Blaise and Wyart, 1992; Wyart *et al.*, 2005). The $5f^{10}7s^2$ ground state, the $5f^{10}7s8s$, and $5f^96d7s^2$ configurations have been established from californium spectra (Warden *et al.*, 1970; Conway, 1976; Conway *et al.*, 1977; for further details see Chapter 16).

11.5.2 X-ray emission spectroscopy

The characteristic X-rays resulting from atomic readjustment to inner shell vacancies provide a very useful means for identification of an element (see Dittner and Bemis, 1972). Several X-ray emissions for heavy elements and their bonding energies are known, and such data have been tabulated for californium (Carlson and Nestor, 1977).

Similar calculations using nonrelativistic Hartree–Slater wave functions (Manson and Kennedy, 1974) and relativistic Hartree–Slater theory (Scofield, 1974) have also provided data for californium. The atomic form factors, the incoherent scattering functions (Hubbell *et al.*, 1975), and a total Compton profile have been tabulated for californium (Biggs *et al.*, 1975).

Systematic X-ray photoelectron spectroscopy (XPS) studies have also been carried out on transplutonium oxides through californium, providing experimental binding energies for their electrons, which can be compared to the calculated energies (Veal *et al.*, 1977). An interpolation scheme has also been reported for determining the binding energies of some lanthanides and actinides, including californium (Johansson and Rosengren, 1975a). The nature of the 5f electrons in the actinide series including californium has also been discussed (Johansson and Rosengren, 1975b).

11.6 THE METALLIC STATE

11.6.1 Preparation

The first attempt to prepare californium metal was made in the late 1960s (Fujita and Cunningham, 1969). Subsequently, several additional attempts have been made to prepare and study this metal. The relatively high volatility of californium metal has made its preparation and study on the microscale more difficult than the first three transplutonium metals. The possibility that the metal may exist in two different metallic valence states has also made it an interesting candidate for study, but it has also complicated the full understanding of californium's metallic state. The potential for californium to exist in two metallic valence states arises due to its f → d electron promotion or excitation energy (see subsequent discussion).

Two preparative approaches have been utilized for californium metal. The first approach utilizes the reduction of the trifluoride with lithium metal at elevated temperatures; the excess reductant and lithium fluoride are removed by vacuum distillation. The second preparative method employs thorium or lanthanum metal to reduce one of the californium oxides, permitting the distillation and subsequent condensation of the metal (Haire, 1982) and leaving the thorium or lanthanide metal and their oxides as residues. With thorium metal, the reaction is a solid–solid reaction and thorium has a lower vapor pressure, which should reduce the presence of the reductant in the vaporized product. With lanthanum, one encounters a liquid–solid reaction, as the lanthanum melts at 920°C; it also has a higher vapor pressure than thorium at high temperatures. The latter property must be considered to avoid incorporating lanthanum into the distilled californium product.

With the halide reduction process, where californium is to be retained as a solid residue, the volatility of californium is greater than that of lithium fluoride. This makes it difficult to volatilize the lithium fluoride completely from the californium product without simultaneously volatilizing away significant amounts of californium. In the oxide reduction procedure, the distillation of microgram quantities of metal yields thin films that are difficult to remove from the collection substrate. Also, a very good vacuum (free of residual materials such as hydrogen, oxygen, water or oil vapor, etc.) is required to avoid the formation of undesired compounds during the distillation of the reactive metal. With multi-milligram quantities, the distillation procedure is the best preparative route. The limited availability of the ^{249}Cf isotope and the radiation fields encountered with this isotope do limit the amount of metal that can be prepared in an unshielded gloved box to 10–20 mg. There is little information about the preparation of ^{252}Cf metal using these procedures, and it is likely little if any has been made by this route.

Some work has been done on preparing californium–palladium alloys via hydrogen reduction of oxide–palladium metal mixtures in conjunction with medical applications of this isotope (Haire and Sato, 1998; Rivard *et al.*, 1999). The latter products are not pure alloys but sufficient for pressing or making extruded sources if the californium content is kept below 20 at%. The malleability of the products is found to decrease with higher californium contents. The reduction in this procedure is driven by the stability of actinide–noble metal alloys. Radchenko *et al.* (1986b) have discussed the formation of $CfPt_5$ on platinum surfaces.

The preparation of pure ^{249}Cf metal to date has been in the 2–10 mg range, with the largest known amount prepared at one time being about 10 mg (Haire, 1978, 1980, 1982). A picture of a 10 mg ^{249}Cf product is shown in Fig. 11.2, where it is compared to the head of a common safety pin. A more detailed account of the preparation of californium metal is available (Haire, 1982).

The limited quantities of californium metal have placed restrictions on the amount of analytical data that can be obtained for products; normally it is not possible to analyze for hydrogen, nitrogen, and oxygen contents. The quality of the metal has then been ascertained mainly by diffraction analysis, total metal impurities by mass spectrometry, its physical properties and appearance and its behavior (such as the rate and extent of dissolution for enthalpy-of-solution

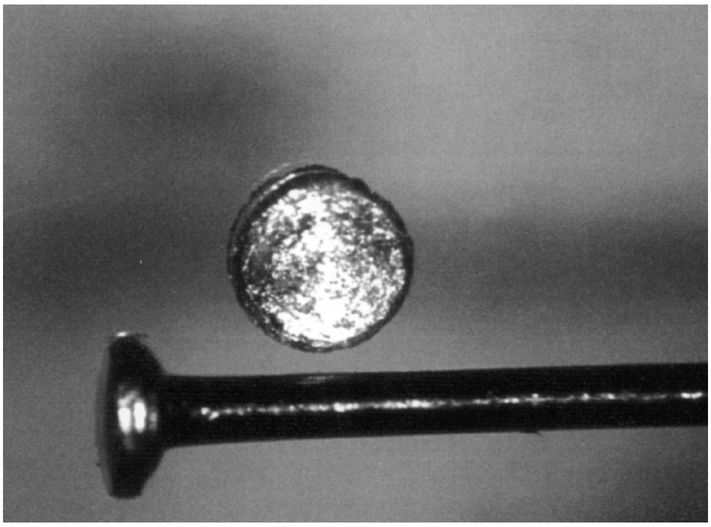

Fig. 11.2 *Ten milligram disc of californium compared to a straight pin.*

measurements) in experiments performed with the metal. Ideally, a larger quantity of metal would be prepared, characterized, and then used for a number of scientific measurements or experiments. But with californium (and some of the other transcurium metals), the preparation of the metal often becomes an integral part of a subsequent study, and either the major portion or the entire preparation is needed and often consumed in the study at hand (i.e. dissolved in acid in determining the enthalpy-of-solution of the metal) in an experiment.

11.6.2 Physical properties

There have been several different reports regarding the crystal data for californium over the years, and these are summarized in Table 11.6. Based on extrapolations from trivalent americium, curium, and berkelium metals, a double hexagonal close-packed structure with parameters on the order of $a_0 = 3.4$ Å and $c_0 = 11.0$ Å, and a face-centered cubic (fcc) high-temperature phase with $a_0 \sim 4.8$ Å would be expected for trivalent californium metal.

In earlier work, a face-centered structure with a parameter of 5.40 Å was reported, which was from a product obtained by the lithium reduction of its fluoride (Cunningham and Parsons, 1970). This is a difficult technique for preparing californium metal (see Section 11.6.1) and this work also involved very small quantities of californium. A potential explanation for this reported parameter is that it represents a poorly crystallized sesquioxide (body-centered cubic (bcc)), lattice parameter of 10.831 Å (see Section 11.7.4), which with the absence of weak diffraction lines in a diffraction pattern of marginal quality may be interpreted as arising from a face-centered material of 5.42 Å (10.831/2).

Subsequently, cubic and hexagonal structures were observed by Haire and Baybarz (1973a,b) in very thin films (<2.5 Å) of californium distilled onto electron microscopy grids and then analyzed by electron diffraction. These data suggested a metallic radius of slightly greater than 2.0 Å, suggesting californium may be a divalent metal. An extrapolation by Zachariasen (1975) also suggested that californium metal would be a cubic lattice and a larger radius than the trivalent metal. Subsequently, very small quantities of apparent metal were also analyzed by X-ray diffraction (Noé and Peterson, 1976) that duplicated the 5.747 Å cubic structure reported by Haire and Baybarz (1973a,b, 1974). Thus, these early data thus suggested californium may be a divalent metal.

With larger quantities of californium, its crystallographic data (Haire and Asprey, 1976; Noé and Peterson, 1976) independently showed that the metal was trivalent with a room temperature double hexagonal close-packed parameters of $a_0 = 3.384$ Å and $c_0 = 11.040$ Å, which suggests an atomic radius of 1.69 Å, which is in line with radii reported for americium, curium, and berkelium metals. The crystal forms of californium metal were also determined by Radchenko *et al.* (1986a) and Seleznev *et al.* (1989) for 1.5 mg of californium.

Table 11.6 *Crystallographic data reported for californium metal.*

Crystal System	*Lattice Parameters*		*Atomic Volume* (Å)^3	*Crystal Density* (g cm^{-3})	*Metallic Radius* (Å)	*References*
	a_0 (Å)	c_0 (Å)				
fcc	5.40	–	39.4	10.5	1.91	Cunningham and Parsons (1970)
fcc	5.743	–	47.4	8.72	2.03	Haire and Baybarz (1970)
hcp	3.988	6.887	47.4	8.72	2.07	Haire and Baybarz (1970)
dhcp	4.002	12.804	44.4	9.31	1.99	Haire and Asprey (1976)
dhcp	3.384	11.040	27.4	15.1	1.69	Haire and Asprey (1976)
fcc	4.94	–	30.1	13.7	1.75	Noé and Peterson (1976)
fcc	5.75	–	47.4	8.72	2.03	Noé and Peterson (1976)
dhcp	3.39	11.01	27.4	15.1	1.69	Noé and Peterson (1976)
fcc	4.78	–	27.4	15.1	1.69	Haire *et al.* (1986)
dhcp	3.380	11.025	27.3	15.0	1.69	Radchenko *et al.* (1986); Seleznyov *et al.* (1989)
fcc	4.994	–	30.1	13.7	1.75	Stevenson (1973)
CfN, fcc	4.94	–	30.1	13.7	–	Haire *et al.* (1986)

Recommended values for californium are: (a) dhcp 3.384(3) Å and 11.040(10) Å and (b) fcc = 4.78(1) Å. Both yield a metallic radius of 1.69 Å, a volume of 27.4 Å and a density of 15.1 g cm^{-3}.

From these efforts double hexagonal lattice parameters of: $a = 3.380(2)$ Å and $c = 11.025(2)$ Å were reported.

A fcc-form (high-temperature form and also a high-pressure form at modest pressures) have been observed for californium. This form of californium was reported to have a fcc structure with a parameter of 4.94 Å (Noé and Peterson, 1976), but this parameter gives an atomic radius for californium that is too large. It agrees better with the parameter for californium nitride ($a_0 = 4.94$ Å; Haire *et al.*, 1986), with an oxynitride (oxygen and nitrogen exchanged in the crystal sites), or could have represented an expanded lattice that was 'quenched in' at elevated temperatures. The proper lattice parameter (4.78 Å) for this cubic form of californium at room temperature and at a pressure 1 atm was observed both with pressure-quenched samples (Haire *et al.*, 1986) and also from larger quantities of californium obtained as foils prepared by distillation (Haire, 1978). The atomic radius derived from this smaller cubic parameter agrees well with that obtained from the ambient temperature, double hexagonal parameters. Pressure-quenched cubic parameters for curium, berkelium, and californium metals have also been found to give identical atomic radii and atomic volumes as obtained from their room temperature, double hexagonal forms, while earlier work with samples quenched from elevated temperatures also resulted in larger (expanded) parameters for curium and berkelium metals (Haire *et al.*, 1986). The preparation and lattice parameters for the californium metal have also been reported by Radchenko *et al.* (1986a) and by Seleznev *et al.* (1989). An alloy of californium and platinum ($CfPt_5$) was obtained when thin films of californium were vapor deposited on platinum surfaces. The products were analyzed as formed on the surfaces (Radchenko *et al.*, 1986b).

The transition temperature for the hexagonal to cubic phase of californium is not well-established, and only limited efforts have been made to determine it (Noé and Peterson, 1976). It is likely to be in the region of 600–800°C. The dhcp to fcc structural transition occurs under pressure at about 16 GPa (Peterson *et al.*, 1983; Benedict *et al.*, 1984). This cubic phase formed under pressure can be retained at atmospheric pressure and 25°C (Haire *et al.*, 1986), and provides a lattice parameter of 4.78 Å. This transition from a hexagonal to cubic state is a low-energy transition in the transplutonium metals. The different crystal data for californium that have been reported are summarized in Table 11.6.

Californium lies very close to the 'border' between a divalent and trivalent metal due to its f- to d-electron promotion energy (see Fig. 12.4 and discussion in Chapter 12). It is possible that in very thin films californium metal may retain a divalent state (i.e. a metastable state) under the conditions of preparation. A similar situation has been observed previously with very thin films of samarium metal (Allen *et al.*, 1978), where the surface atoms of samarium metal in these films remain divalent, although atoms in bulk metal are normally trivalent. Samarium also exhibits a unique rhombohedral crystal form in bulk form. The next element after samarium in the lanthanide series is europium, and it is a divalent metal. Thus, the situation with the californium structures may be similar to the samarium case, as the next element after californium, einsteinium, is also a divalent metal (see Chapter 12). However, californium metal is correctly identified as being a trivalent metal in bulk forms, but does display aspects of this 'closeness' to being divalent (see discussion of its enthalpy of sublimation of the metal in section 11.6). The best lattice parameters for both the dhcp and fcc crystal forms of californium metal are those that give an atomic radius of about 1.69 Å.

There has been only one reported value for the melting point of californium metal, which is (900 ± 30)°C (Haire and Baybarz, 1973a,b). This value was obtained by observing the 'puddling' of metal particles in an electron microscope with thin films of californium metal. This melting point is lower than those reported for americium, curium, and berkelium metals, but is close to the melting point of einsteinium metal (Haire and Baybarz, 1979). Californium's lower melting point is also in accord with some of its physical properties, and the trend toward divalency (which would yield lower melting points) in going across the actinide series. The properties for californium and the other transplutonium metals are compared in an ASM report by Haire (1990).

Californium metal has been examined under high pressure using X-ray diffraction techniques. Early high-pressure studies showed that its dhcp form transformed to a fcc form at 16 GPa (Peterson *et al.*, 1983). A bulk modulus of (50 ± 5) GPa was derived from those data, which is similar to moduli for many of the trivalent lanthanide metals but much lower than those of the earlier actinides with itinerant 5f electrons (i.e. Pa–Pu). Subsequent work with californium metal under higher pressures up to 48 GPa showed a transition of the fcc structure to a new lower symmetry structure (reported to be orthorhombic, alpha-uranium structure; Benedict *et al.*, 1984). Formation of this structure was interpreted as reflecting the delocalization of californium's 5f electrons and their participation in the metal's bonding. Very recently californium metal has been reexamined under much higher pressures and with the use of synchrotron radiation (Haire *et al.*, 2004). These studies have provided much higher quality data, which have shown the occurrence of three structural transitions, and confirmed that the 5f electrons of californium do indeed delocalized and become involved in bonding at these higher pressures. But the new californium structures observed at higher pressures (after the fcc phase), are very similar to those noted in the behavior of americium metal under pressure (Heathman *et al.*, 2000). Work on the structures of californium observed at pressures above 40 GPa are being finalized and details will be published later. However, in this work on californium, it was very clear that when progressing across the actinide series, it takes higher and higher pressures to force the delocalization of the 5f electrons, as they become further withdrawn from the Fermi surface due to the greater nuclear charges (Haire *et al.*, 2004). Thus, californium requires much higher pressures to force the delocalization of its 5f electrons than do the first three transplutonium metals.

The vapor pressure and enthalpy of sublimation of californium metal have been measured using the Knudsen effusion technique (Ward *et al.*, 1979). The vaporization of californium metal, starting at 298 K with the dhcp crystal form, and over the temperature range of 733–973 K, is described by the following equation:

$$\log p(\text{atm}) = (5.675 \pm 0.0319) - (9895 \pm 34)\ \mathrm{T}^{-1}$$

The $\Delta_{\text{sub}}H^{\circ}_{298.15\ \text{K}}$ was calculated to be (196.23 ± 1.26) kJ mol^{-1}, and $\Delta_{\text{sub}}S^{\circ}_{298.15\ \text{K}}$ was derived to be 120.6 J K^{-1} mol^{-1}. The estimated boiling point for the metal is 1745 K. Nugent *et al.* (1973b) had estimated the enthalpy of sublimation of californium to be 163 kJ mol^{-1} and David *et al.* (1976a,b) had predicted a value of 197 kJ mol^{-1}. By comparison, the vapor pressure behavior of californium is intermediate between that of samarium metal (a trivalent metal) and europium metal (a divalent metal), which is discussed by Ward *et al.* (1979).

The enthalpy of sublimation is an important bulk property of an element, and can be a measure of the metal's cohesive energy. From the magnitude of the enthalpy, the number of bonding electrons can be inferred from it, and this allows systematic comparisons to be made between the two f-electron elements series.

The experimental sublimation data for californium (Ward *et al.*, 1979) are in accord with it being a trivalent metal up to 1026 K, although it is one of the most volatile (has one of the lowest sublimation enthalpies) of the trivalent actinide metals; its high volatility precludes vaporization studies of it above 1073 K. Evidence for CfO was not obtained in this mass spectrometry study, and this finding is in accord with subsequent studies on californium oxides (Haire, 1994; see Section 11.7.3).

Thermochromatographic studies (involving sublimation and adsorption) of californium, einsteinium, and fermium using different metal columns (titanium, tantalum, etc.) were performed to yield enthalpies of adsorption for these actinides. Attempts have been made to relate these adsorption enthalpies to enthalpies of sublimation, but there is a significant difference in the actual numerical values, as they measure different properties. A comparison between the enthalpies of sublimation for the americium through californium trivalent actinide metals and their enthalpies of absorption is striking, and efforts have been made to compare them (Haire, 1997). Fig. 11.3 shows plots of these values for selected actinides. The enthalpies of sublimation range irregularly for the first four transplutonium elements with the values reflecting in part differences in 5f to 6d promotion energies – smaller promotion energies link with larger, more positive enthalpies of sublimation.

The enthalpy of sublimation for californium is 196 kJ mol^{-1} (Ward *et al.*, 1979, 1986). In contrast, the enthalpy of adsorption for californium ranges from –302 to –310 kJ mol^{-1} (Hübener, 1980; Hübener *et al.*, 1994). The exact value depends on the particular metal substrate used for its adsorption. A comparison between these enthalpies of vaporization and adsorption is shown

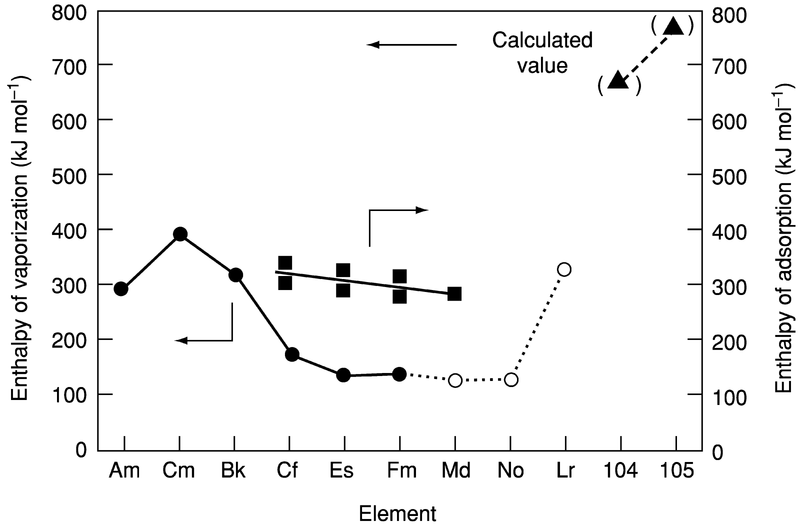

Fig. 11.3 *Vaporization and adsorption enthalpies for selected actinides.*

in Fig. 11.3 (Haire, 1997) for californium through mendelevium elements, and using some extrapolated values for sublimation of the two transfermium elements. The sublimation values for element 104 (Johnson and Fricke, 1991) and 105 (Pershina *et al.*, 1994) are calculated values, and are included here for comparison purposes. Their larger more positive enthalpies of sublimation reflect that greater bonding (i.e. greater than three electrons) is present in these latter two elements. One advantage of the adsorption technique versus the sublimation method is the former can be used for smaller quantities of materials (tracer levels).

It can be seen from Fig. 11.3 that the sublimation enthalpy for californium and the adsorption enthalpy are close to the comparable enthalpies for divalent einsteinium and fermium; the sublimation enthalpy for californium is considerably smaller (less positive, lower energy required) than values for americium, curium, and berkelium, which are trivalent metals.

Initially, the adsorption behavior (i.e. temperature of adsorption) of californium with different metal columns was taken as an indication of a metallic divalency (Hübener and Zvara, 1982) but more recent interpretations of adsorption enthalpies and the relative behavior of californium through nobelium elements suggests that californium is trivalent but close to the divalent–trivalent border Eichler *et al.* (1997). Using adsorption enthalpies, fermium is considered unquestionably as being divalent (Taut *et al.*, 1997), while californium is trivalent an atomic from source for actinide elements has been discussed (Eichler *et al.* 1997.)

The initial enthalpy of solution of californium metal (dhcp crystal form, trivalent metal) in 1.0 M HCl at 298 K is $-(617 \pm 11)$ kJ mol^{-1} (Raschella *et al.*, 1982).

This value was corrected in a subsequent determination of this important thermodynamic quantity using larger samples of well-characterized metal to yield an enthalpy of solution value of $-(576.1 \pm 3.1)$ kJ mol^{-1} for 1 M HCl (Fuger *et al.*, 1984; for further details see Chapter 19). This less-negative enthalpy value shows a trend among the transplutonium metals from americium through californium of less-negative enthalpies with increasing atomic numbers, and is in accord with an increasing trend toward metallic divalency in progressing across the series. This enthalpy of solution of the metal is important for providing the enthalpy of formation of the Cf(III) ion in solution and discussed in a subsequent section (see Section 11.8.3) on thermodynamic properties.

Several efforts have been made to obtain the magnetic susceptibility of californium metal. Magnetic information is valuable in ascertaining the metallic valence of metals and the bonding present. However, in the case of californium, such information is not useful and cannot differentiate between a divalent form (presumable a $5f^{10}$ state) that would have an effective moment of 10.22 μ_B, while the trivalent form (for an $5f^9$ state) would have an effective moment of 10.18 μ_B.

The first magnetic measurements were made by Fujita *et al.* (1976) using two samples believed to represent a fcc form of divalent californium metal from 22 to 298 K. Both samples followed a Curie–Weiss relationship, and the data produced an average moment of 9.75 μ_B. Subsequent magnetic measurements were made on well-characterized samples of the dhcp, trivalent form of californium from 4.2 to 350 K and in applied fields of up to 50 kG (Nave *et al.*, 1983, 1984). These data showed that californium exhibits at least two differing magnetic behaviors as a function of temperature. Below 51 K, the metal was either ferro- or ferrimagnetic; a distinction between the transition type could not be made owing to the inability to obtain a saturated moment of greater than 6.1 μ_B in the highest field of 50 kG. There was also evidence for antiferromagnetic behavior in the temperature range of 48–66 K. Additional magnetic studies of californium compounds (i.e. oxides and nitrides in particular) need to be done to rule out the possibility that their presence as impurities may be responsible for this latter behavior. Above 160 K, californium exhibits paramagnetic behavior. An average effective moment of (10.6 ± 0.2) μ_B was obtained for three different samples, whereas a fourth sample produced a moment of (9.7 ± 0.2) μ_B. Results from Nave *et al.* (1983) indicate that the magnetic behavior of californium is similar in some respects to that of its electronic homolog, dysprosium. Additional comments on magnetic behavior of californium and its compounds are given in Section 11.7.5 and in Table 11.11.

11.6.3 Chemical and mechanical properties

Californium is a fairly reactive metal, comparable to those of the lighter lanthanide metals but is less reactive than europium, which is considered as the most reactive lanthanide metal. This reactivity of europium is related to several factors but in part arises from it being a divalent metal. On standing to air or when exposed to moisture at room temperature, small bulk pieces or foils of californium quickly form an oxide, but it is not a violent reaction. Moisture and temperature increase the rate of the reaction. One of the difficulties of preparing small quantities of californium metal is that it only takes small amounts of impurities to form reaction products with it. When the temperature is elevated, the reactivity of californium metal increases, and reactions occur readily with hydrogen, nitrogen, the chalcogen elements, etc. The silver colored, relatively soft californium metal quickly adopts a golden or bluish color on its surface when reacting with small amounts of other materials. Pure californium metal is easily cut with a 'razor' blade and is also malleable in its pure state.

When californium is sealed in evacuated quartz containers and when heated to 300°C, especially when it is a film on the quartz surface, the metal quickly deteriorates. Solid pieces of californium metal stored in quartz under vacuum and heated to moderate temperatures (i.e. 300°C) can vaporize sufficiently to form 'mirrors' on the quartz surface. Vaporization and reaction with the quartz worsens at higher temperatures. Products are usually oxides or silicates.

The metal reacts very rapidly with dry gaseous hydrogen halides and aqueous mineral acids to evolve hydrogen. In aqueous media, a Cf(III) solution is obtained, except with the case of hydrogen fluoride, where an insoluble californium trifluoride precipitate is formed.

Californium forms alloys when heated with the lanthanide metals but these products have not been well-characterized. When heated, it 'wets' tantalum, which usually limits the use of tantalum containers for high-temperature work with it. Tungsten containers are preferred, especially those made from single crystals, which prevents the metal from entering the grain boundaries of the containers.

11.6.4 Theoretical treatments

The chemistry of the actinide series can be complex and changes considerably when progressing across the actinide series. The development of a self-consistent model for these elements has had limited success in the past but more recent computational approaches have been more successful. However, even plutonium is still not completely understood, and total agreement on details of its fundamental science is not realized fully even after some 60 years of extensive studies. In comparison, far less effort has been done on californium, although its behavior is more lanthanide-like and has fewer complexities than plutonium, which has delocalized 5f electrons. However, the increased promotion energy for the 5f electrons of californium makes it close to being a divalent metal, and therefore its properties and behavior deviate somewhat from those of the americium through berkelium metals, as well as some of the trivalent lanthanide metals.

Efforts have been made to describe the overall fundamental aspects of these actinide metals, and be able to correlate them with other members of the periodic table (Brewer, 1971a,b; Nugent *et al.*, 1973a,b; Johansson and Rosengren, 1975a,b; Nugent, 1975; David *et al.*, 1976a,b, 1978; Samhoun and David, 1979;

Brooks *et al.*, 1984). These authors provide useful considerations for understanding the series in general and the changes that are observed when moving across it.

With respect to californium, the important questions often have to do with the role of its 5f electrons, their position with respect to the Fermi level, the narrowing of its 5f levels relative to earlier members of the series and the position of the 5f electrons with respect to the other outer electrons. The concept of promotion energy for the 5f electrons (f → d) is an important factor here. At 1 atm and room temperature, the 5f electrons in californium and its compounds are fully localized, much like the 4f electrons in the lanthanide series.

Several predictions for the properties of californium have been made with regard to its 5f electrons. One of the predictions was addressed by Brooks *et al.* (1984). It was accepted that californium was close to the divalent–trivalent metallic boundary. This pseudo-boundary considered that the crystal energy gained from acquiring three bonding electrons versus two in isolated atoms, had to be greater than the promotion energy needed for promoting a 5f electron to a d-state (to provide three bonding electrons). As with many of the other actinide metals, atomic californium in the vapor state has only two bonding electrons, but upon condensation, a third bonding electron can be acquired by promoting a 5f electron to a '6d' state. True divalency in the metallic state is believed to occur first in the higher members of the series, starting with einsteinium and fermium metals (see Chapters 12 and 13, and Johansson and Rosengren, 1975a,b; Brooks *et al.*, 1984). Additional discussions in this regard on the nature of californium can be found in the literature and in Section 11.9.

Correlation between crystal entropy and metallic radius, atomic weight, magnetic properties, and electronic structure have permitted an accurate calculation of unknown entropies for the actinide elements, including californium (Ward and Hill, 1976). This required a defined electronic structure to predict the entropy values. In addition, thermodynamics for the transplutonium metals have been summarized (Ward *et al.*, 1980; Ward, 1983). A pattern of superconductivity in f-band metals has also received attention over the years. It is unlikely that californium would show superconductivity, due to its large magnetic moment (see Section 11.6.2 on metal properties) and localized 5f electrons. Prospects for superconducting behavior in other actinides have been discussed (Smith, 1979, 1980; Baring and Smith, 2000). Of the first four transplutonium metals, ending with californium, only americium metal (Smith and Haire, 1978) is known to become superconducting at low temperature.

11.7 SOLID COMPOUNDS

11.7.1 General comments

A wide variety of californium compounds have been reported, even though only small amounts of this element (especially the ^{249}Cf isotope) have been available an overview of Cf solid state chemistry is available (Haire & Gibson, 1989). Most of the expected halides and oxides for californium are established. It is accepted that californium exhibits three oxidation states, II, III, IV, in solids. There are reports that suggest the possibility of a Cf(V) state in solution (see Section 11.8); this state for californium is questionable. The II, III, and IV states are observed in different halides, and the III and IV states are found in oxides. The existence of stable, solid CfO is less probable and a minor product (see Section 11.9 on gas-phase behavior of californium). The trivalent state is the most prevalent state in both compounds and solutions, and the tetravalent state is only observed in the compounds, CfO_2, $BaCfO_3$, and CfF_4 and special solutions. The divalent state is found in the pure solids $CfCl_2$, $CfBr_2$, and CfI_2.

There are other compounds of californium where the oxidation state is less well-defined, such as in compounds with pnictogens, chalcogens, hydrides, etc. For example, in CfN, a formal state of Cf(III) can be assigned but it is not fully clear if this state is correct for a potentially more covalent material, as expected in its nitride. With hydrides, stoichiometries can range between a value of two (dihydride) and three (trihydride), in addition to intermediate hydrogen stoichiometries (i.e. CfH_{2+x} cubic materials and CfH_{3-y} hexagonal products.). This suggests that the bonding in hydrides is other than purely ionic.

Ionic radii for each oxidation state of californium can be established from crystallographic data for these compounds, and some radii are provided in Table 11.7 for comparison. Many similarities in behavior between californium

[d] Radius from plot of r^3 vs volume.

and other actinides and the lanthanides can be made based on ionic radii. It is important when making such comparisons that the radii were calculated in the same manner and perhaps even from the same compounds. In many cases, the transplutonium elements (i.e. californium specifically) with similar radii will likely form the same compounds, have the same structures, display similar phase behaviors, and may even have similar lattice parameters. This affords some predictability for properties of different californium compounds.

It must be recognized that a shift in radii is found between the lanthanide and actinide series, such that Cf(III) has a similar radius to Gd(III) rather than Dy(III), its apparent electronic homolog. Crystallographic data for a number of californium compounds are given in Table 11.8. This ionic radius relationship contrasts with the behaviors of the f-electron metals; metallic radii for the trivalent actinide metals are smaller than their lanthanide counterparts, and the metallic radius for californium is smaller than that of the smallest lanthanide metal, lutetium.

11.7.2 Halides and oxyhalides

Based on the estimated IV and III reduction potentials (Nugent *et al.*, 1971; David *et al.*, 1978) for californium, it would be expected that the only stable, bulk binary Cf(IV) halide would be its tetrafluoride. This compound can be prepared by fluorinating materials such as the oxides or CfF_3 with F_2 or ClF_3 (Asprey, 1970; Asprey and Haire, 1973; Haug and Baybarz, 1975). General preparative routes for the halides are summarized in Table 11.9 and their preparations have been summarized by Haire (1982).

The tetrafluoride has limited thermal stability and decomposes to CfF_3 (Haire and Asprey, 1973a,b) at 300–400°C. This temperature has limited the degree of crystallinity that can be obtained for it. There has been some variation in the lattice parameters reported for CfF_4, which arises mainly from indexing the monoclinic structure using powder diffraction data from samples of moderate crystallinity. A solid-state absorption spectrum has been obtained for the compound, its thermal stability examined and new X-ray data for the compound evaluated using small differences between the reported values (Haire *et al.*, 1980).

Ternary alkali-metal fluoride complexes of the types $MCfF_5$, M_2CfF_6, M_3CfF_7, and $M_7Cf_6F_{31}$ ($M = $ Li through Cs) are expected to exist, and these complexes should provide added stability for the Cf(IV) state. These complex salts are well-established for the tetravalent state of lanthanides (Brown, 1968). The existence of CfF_4 in the vapor state has been claimed based on high-temperature (>500°C) chromatographic studies using tracer quantities of californium (Jouniaux, 1979; Bouissières *et al.*, 1980), which appears to conflict with the thermal decomposition of bulk CfF_4 at low temperatures (i.e. 300–400°C).

All of the trihalides and oxyhalides of Cf(III) are known (see Table 11.8), and many of these compounds were among the first prepared and reported for

californium. Their crystal structures vary between the different compounds, but are often isostructural with the lanthanide trihalides for lanthanides having comparable ionic radii (i.e. Gd(III)).

The oxyhalides can be prepared by incomplete halide formation starting from oxides, careful hydrolysis of the anhydrous halides or thermal decomposition of hydrated halides. They are also prepared by hydrohalogenation of Cf_2O_3 or via treatment of a californium oxide with moist interhalogens at an elevated temperature. The anhydrous trihalides can be prepared by treating californium oxides with dry hydrogen halides or the metals with hydrogen halides or elemental halogens. However, the reaction of the oxide with hydrogen iodide does not give satisfactory results; the triiodide can be prepared by treating $CfBr_3$ or $CfCl_3$ with hydrogen iodide, or the metal with iodine. The trihalides have relatively low-melting temperatures and can be melted in inert atmospheres and/or in vacuum. Careful melting and cooling of such anhydrous halide melts have been used to create single crystals.

The trifluoride is dimorphic (orthorhombic, YF_3-type; high-temperature form, trigonal, LaF_3-type) with the transition temperature above 600°C (Cunningham and Ehrlich, 1970; Stevenson and Peterson, 1973). Treatment of CfF_3 with water vapor above 700°C or non-purified/moist HF produces CfOF (Peterson and Burns, 1968). The enthalpy of formation of CfF_3 at 298.15 K is accepted as being –1553(35) kJ mol^{-1} (see Chapter 19).

Californium trichloride is also dimorphic, exhibiting the UCl_3-type hexagonal structure (low-temperature form) and the $PuBr_3$-type orthorhombic structure (Green and Cunningham, 1967; Burns *et al.*, 1973). The melting point of $CfCl_3$ is 545°C (Burns *et al.*, 1973).

Treatment of Cf_2O_3 with moist hydrogen chloride, or $CfCl_3$ with water vapor, at elevated temperatures produces tetragonal CfOCl (Copeland and Cunningham, 1969). The preparation and measurement of the enthalpy of solution for CfOCl was also reported (Burns *et al.*, 1998). From the solution data, the enthalpy of formation ($\Delta_f H°(CfOCl_{cr})$) at 298 K was calculated to be –970(7) kJ mol^{-1}. This value is also discussed in Chapter 19.

Californium tribromide is trimorphic, but only two of these forms have been prepared by a direct synthetic route. The high-temperature form (>500°C) is an $AlCl_3$-type, monoclinic structure (Fried *et al.*, 1968; Burns *et al.*, 1975; Young *et al.*, 1976). A less well-characterized form, a $FeCl_3$-type rhombohedral structure, has also been reported (Burns *et al.*, 1975). A third form, a $PuBr_3$-type orthorhombic structure was acquired indirectly, aged (after a few half-lives of decay) from an orthorhombic form of its $BkBr_3$ parent (Young *et al.*, 1980). Interestingly, when mixed tribromides of californium–berkelium were synthesized, the orthorhombic structure did not form if the californium content exceeded 45 at%. And, when heating the orthorhombic $CfBr_3$ above 330°C, it immediately transforms into the monoclinic structure, which illustrates that the orthorhombic form is limited to the region of the ionic radius of californium (Young *et al.*, 1980). In contrast, applying pressure on monoclinic $CfBr_3$ (>3 GPa) transforms it to the orthorhombic structure (Peterson *et al.*, 1985). The oxybromide of californium, CfOBr (Fried *et al.*, 1968), is isostructural with CfOCl (Copeland and Cunningham, 1969), and both are prepared by the same methods (see Table 11.9). The molar enthalpy of formation of $CfBr_3$ has been reported to be –752.5 (3.2) kJ mol^{-1} at 298.15 K (Fuger *et al.*, 1990; see Chapter 19).

Californium triiodide is monophasic, and exhibits the BiI_3-type hexagonal structure (Fried *et al.*, 1968; Wild *et al.*, 1978). It is prepared by treating 'californium hydroxide' with hydrogen iodide at 800°C (Fried *et al.*, 1968), but a preferred synthetic route is to heat $CfBr_3$ or $CfCl_3$ with hydrogen iodide (Wild *et al.*, 1978). The CfOI is isostructural with CfOCl and CfOBr, and is prepared by the same procedure used for the latter two compounds (see Table 11.9).

The dichloride, dibromide, and diiodide of californium have all been prepared but the difluoride has not been reported. It would be expected that the Gibbs energy change between the di- and trivalent compounds would be the least for the iodides and hence the diiodide would be the most stable. The first compound of Cf(II) was $CfBr_2$ prepared by hydrogen reduction of $CfBr_3$ at elevated temperature (Peterson and Baybarz, 1972; Fried *et al.*, 1973). Subsequently, it was observed, and shown by absorption spectra, that lime-green $CfBr_3$ could also be reduced by thermal treatment alone (760°C) to produce an amber-colored $CfBr_2$ (Young *et al.*, 1975). The structure of $CfBr_2$ is tetragonal ($SrBr_2$-type; Peterson and Baybarz, 1972). Table 11.8 gives some crystallographic data for these compounds.

The first preparation of CfI_2 produced the high-temperature CdI_2-type hexagonal form (Young *et al.*, 1975); subsequently, a second structural form ($CdCl_2$-type rhombohedral structure) was reported (Wild *et al.*, 1978). The diiodide can be obtained via hydrogen or thermal reduction of the triiodide.

Of the three californium dihalides, $CfCl_2$ proved to be the most difficult to prepare, and many early attempts to prepare it were unsuccessful (Fujita and Cunningham, 1969; Young *et al.*, 1980). It was eventually prepared by hydrogen reduction of the trichloride at 700°C (Peterson *et al.*, 1977). The X-ray structure of $CfCl_2$ still has not been resolved; the existence of this compound is based on its solid-state spectra. It is expected that $CfCl_2$ would exhibit either the $PbCl_2$-type orthorhombic or the $SrBr_2$-type tetragonal structure (Young *et al.*, 1975; Peterson *et al.*, 1977).

There is some evidence that californium halides may form so-called mixed-valence compounds (M_5X_{11}, $M_{11}X_{24}$ or M_6X_{13}, where M = metal ion and X = halide ion) like those reported for some of the lanthanide elements (Bärnighausen, 1976; Haschke, 1976; Luke and Eick, 1976). To avoid the necessity of carefully controlling reduction of californium to the proper stoichiometry, mixtures of gadolinium and californium (both have comparable III radii; see subsequent section) were used such that total reduction of the californium to Cf(II) would produce the desired cation II/III stoichiometry for formation of the structures, Cf_4GdCl_{11} and Cf_4GdBr_{11} (Haire *et al.*, 1978).

It has been reported that Cf(II) can be obtained in crystalline strontium tetraborate matrices (Peterson and Xu, 1996). It appears that this tetraborate matrix provides stability for the divalent state of the lanthanides and actinides. It was concluded from spectral data that Cf(II) existed in the material.

Except for the trifluoride, anhydrous californium trihalides are hygroscopic and must be protected from moisture. The dihalides are very sensitive to both moisture and oxygen. Normally, their syntheses are carried out in glass (except for the fluorides) so that products can be flame-sealed *in situ*, avoiding subsequent transfers of the products. Some preparative and experimental techniques for studying californium halides have been reviewed (Young *et al.*, 1978; Haire, 1982). In general, californium forms the same halide compounds and structures as lanthanide elements having a similar ionic radius.

11.7.3 Oxides

Oxides of californium have received a great deal of study, in part because they are primary compounds of interest and use, and were among the first compounds of this element that were investigated given their ease of formation. Oxides often serve as starting materials for preparing other compounds and can be obtained by calcining in air different materials (e.g. nitrates, oxalates, etc.) obtained from solutions. The stoichiometries (O/M ratios), crystal structures, and oxidation states of the californium oxide obtained, all depend on the experimental conditions employed. Haire *et al.* (1972) have discussed the californium-oxygen system.

Oxides of both Cf(III) and Cf(IV) (the sesquioxide and dioxide) are well known, as well as oxides with intermediate oxide compositions (i.e. between O/M of 1.5 and 2.00). The compound, Cf_7O_{12}, which is isostructural with Tb_7O_{12}, has also been established and its crystal structure and stability are known. It exists as a rhombohedral structure over a very narrow stoichiometry range (Turcotte and Haire, 1976). Although the monoxide has been observed in the vapor state, a true CfO solid has not been identified. This is in accord with the difficulty of preparing a true monoxide of ytterbium, although EuO is known. It is likely that a oxynitride (i.e. Cf(O,N)) or oxycarbonitride (i.e. Cf(O, N,C)) may exist as a solid phase; if so, a variation of lattice parameter (likely fcc-type structure) would be expected for these compounds depending on the actual O/N/C ratios. The formation of californium monoxide may be possible by reacting stoichiometric quantities of the metal and sesquioxide under high pressure and at elevated temperatures. If formed, it would be expected to exhibit a fcc structure with a parameter of 4.8–5.0 Å. This high-pressure preparation of monoxides has been used with selected lanthanides to prepare their monoxides (Leger *et al.*, 1980), but often small residues of metal or oxides remain in the products.

Crystallographic data for the sesquioxides are listed in Table 11.8. Three structures are known for californium sesquioxide: a bcc, a monoclinic, and a hexagonal form. A phase diagram for the transneptunium sesquioxides is shown in Fig. 11.4, where it can be seen that the hexagonal form of californium sesquioxide exists only over a very narrow temperature range up to its melting point of about 1750°C (Haire and Eyring, 1994). There is a trend of decreasing melting point of the actinide sesquioxides with atomic number, which contrasts with the trend observed with the lanthanide compounds. The cubic sesquioxide exists below 1400°C but the monoclinic to cubic transition is very difficult to achieve and appears irreversible, whereas the reverse transition occurs readily. Fig. 11.5 shows the relationship in the molecular volumes for the sesquioxides of the f-elements, where it can be seen that the density for the three californium

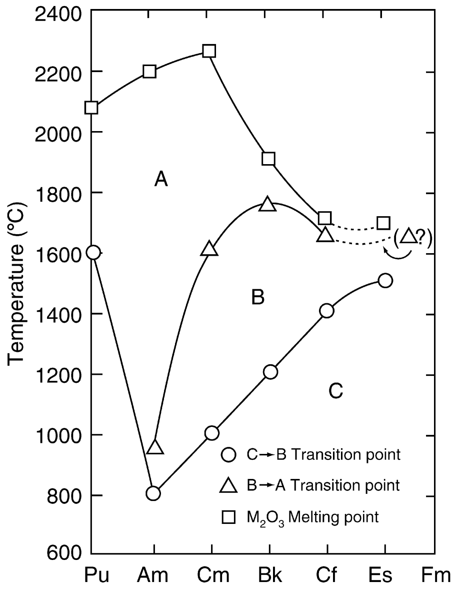

Fig. 11.4 *Phase diagram for the Pu through Es sesquioxides.*

forms increases in going from the cubic to the monoclinic to the hexagonal structures (Baybarz and Haire, 1976; Haire and Eyring, 1994). This trend for the californium compounds is in accord with those seen for the other f-element sesquioxides.

The monoclinic form of Cf_2O_3 (Sm_2O_3-structure type) was established early (Green and Cunningham, 1967) and the bcc (α-Mn_2O_3-type) was observed subsequently (Copeland and Cunningham, 1969). It was noted that slight oxidation of the bcc form may occur when it was heated in air. The hexagonal form of Cf_2O_3 was established later and was difficult to retain on cooling – it could be retained in samples quenched rapidly with helium from the melt (Baybarz, 1973; Baybarz and Haire, 1976; Haire and Eyring, 1994). One aspect of this monoclinic sesquioxide is its oxygen to metal ratio is 'fixed' at 1.5, whereas the cubic sesquioxide readily adds oxygen to its lattice up to a oxygen to metal ratio of 1.67.

As stated above, the hexagonal form of the californium sesquioxide exists over a narrow temperature region (Fig. 11.4). This structural form of berkelium sesquioxide is known and the hexagonal form of californium sesquioxide has also been observed in old samples of hexagonal Bk_2O_3 after berkelium has decayed to californium.

The transition temperature for the bcc to monoclinic form of californium sesquioxide was reported to be both 1100°C (Green and Cunningham, 1967) and 1400°C (Baybarz, 1973; Baybarz and Haire, 1976). The transition from the monoclinic to the hexagonal form was set at 1700°C, just 50°C below the oxide's melting point. While the monoclinic to cubic transition appears irreversible, the hexagonal to monoclinic form is readily reversible.

The fcc dioxide has been prepared by heating lower oxides of californium with atomic oxygen or under high-pressure molecular oxygen (Baybarz *et al.*, 1972; Haire, 1976). It usually appears as a black or dark-brown material, whereas the sesquioxide is very light green to light-tan color. With time, the dioxide's lattice parameter increases slightly, due to swelling and/or small losses of oxygen, both processes probably being due to self-irradiation. When heated in air above 200°C, the dioxide begins to lose oxygen and eventually forms Cf_7O_{12} or lower oxides at temperatures above 400°C (Haire, 1976).

A capacitance manometer system, capable of analyzing oxygen overpressures for samples as small as 1.4 mg of californium, together with X-ray diffraction analyses have established the californium–oxygen system between $1.50 < O/Cf < 1.72$ (Turcotte and Haire, 1976). In that work it was shown that Cf_7O_{12} (a rhombohedral structure) was the stable oxide in air or oxygen up to 750°C. At higher temperatures this compound loses oxygen to eventually form the sesquioxide. A stoichiometric bcc sesquioxide is obtained when these higher oxides of californium are heated in vacuum to 800–1000°C, or when an air-calcined oxide is subsequently treated in hydrogen or carbon monoxide at 850–1000°C.

Thus, the californium sesquioxide system is trimorphic, and there are also the established Cf_7O_{12} and CfO_2 compounds. The bcc sesquioxide lattice can also accept additional oxygen, and this structure exists for an O/M ratio of 1.5 to 1.67. It is expected that californium oxides with O/M compositions between 1.8 and 2.0 would have fcc structures but this has not been well established. Both the bcc lattice parameters for the sesquioxides up to an O/M of 1.67, and the fcc lattice parameters for the oxides having an O/M of 1.8–2.0, decrease in magnitude with the addition of oxygen to the lattices. In many respects (e.g., stability, formation of specific oxides, structures with specific O/M ratios, etc.), the californium–oxygen system is similar to that of the terbium–oxygen system (Haire and Eyring, 1994).

One other aspect regarding californium oxides is the behavior of (Bk,Cf) oxides as a function of the californium content (Turcotte, 1980). It appears that with californium contents up to 25 at%, the actinides can be oxidized up to an O/M of 2.0 (behaving like pure berkelium oxide). When the californium content is 64 at% or greater, the californium now controls the behavior of berkelium and limits the stoichiometry of the products to M_7O_{12}.

Although the preparation of CfO_2 normally requires strong oxidizing conditions and moderate temperatures, under certain conditions lower oxides of californium stored in air or oxygen can 'self-oxidize,' presumably due to an active oxygen species (atomic oxygen?) generated by the alpha radiation field (Haire, 1976); in contrast, small (few micrograms) samples of CfO_2 may lose oxygen under these conditions. The exact composition of aged californium oxides is difficult to ascertain by X-ray analyses alone, as the lattice parameters measured reflect both radiation damage to the lattice (swelling, larger parameter) and/or oxidation that affects the O/M ratios (decrease in parameter with greater oxygen content). Both effects may be operational in these systems. There are reviews on the effects of radiation damage on actinide oxides (Fuger, 1975; Fuger and Matzke, 1991).

The high-temperature vaporization of californium oxides has been explored by Knudsen effusion studies (Haire, 1994). With californium, oxides with O/M ratios > 1.5 lose oxygen, especially in vacuum, when heated (see above discussion) so that vaporization studies at higher temperatures basically deal with the sesquioxide. From the phase behavior in Fig. 11.4, vaporization from solid Cf_2O_3 should involve its monoclinic or hexagonal phases. Vaporization products observed for Cf_2O_3 were atomic Cf and CfO, in a ratio of $\sim$1:10 at 1800 K. This low concentration of CfO (i.e. CfO is not a dominant species, even though CfO may be expected) is due to the relatively low dissociation energy of CfO (about 498 kJ mol^{-1}) as compared to CmO (about 728 kJ mol^{-1}; Cm/CmO < 0.1) (Haire, 1994). A value for the enthalpy of formation of the Cf_2O_3 from the vaporization studies was reported as between –1650 and –1700 kJ mol^{-1} (Haire, 1994), which compares to –1653(10) kJ mol^{-1} obtained from solution calorimetry experiments (see Chapter 19).

A systematic treatment of data for the lanthanide and actinide oxides has generated estimated thermochemical values for the oxides of californium (Morss, 1983). A comparison of the lanthanide and actinide oxygen systems in detail, which includes discussions of the californium oxides, is also available (Haire and Eyring, 1994). In Section 11.9, discussions on the gas-phase behavior of californium are presented and include other chemical aspects of californium oxides. Both experimental and computational thermochemical data for californium oxides are given in Chapter 19.

There are a number of more complex oxide materials (i.e. ternary systems for one) that are outside the scope of the present chapter. However, one system, the zirconium–californium oxide pyrochlores, is discussed given its potential applications and systematic comparisons with other comparable actinide pyrochlores. The zirconium–californium–oxygen compound has the stoichiometry of $Cf_2Zr_2O_7$. These f-element materials are called pyrochlores given their similarity of their structures to that of the mineral, 'pyrochlore.' A related system to these pyrochlores involves solid solutions of zirconium and californium dioxides, which can be prepared from the pyrochlores by adding oxygen to their lattice.

Applications for the americium and curium pyrochlore counterparts include transmutation and nuclear waste matrices, although these uses are not considered for the californium products. The californium–zirconium oxide pyrochlore is cubic with a lattice parameter of 10.57 Å, and it is isostructural with comparable compounds formed with the trivalent actinides plutonium through presumable einsteinium and zirconium or hafnium (Haire *et al.*, 2002). The fit of the lattice parameter of the californium compound with the plutonium through californium and lanthanide zirconium pyrochlores is shown in Fig. 11.6, which can be used to generate a linear equation for the parameters of mixed f-elements or ascertain the oxygen content of a particular pure pyrochlore. This relationship is useful to analyze mixed actinide or lanthanide–actinide pyrochlores when encountered.

11.7.4 Other compounds of californium

In addition to the oxides and halides, several other compounds of californium have been prepared and their crystallographic data reported (see Table 11.8). Some of these data represent preliminary values or even results from a single experiment. In some cases (pnictides, chalcogenides, etc.), the limited supply of californium metal has precluded the preparation of specific compounds via the reaction of the metal, especially where close control of the stoichiometries is required (for example, the preparation of the potential compound, CfS). The general preparative techniques for the different pnictides and chalcogenides of the transuranium elements have been reviewed (Damien *et al.*, 1979).

Stoichiometries other than 1:1 ratio are not expected for the californium pnictides. These materials can be prepared by direct reaction of the elements, and exhibit a NaCl-type, cubic structure. From preparations of CfN, a fcc lattice constant of 4.94 Å has been derived (Haire, 1988). This parameter is only slightly different or the same as reported for samples of fcc californium metal (4.994 Å, Stevenson, 1973; or 4.94 Å, Noé and Peterson, 1976; see Section 11.6)

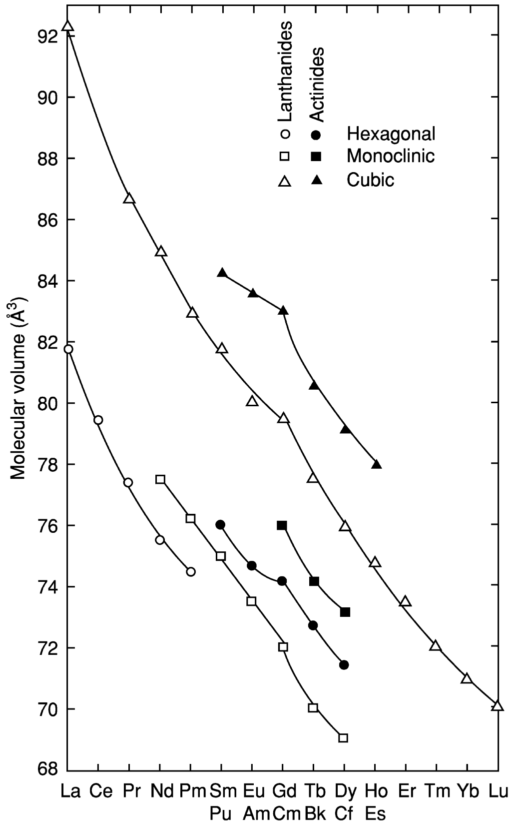

Fig. 11.5 *Molecular volumes of f-element sesquioxides.*

but much larger than the 4.78 Å parameter reported for the metal by Haire (1978) and Haire *et al.* (1986). It should be noted that carbon, nitrogen, and oxygen can replace one another in f-element, cubic NaCl-type compounds as the mononitride. The substitution going from carbon to nitrogen to oxygen increases the compound's parameter. For the remaining pnictogens, the monophosphide of californium has not been reported, but the monoarsenide and monoantimonide have been prepared (Damien *et al.*, 1980; see Table 11.8).

In contrast to the pnictides, californium chalcogenides of different stoichiometries can be prepared (Damien *et al.*, 1980). Preparation of the monochalcogenides requires close control of the reactant stoichiometries to avoid the formation of higher chalcogenides, and attempts to prepare californium monochalcogenides as single-phase products have not been successful to date. Another difficulty is that the monosulfide can convert to higher sulfides by volatilizing californium metal and driving the stoichiometry to a higher sulfide. The tritelluride, ditelluride, diselenide, disulfide, sesquiselenide, and sesquisulfide of

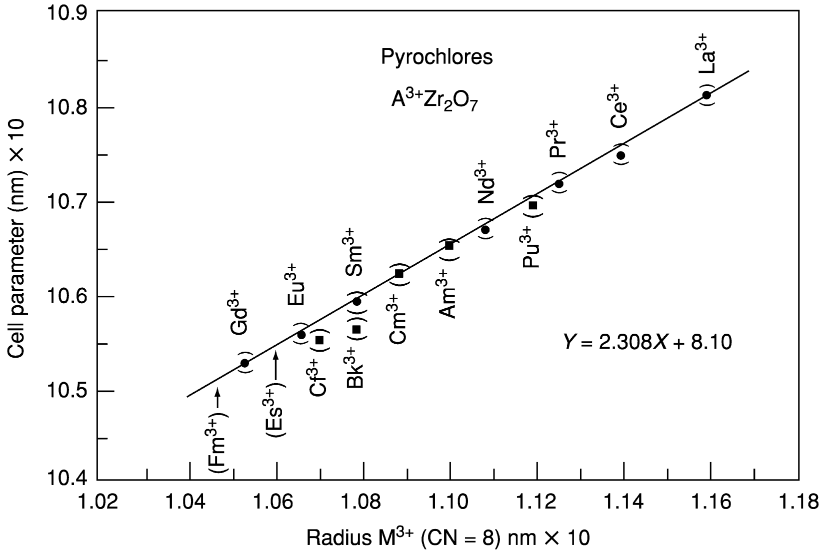

Fig. 11.6 *Relationship of lattice parameters and radii for f-element pyrochlore oxides. (units shown are equivalent to Ångströms)*

californium have all been prepared (Damien *et al.*, 1980). These higher chalcogenides are normally prepared by direct combination of the elements, and lower stoichiometries can be obtained by thermal decomposition of compounds having higher compositions. Lattice parameters for many of these californium compounds have not been reported. It is believed the tritelluride of californium has an orthorhombic structure isomorphous with the NdFe structure. All the dichalcogenide compounds crystallize in the anti-FeAs-type of tetragonal structure (as do the corresponding plutonium, americium, curium, and berkelium compounds). Four transuranium sesquichalcogenide structure types are known; but the sesquisulfide and sesquiselenide of californium have been obtained as the alpha form (bcc; anti-Th_3P_4 type of structure; Damien *et al.*, 1980).

There have been different reports on the preparation of californium hydrides (Gibson and Haire, 1985). The hydrides are generally prepared by reaction of californium metal with hydrogen at elevated temperatures. It was believed that the stoichiometries of the products were close to that for the dihydride (CfH_{2+x}). The products exhibited fcc structures with an average lattice parameter of $a = 5.285$ Å, which is slightly larger than expected for the compound based on extrapolations of parameters for preceding actinide dihydrides. This larger parameter and the inability to prepare a trihydride of californium in the initial efforts were believed to reflect a tendency for californium to be divalent. In the lanthanide–hydrogen system, the hydrides of divalent europium and ytterbium metals also deviate from the behavior of the other lanthanide hydrides (Topp, 1965). Reports of californium hydrides up to trihydride were subsequently published, which also included stoichiometries intermediate to the dihydride and trihydride (Gibson and Haire, 1987).

The oxysulfate (orthorhombic) and the oxysulfide (trigonal) of californium have also been reported (see Table 11.8); Baybarz *et al.*, 1974). These compounds can be prepared by thermally decomposing either Dowex ion-exchange resin beads containing Cf(III) or hydrated $Cf_2(SO_4)_3$ salt. The oxysulfide is obtained by heating these materials in a vacuum or a reducing (hydrogen-containing) atmosphere. The oxysulfate does not decompose to the sesquioxide when heated in air until the temperature exceeds 860°C.

A solid organocalifornium compound, $Cf(C_5H_5)_3$, has been prepared and characterized crystallographically (Laubereau and Burns, 1970a,b; see Table 11.8). Both powder and single-crystal X-ray data were obtained for this orthorhombic, cyclopentadienyl compound, which was prepared by reacting anhydrous $CfCl_3$ and molten $Be(C_2H_5)_2$, and the crystalline product was isolated by vacuum sublimation (135–200°C). A solid-state absorption spectrum of Cf $(C_5H_5)_3$ was obtained from these crystals, which showed a broad absorption from 600 nm to lower wavelengths. This was accredited to the presence of an electron-transfer process in the system.

Some work has also been reported on a californium dipivaloylmethanato complex, where the volatility of the complex was compared to complexes of other lanthanides and actinides (Sakanoue and Amano, 1976). These tracer studies suggested that the californium complex deposited at lower temperatures than the americium or plutonium complexes. Other studies have been done on formation of californium β-diketonates, and their thermochromatography behavior has been described (Aizenberg *et al.*, 1988).

11.7.5 Magnetic properties of compounds

A limited amount of magnetic work has been reported for californium and its compounds. Magnetic data for the metallic state of californium have been described in Section 11.6. The transplutonium metals with localized 5f electrons behave as though they consist of ions embedded in a sea of conduction electrons. It is these 5f electrons that are then mainly responsible for the susceptibility. With this simple model, the effective moment for californium metal should be the same as that for a californium ion, where the same number of nonbonding 5f electrons is present.

In Table 11.10 magnetic data for some f-element metal ions are listed, including californium, and their calculated magnetic moments based on LS coupling and Hund's rule. On this basis, the moments of Cf(IV), Tb(III), or Bk(III) would be the same, the moments of Cf(III), Dy(III), or Es (IV) would be identical, and the moments of Cf(II), Es(III), or Ho(III) would be equal. It is unfortunate that the measured moments cannot differentiate between Cf(II) and Cf(III),

Table 11.10 *Electronic states* (3+) *and effective magnetic moments given by LS coupling and Hund's rule: expected moments of californium.*[a]

Lanthanide	*Actinide*	3+ *Ion configuration*	*Basic level*	*L*	*S*	*J*	g_J	g_J $[J(J+1)]^{1/2}$	μ^*_{eff}
Gd	Cm	f^7	$^8S_{7/2}$	0	7/2	7/2	2	7.94	7.66
Tb	Bk	f^8	$^9F_6$	3	3	6	3/2	9.7	9.40
Dy	Cf	f^9	$^6H_{15/2}$	5	5/2	15/.2	4/3	10.63	10.22
Ho	Es	f^{10}	$^5I_8$	6	2	8	5/4	10.60	10.18

Based on these assumptions: Cf(II) = 10.60 μ_B; Cf(III) = 10.63 μ_B; and Cf(IV) = 9.72 μ_B.

[a] Edelstein and Karraker (1976) and Huray and Nave (1987). Based on intermediate coupling as opposed to pure *LS* coupling.

and that the calculated difference between Cf(III) and Cf(IV) is only 0.9 Bohr magnetons (see Table 11.10). However, the magnetic behavior of these materials as a function of temperature and/or magnetic field can still provide very useful information, and by itself may be sufficient to differentiate between these states.

The first magnetic data reported for californium compounds were obtained from 56 ng of californium; this small quantity required a microscope to measure the deflections of a Faraday apparatus (Cunningham, 1959). The objective of this experiment was to confirm that californium, deposited on an ion-exchange resin bead, had a radon core plus $5f^9$ electrons. The results showed that the sample followed the Curie–Weiss law and produced a moment of 9.2 μ_B. A subsequent experiment with larger samples (0.3–1.2 μg) of californium on resin beads gave effective moments of 9.1–9.2 μ_B. Magnetic studies on oxides, Cf_2O_3, Cf_7O_{12}, CfO_2, and $BaCfO_3$, have been reported (Moore *et al.*, 1986). The magnetic moments obtained in these studies were in agreement with the charge states assigned to californium based on the stoichiometries in the materials. Magnetic studies have also been carried out on three monopnictides, CfN, CfAs, and CfSb (Nave *et al.*, 1985) and on the two structure types of $CfCl_3$ (Nave *et al.*, 1986).

In other studies, the moment of californium in a Cs_2NaYCl_6 host has been measured (Karraker and Dunlap, 1976). An electron paramagnetic resonance study on Cf(III) in a cubic $NaLuCl_4$ host (<1% Cf by weight) produced a 10-line spectrum to confirm the nuclear spin to be 9/2 (Edelstein and Karraker, 1976). The crystal field ground state was also identified in this work and the nuclear dipole moment of ^{249}Cf was determined to be –0.28 μ_n. The magnetic properties of californium compounds and metal are summarized and compared in Table 11.11.

11.7.6 Solid-state absorption spectra

The anhydrous transplutonium halides have been extensively studied by absorption spectrophotometry. The f–f and f–d transitions in californium spectra

can be utilized to ascertain the oxidation state and coordination number of californium in the compounds. A valuable technique in these spectroscopy studies was the use of a 'fingerprint' approach, where spectra of materials with known structures were used to compare with other compounds. Some of these experimental techniques employed for studying microgram quantities of californium halides have been reported (Green, 1965; Green and Cunningham, 1966; Fujita and Cunningham, 1969; Young *et al.*, 1978). One of the first absorption spectra for californium was obtained from a single crystal of anhydrous $CfCl_3$. Subsequently, other spectra have also been obtained for this compound (Carnall *et al.*, 1972; Peterson *et al.*, 1977) and for $CfCl_2$ (Peterson *et al.*, 1977). Absorption spectra have also been obtained for anhydrous $CfBr_3$ (Young *et al.*, 1975, 1980); $CfBr_2$ (Young *et al.*, 1980), CfI_3 and CfI_2 (Wild *et al.*, 1978), plus CfF_4 and CfF_3 (Haire *et al.*, 1980).

In Fig. 11.7 solid-state absorption spectrum for $CfCl_2$ is shown, which is compared with a spectrum for $CfCl_3$. There is a distinct difference between the absorption spectrum for Cf(III) and Cf(II) states. For a given oxidation state, differences in absorption spectra as well as emission spectra can be noted when the crystal structures are different. This arises from symmetry conditions and how they affect the splitting of electronic levels in the californium compounds. These spectra, once assigned to specific structures, may be used to identify the

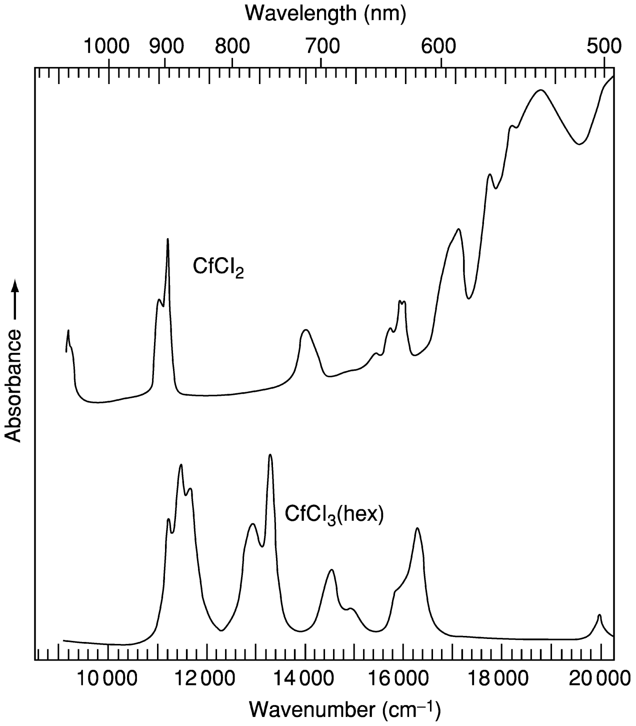

Fig. 11.7 *Solid-state spectra for $CfCl_2$ and $CfCl_3$.*

structure type by a 'fingerprint' technique. Thus, one finds the spectral envelops of the absorption spectrum for the hexagonal form of $CfCl_3$ differs from that of the orthorhombic form of this compound. A review of solid-state spectral studies on californium halides is available (Wilmarth and Peterson, 1991a,b). In this review the authors also give a discussion of Raman spectra obtained for californium.

Laser-induced fluorescence of Cf^{3+} in a $LaCl_3$ host has also been reported (Caird *et al.*, 1976; Hessler *et al.*, 1978). A limited amount of spectral information has been reported for the dicyclopentadienyl californium compound, where Cf exists as Cf(III) (Laubereau and Burns, 1970a,b). The spectra of Cf(IV) in CeF_4 matrices has also been discussed (Liu *et al.*, 1993) and information obtained was interpreted in terms of line broadening.

Infrared spectra for californium materials have also been obtained (Conway *et al.*, 1977). Crystal field calculations and parameters for the trivalent actinides in crystal hosts have been made and published (Carnall and Fried, 1976; Conway *et al.*, 1977; Crosswhite, 1977). The spectroscopic properties of californium compounds pertinent to potential laser applications have also been discussed, and the transition from the $J = 11/2$ state at 6500 cm to the $^6H_{15/2}$ ground state appears to be a likely candidate in this regard (Weber, 1980). Free-ion energy levels and the optical properties for californium have also been published (Hessler and Carnall, 1980).

In addition, absorption spectra of californium halides have been obtained and examined as a function of time, looking at the daughter or granddaughter products in studies that examined the chemical and structural consequences of the radioactive decay processes (Young *et al.*, 1980, 1981, 1984). Following the chemistry and structural forms through radioactive decay processes by examining the californium granddaughter products produced from the decay of Es-253 halides (i.e.Es-253 → Bk-249 → Cf-249 → ⋯) is an example. It is worthwhile to note that in the latter decay sequence, Cf(III) halide product was produced from an initial Es(III) halide product and a Cf(II) halide product when starting with a Es(II) halide. Essentially, the oxidation state was retained through two decay events, first an alpha and then a beta decay). This implies that a Bk(II) product was formed in the transition although Bk(II) has not been synthesized directly.

11.8 SOLUTION CHEMISTRY

11.8.1 General comments

Although californium exhibits oxidation states of II, III, and IV in the solid state, its solution chemistry is basically that of a trivalent ion. There has been only a couple of unsubstantiated reports of an oxidation state above Cf(IV) in solution even though formation of Cf(V) presumably would acquire some stabilizing influence by attaining a half-filled, 5f-orbital state ($5f^7$).

To retain the tetravalent state in solution is also more difficult than generating it in the solid state, and for solutions it requires a high degree of complexation to afford sufficient stabilization to maintain this state. It has been reported (Kosyakov *et al.*, 1977) that Cf(IV) was stabilized in phosphotungstate solutions, where M(IV)/M(III) couples can be shifted by as much as 1.0 V (Barnanov *et al.*, 1981). Another report for stabilizing Cf(IV) in solution involved the use of triphenylarsine oxide in acetonitrile (Payne and Peterson, 1987).

It is expected to be easier to stabilize Cf(II) than Cf(IV) in solutions. Nonaqueous solvents also offer some promise for obtaining both the II and IV oxidations states of californium. But in all cases, the effects of self-irradiation and the potential for generating oxidizing and/or reducing conditions must be considered and factored into the picture.

Although californium is the electronic homolog of dysprosium, its divalent–trivalent behavior in solution should be considered to be more similar to that of samarium, and its trivalent–tetravalent behavior may be comparable to that of terbium. Thus, samarium and terbium can be used as template elements for testing the oxidation behavior of californium.

Trivalent californium's behavior in solution is very similar to the behaviors of the trivalent lanthanide ions in solution, except californium has a greater tendency to form complexes (is more covalent). This arises from the somewhat extended 5f orbitals of actinides compared to the 4f orbitals, which provides a slightly greater degree of complexing ability to afford californium's greater covalent nature. The higher degree of complexation found with the transplutonium (III) ions in ethanol–HCl solution, as compared to the lanthanide (III) ions (see Section 11.4), has used this condition as one method for a group separation.

As with the lanthanides, both fluoride and oxalate ions will precipitate trivalent californium from dilute acid solutions. Addition of hydroxide to a Cf(III) solution produces a gelatinous, light green-tinted precipitate, which is presumably its trihydroxide. In non-complexing solutions (i.e. dilute acid solutions, 0.1 M perchloric or hydrochloric acids), Cf(III) exists as a hydrated cation; at higher acid concentrations (i.e. 6 M HCl), complexation is sufficient so that californium will not be held on cation-exchange resins but will elute as an anion complex. This difference in complexation forms the basis for a number of group separations between trivalent lanthanides and actinide ions. The greater complexing nature of the actinides allows them to be removed from cation-exchange resins with different reagents while the lanthanides are retained on the columns.

11.8.2 Oxidation–reduction reactions

Several reduction potentials for californium have been derived from both experimental data and from systematic calculations, and some of these values are given in Table 11.12. The calculated Cf(IV)/(III) couple of 3.2 V (Nugent *et al.*, 1971) is in accord with the inability to obtain Cf(IV) in most aqueous media. This value for californium can be compared to the Tb(IV)/Tb(III) couple of 3.1–3.3 V, the Am(IV)/Am(III) couple of 2.2–2.5 V, and the Cm(IV)/Cm(III) couple of 3.1–3.5 V (Nugent *et al.*, 1973a,b). It is difficult to maintain Am(IV) and essentially not feasible to produce Cm(IV) in most aqueous solutions. Preparation of these higher oxidation states for the actinides in general should be more favorable in alkaline than acidic media, but complexation can also offer stabilization. Thus, in principle, the ease of forming Cf(IV) should be comparable to forming Tb(IV) or Cm(IV) in solution, which are more difficult than forming Am(IV) in solution. This relative behavior of californium in solution may be likened to that in the solid state: the formation of californium dioxide is comparable to preparing terbium dioxide, with both being more difficult to prepare than americium or curium dioxide (see Section 11.7.3).

The ability to oxidize Cf(III) to Cf(IV) in a phosphotungstate solution has been summarized in a paper on the solution behavior of the transplutonium elements (Myasoedov, 1982). Both Tb(IV) and Am(IV) can be stabilized in strong carbonate; thus, it would appear possible to prepare Cf(IV) in a strong carbonate medium, utilizing the expected shift of 1.7 V in the Cf(IV)/Cf(III) couple arising from carbonate complexation of the Cf(IV). Two conflicting reports exist on the

oxidation of Cf(III) in carbonate. One group (Hobart *et al.*, 1981, 1983) was unable to find evidence for Cf(IV) after chemical or electrical treatments, while a second team (Myasoedov *et al.*, 1986) reported that 20% of the Cf(III) present in a K_2CO_3 solution could be oxidized electrochemically.

The behavior of californium and the next two actinide elements in molten salts where strong reducing agents were present has been reported (Kulyukhin *et al.*, 1997). The ease of preparing the divalent state increases in going across the series to einsteinium.

A number of studies have supported the potential for the existence of Cf(II) in solution. In one study, the tendency for californium to form amalgams rapidly is compared to the behavior of the lanthanides known to acquire a divalent state (Maly, 1967; Maly and Cunningham, 1967; Nugent, 1975). In early work, the inability to reduce Cf(III) in 0.1 M NH_4Cl suggested a potential limit of −1.4 V for the Cf(III)/Cf(II) couple (Cunningham *et al.*, 1970). David (1970a–c) also proposed a value of –1.4 V from radiopolarographic and amalgamation behaviors using tracers.

Studies on the coprecipitation behavior of californium (Cohen *et al.*, 1968; Fried and Cohen, 1968; Mikheev *et al.*, 1972a,b) have also supported the existence for Cf(II) in solution. The difference in formal potentials between the Sm(III)/Sm(II) and Cf(III)/Cf(II) couples has been estimated to be 0.045 V (californium being more negative) by studies on coprecipitation of chloride salts in aqueous ethanol solutions (Mikheev *et al.*, 1972a,b). Another comparison between the reduction behavior of californium and samarium was made in anhydrous acetonitrile (Friedman *et al.*, 1972), where the Cf(III)/Cf(II) and Sm(III)/Sm(II) couples were found to be nearly identical; a value of –1.58 V was proposed for the Cf(III)/Cf(II) couple. Essentially the same value (–1.60 V) for this couple was reported from co-crystallization studies (Mikheev *et al.*, 1972a,b). Nugent *et al.* (1969, 1973a) have suggested the potential for the Cf(III)/Cf(II) couple is –1.6 V, based on systematic analyses of electron-transfer bands. Radiopolarographic experiments on californium have resulted in two reports regarding its behavior. The first report (David, 1970a) suggested two couples: –2.32 V for Cf(III)/Cf(0) and –1.4 V for Cf(III)/Cf(II). Subsequent work (Samhoun and David, 1976) concluded that the first radiopolarographic results were incorrect, and that Cf(III) is reduced directly to Cf(Hg) in one step ($E_{1/2} =$ 1.503 V): correcting for the amalgamation process yields a Cf(III)/Cf(0) couple of –2.01 V. Guminski (1996) has discussed the Hg-Cf system.

Subsequently, a polarographic and voltammetric study (Musikas *et al.*, 1981) on larger amounts of californium concluded that californium is reduced via a two-step process as is found with samarium: (1) Cf(III) → Cf(II) and (2) Cf(II) → Cf(Hg). Potentials for these processes were given as –1.47 and –1.68 V, respectively. These data yield a calculated value of –1.61 V for Cf(III)/Cf(0). An evaluation of earlier amalgamation experiments has also led to a proposed value of –2.2 V for the Cf(II)/Cf(0) couple (Nugent, 1975).

These reported differences for californium have not been resolved and additional work needs to be done to resolve the system. Since Cf(II) can be prepared and maintained in the solid state, there still remains a good possibility that Cf(II) can be stabilized in aqueous and/or nonaqueous solvents. David *et al.* (1990a,b) and David and Bouissières (1968) discuss the electrochemical reduction in aqueous solution for separations, and for the formation of intermetallic compounds and amalgams. Other work on the radiopolarography of californium has also been published (Skiokawa and Suzuki, 1984).

Evidence for Cf(II) in molten-salt systems has also been reported (Ferris and Mailen, 1971). The distribution coefficient of californium between molten lithium chloride and lithium–bismuth metals at 640°C indicated that divalent californium was present in the salt phase. However, evidence for the existence of Cf(II) was not found in lithium fluoride–beryllium fluoride melts (Ferris and Mailen, 1970).

It is generally accepted that the stability of the divalent state increases for the second half of the actinide series of elements, and it has been accepted that californium metal is close to being a metal having only two bonding electrons (see earlier section). Starting with californium, the M(III)/M(II) couples increase regularly in the order: No > Md > Fm > Es > Cf, with values ranging from –1.45 V for nobelium to –1.60 V for californium (Myasoedov, 1982).

In discussing the oxidation states of californium in solution, the possibility of attaining Cf(V) could be enhanced by the attainment of a $5f^7$ electronic state.

Some early coulometric data obtained with a few micrograms of californium suggested that Cf(v) may have been attained in a 1 M H_2SO_4 solution (Propst and Hyder, 1969), but these results have not been confirmed and are likely to be incorrect. More recently, a claim for the generation of Cf(v) in a carbonate media was made based on results of coprecipitation experiments (Kosyakov *et al.*, 1982a,b). In this work, small amounts (<10%) of californium, generated from the decay of Bk(IV) in the solution, were found in $Na_4UO_2(CO_3)_3$ 'wet' solids precipitated from the solutions. The presence of 'co-precipitated' californium in these precipitates was interpreted as reflecting the presence of an oxidized form of californium (Cf(IV) or Cf(v) i.e. as the CfO^{2+} or CfO_2^+ ion) within the uranium precipitate. These results must be accepted with some caution, as other explanations for the behavior can be given. It is likely that Cf(IV) would accompany Bk(IV) in such situations. Thermodynamic (David *et al.*, 1978) and quantum-chemical calculations (Ionova *et al.*, 1980) have been made that indicate it may be possible to obtain Cf(v) state in the solid state, which could be considered for the solid phases mentioned above. However, it would seem most plausible that Cf(IV) or Cf(v) would be stabilized in alkaline conditions/materials, oxygenated complexes, complex polyanion materials (i.e. polytungstates), etc.

11.8.3 Complexation chemistry

A considerable portion of the published data dealing with californium concerns the complexation and solvent extraction chemistry of Cf(III). This is in part a consequence of the fact that a large amount of this information could be obtained using tracer quantities of the more abundant ^{252}Cf isotope, which also has a higher specific activity. In addition, there was an impetus to perform this type of study using the small quantities available during the investigation/development of californium's separation chemistry for processing. A compilation of stability constants for californium complexes and chelates is given in Table 11.13.

Some of the first data on californium complexes involved materials such as halides, citrates, lactates, α-hydroxyisobutyrate complex, etc., as these materials played a role in early separation/purification schemes (Katz and Seaborg, 1957; Keller, 1971) for californium (see Section 11.4). In general, it is expected that only small differences in stability would exist between Cf(III) and its two trivalent near neighbors, Bk(III) and Es(III), with potentially larger differences existing between Cf(III) and Am(III). A general discussion of actinide complexes (including californium) in aqueous solution is available (Jones and Choppin, 1969). Horwitz *et al.* (1997) discuss complexer in solution.

From the initial studies on Cf(III) and sulfate ions (De Carvalho and Choppin, 1967) it was concluded that 1:1 and 1:2 complexes $Cf(SO_4)^+$ and $Cf(SO_4)_2^-$ were formed, but subsequent work in the sulfate system suggested that mono-, di-, and trisulfate species were formed (McDowell and Coleman, 1972).

[a] Overall formation constants:

$$\beta_1 = \frac{[\mathrm{CfA}^{(3-n)+}]}{[\mathrm{Cf}^{3+}][\mathrm{A}^{n-}]}, \quad \beta_2 = \frac{[\mathrm{CfA}_2^{(3-2n)+}]}{[\mathrm{Cf}^{3+}][\mathrm{A}^{n-}]^2} \quad \text{etc.}$$

stepwise constants:

$$K_2 = \frac{[\mathrm{CfA}^{(3-2n)+}]}{[\mathrm{CfA}^{(3-n)+}][\mathrm{A}^{n-}]} \quad \text{etc.}$$

A similar situation exists for the thiocyanate complexes reported for Cf(III). Initially a 1:1 complex, $Cf(SCN)^{2+}$, was reported (Choppin and Ketels, 1965), but subsequent work indicated that three different complexes could form: $Cf(SCN)^{2+}$, $Cf(SCN)_2^+$, and $Cf(SCN)_3$, where the 1:3 complex was of the inner-sphere type (Coleman, 1972).

The hydrolysis behavior of Cf(III) is expected to be similar to that of trivalent lanthanides, and more specifically to that of Eu(III) or Gd(III), which have nearly the same ionic radii. The first hydrolysis reaction (i.e. $Cf^{3+} + H_2O \rightarrow CfOH^2 + H^+$; i.e. the K_1 value) has also been determined for Cf(III); log K_1 values for it were given as –5.62 (Desiré *et al.*, 1969) and –5.05 (Hussonnois *et al.*, 1973).

Several quite stable complexes can be formed with Cf(III) (see Table 11.13). Complexes of diketones and aminopolycarboxylic acids have been found to be considerably more stable than those of tartrate, lactate, oxalate, etc. In some cases, adduct chelates can also form with Cf(III), such as with the californium thenoyltrifluoroacetone (TTA) chelate and methyl isobutyl ketone (MIBK) (i.e. $Cf(TTA)^{3+}$ and $Cf(TTA) \rightarrow$ MIBK or Cf(TTA)3–2 MIBK; Desiré *et al.*, 1969).

With the monodentate ligands, such as tributyl phosphate (TBP), the extractable californium adduct from nitric acid solutions has been assigned as being a 1:3 species $Cf(NO_3)_3 \cdot 3\,TBP$ (Healy and McKay, 1956). Quaternary ammonium bases and alkylpyrocatechols (i.e. 4-dioctylethyl pyrocatechol) can form californium complexes in alkaline solutions (Derevyanko *et al.*, 1976), which affords a different medium for complexation. One recent extraction study has examined the influence of the extractant's structure on the extraction behavior of californium (Derevyanko *et al.*, 1976). A large number of materials have been investigated for forming extractable complexes of californium, and the reader is referred to reviews on the subject (Ishimori, 1980; Myasoedov *et al.*, 1980; Shoun and McDowell, 1980). Takeiski *et al.* (2001) have discussed the solvent extraction of californium by deratives of bis(1-phenyl-3-methyl-4-acylpyrazol-5-one) .

Exchange kinetics of Cf(III) with europium ethylenediaminetetraacetate (Eu EDTA) in aqueous solution ($\mu = 0.1$) has also been reported (Williams and Choppin, 1974). The exchange was found to be a first-order reaction having both acid-dependent and acid-independent terms.

From a study of the relationship between distribution coefficients for californium with sodium nitrate in extractions using organic ammonium nitrates, the apparent mean molar activity coefficient of Cf(III) was calculated in terms of a polynomial (log $k = a + bm + cm^2 + dm^3$, where $a = 0.00397$, $b = –0.154$, $c = 0.0252$, and $d = 0.00119$) (Chudinov and Pirozhkov, 1973).

Some initial studies of californium complexes involving 6-methyl 2-(2-pyridyl)-benzimidazole and derivatives of it have been carried out. The initial studies involved photoluminescence and Raman spectroscopy investigations, where it was concluded that 1:1, 1:2, 1:3, and 1:4 complexes were formed (Assefa *et al.*, 2005).

A general discussion of the hydrolysis of actinide ions is given in a review by Ahrland (1991). Although little is mentioned about californium, several general concept discussed there are useful for the trivalent actinides. In another review, Bhattacharyya and Natarajan (1991) discuss the radiation chemistry of actinide solutions. A rate constant for the oxidation of Cf^{2+} by water ($K = 7 \times 10^4\ \text{M}^{-1}\ s^{-1}$) and a rate constant for the reduction of Cf^{3+} ($K = 3 \times 10^9\ \text{M}^{-1}\ s^{-1}$) at a pH of 5.3 are quoted.

11.8.4 Thermodynamic data

The thermodynamic behavior of californium has been addressed in Chapter 19. Given there are the recommended values for californium that have been arrived at after considering various reports.

Selected thermodynamic data for the formation of Cf(III) in solution (according to the following reaction):

$$\mathrm{Cf}_{(s,a)} + 3\mathrm{H}^+_{(aq)} = \mathrm{Cf(III)}_{(aq)} + 3/2\mathrm{H}_{2(g)}$$

are given in Table 11.14 (also see Section 11.6.2 on californium metal for comments on its enthalpy of solution), which has been used for calculating the enthalpy of formation of aqueous ions. The enthalpy of formation, $\Delta H^{\circ}_{298,f}(Cf^{3+},aq))$ was derived from the enthalpy of solution (Fuger *et al.*, 1984) as being –577(5) kJ mol^{-1}. The entropy, S° (Cf^{3+}, aq)), has been accepted as –197(17) J $K^{-1} \cdot mol^{-1}$ (see Chapter 19). Using these values and S°(Cf, cr, α phase, 298.15 K) = 81(5) (Ward, 1983; see Chapter 19) one obtains $\Delta_f G(Cf^{3+},aq)$ = –533(7) kJ mol^{-1}. A standard potential for the Cf(III)/Cf(0) couple was calculated to be –(1.92 ± 0.03) V in that work. Earlier estimates for this potential ranged from –1.95 to –2.03 V (Nugent, 1975; David *et al.*, 1976a,b; David *et al.*, 1978; Samhoun and David, 1979).

Other estimates for ΔH_f (Cf^{3+},aq) have appeared in the literature. Nugent *et al.* (1973a,b) proposed a value of –623 kJ mol^{-1}; David *et al.* (1986) suggested −(586 ± 21) kJ mol^{-1}; and Nugent (1975) subsequently arrived at a value of –(602 ± 21) kJ mol^{-1}. A value of –603 kJ mol^{-1} was estimated for californium in a comparison given for thermochemical properties for the lanthanide and actinide elements (Morss, 1983). This latter work also presents other thermochemical values for californium.

Predictions of the standard free energy (ΔG_f) and the enthalpy of hydration (ΔH_{hyd}) for the trivalent californium ion have been made based on an electrostatic hydration model (Goldman and Morss, 1975). Assuming a crystallographic radius of 0.94 Å and a gas-phase radius of 1.516 Å for Cf(III), and using a primary hydration number of 6.1, ΔG°_{298} and ΔH°_{298} were calculated to be –3385 and –3582 kJ mol^{-1}, respectively.

Thermodynamic data for the 1:1 complex, $Cf(SO_4)^+$, have been calculated from the temperature dependence of the stability constant (De Carvalho and

Choppin, 1967). Values for this complex are: $\Delta G_{298} = -7.9$ kJ mol^{-1}, $\Delta H_{298} =$ 19 kJ mol^{-1}, and $\Delta S_{298} = 88$ kJ mol^{-1}. Similarly, data for the 1:1 CfF^{2+}complex have been calculated (Nugent *et al.*, 1973a,b), and have been given as: $\Delta G_{298} =$ 17.3 kJ mol^{-1}, $\Delta H_{298} = 27.2$ kJ mol^{-1}, and $\Delta S_{298} = 14$ kJ mol^{-1}.

Other thermodynamic data have also been reported for californium (David *et al.*, 1978). The reader is also referred to Chapter 19 for a more complete summary of thermodynamic data for californium.

11.8.5 Solution absorption spectra

The first absorption spectrum for Cf(III) was obtained from the solid state (Green, 1965; see Section 11.7.6). The first solution absorption spectrum was obtained shortly thereafter, using 592 μg of mainly ^{252}Cf isotope, which introduced experimental problems regarding both shielding and radiolytic gassing. Nineteen absorption bands were recorded between 280 and 1600 nm from a 1 M $DClO_4$ solution (see Table 11.15; Fig. 11.6). The absorption spectrum from this work was confirmed using milligram quantities of ^{249}Cf (Carnall and Fried, 1976).

Table 11.15 *Absorption data for Cf(III) in 1 M $DClO_4$.*[a]

[a] Hobart *et al.* (1983).

The absorption spectrum of Cf(IV) and Cf(III) in a potassium phosphotungstate medium has been reported (Kosyakov *et al.*, 1977; Myasoedov, 1982). The phosphotungstate ion stabilizes the Cf(IV) oxidation state sufficiently to permit spectra to be obtained (half-life approximately 70 min at room temperature). This Cf(IV) oxidation state was achieved by using potassium persulfate at elevated temperatures; attempts to oxidize (Cf(III) electrochemically in this medium were not successful. The absorption spectrum of Cf(IV) in this medium is characterized by a broad absorption band beginning at 1030 nm and increasing in intensity down to 390 nm. The maximum absorption appears at about 450 nm, which is similar to the absorption maximum obtained for Cm(IV) and Tb(IV) in this medium (Myasoedov, 1982). The absorption of a comparable Cf(III) phosphotungstate solution did not show a significant absorbance over this spectral region.

11.9 GAS-PHASE STUDIES

In addition to studies in the solid phase and in solution, investigations of reactions in the gas phase provide important insights into the chemistry and electronic make-up of californium. These studies in the gaseous state examine the reactions of Cf ions with other molecules, as opposed to addressing the vaporization of the metal (see Section 11.6), or other solids such as oxides (see Section 11.7.3), which can provide important thermodynamic parameters for these materials (i.e. their enthalpies of vaporization and formation).

The gas-phase chemistry of californium has been studied by mass spectrometry time-of-flight, and Fourier transform ion resonance mass spectrometry (FTIRMS), and the latter offers an especially powerful technique in this regard. In this technique, metal ions can be isolated and then reacted with other specific materials, which can lead to bond dissociation energies, reaction kinetics, and ionization potentials for the metal ions being studied. Important information about californium's electronic configuration, which can be used for systematic comparisons with other actinides, is also be obtained from these gas-phase reactions.

One area of this californium gas-phase chemistry has involved the dehydrogenation of alkenes, thiols, ethers, and perfluorohydrocarbons by Cf^+ (Gibson and Haire, 2000). The emphasis in that work was on the efficiency of dehydrogenation of alkenes by Cf^+ ions, and direct comparisons with the comparable reactivities of Cm^+, Pr^+, and Tm^+ for similar reactions. It was determined that Cf^+ is inefficient at C–H bond activation, due to its particular electronic structure and energy levels, and evidence was not found for the direct participation of its 5f electrons in the reactions studied.

In related studies, organometallic ions of californium were produced in the gas phase by laser ablation of Cf_2O_3 dispersed in polyimide matrices. This process was followed by mass spectrometric analyses (Gibson and Haire, 2001). Primary products formed were: CfC_2H^+, $CfCN^+$, CfC_4H^+, $Cf(OH)(CN)^+$, $CfOCN^+$, $CfOH^+$, $Cf(OH)_2^+$, and CfO^+. Some of these products represent the first organometallic materials for californium where it is directly bonded to carbon. It was concluded that the composition and abundance of the products are dependent on the ability of californium to have two non–5f valence electrons at the Cf^+ center for participation in the bonding, which involves a single sigma-type bond with the organic material. Thus californium exhibits 'monovalent character' (one direct actinide–carbon bond; as do americium and berkelium) versus 'divalent character' of thorium, uranium, neptunium, plutonium, and curium (two direct actinide-carbon bonds)

This behavior is electronically orientated and associated with the $f \rightarrow d$ promotion energies of the actinides to give a chemically active 6d orbital. As the promotion energy for californium is higher (i.e. ~ 200 kJ mol^{-1}, see Fig. 11.10) than earlier actinides, this diminishes the generation of reaction products for it. More recent work with Cf^+ and Es^+ (see Chapter 12) has shown that a greater reactivity is observed with pentamethylcyclopentadiene than with most other alkenes. It was found that Cf^+ reacts with this reagent to produce $[MCp^*]^+$ and other products. This behavior of Cf^+ allows estimates for low-lying electronic levels (Gibson and Haire, 2005).

In studies of californium with several alkenes (Gibson and Haire, 2004), it was determined that the relative C–H activation of Cf^+ was $<1\%$ of that for Cm^+. Thus, instead of C–H activation from insertion of the metal center into a

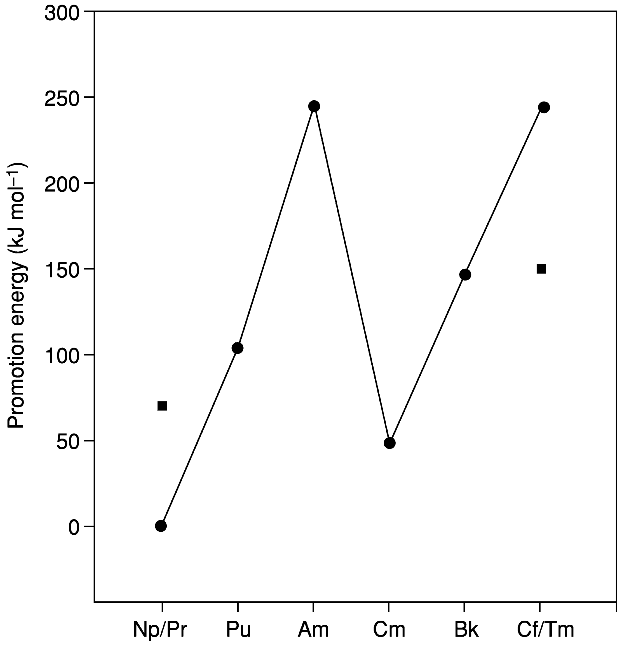

Fig. 11.10 *The f–d promotion energies for selected actinides. Values for Pr and Tm (solid blocks) are given for comparison. (Gibson,* 2003).

C–H bond (i.e. C–Cf^+–H), reactions of Cf^+ with butryonitrile produces an adduct, M^+-butrynitrile. Californium also resisted the formation of CfO^+ ions, consistent with its preference to be 'divalent' rather than 'trivalent' – attempts to oxidize Cf^+ with N_2O to yield CfO^+ in the gas phase were not successful.

In reactions of Cf^+ with perfluorophenanthrene (Gibson and Haire, 2005) only minor yields of CfF_2^+ were observed, again in accord with its propensity to remain divalent. This is also in accord with results noted in the vaporization of Cf_2O_3 at high-temperatures (Haire, 1994). Very little CfO is found in the vapor state as compared to atomic Cf vapor (see Section 11.7.3). This latter behavior is similar to that observed with Eu_2O_3 and Yb_2O_3 and results from the lower dissociation energy of CfO compared to CmO (Haire, 1994). The dissociation energies of the monoxides are also linked to the f–d promotion energies for f-electrons and the formation and availability of active 6d orbital–7s electron orbitals (Haire, 1994; Gibson, 2003).

11.10 CONCLUDING REMARKS

A considerable quantity of chemical and physical data have been acquired for californium over the years. In many instances this information was obtained using tracer levels or microgram quantities of the element, often using the ^{252}Cf isotope. With the availability of multi-milligram amounts of ^{249}Cf isotope, it became possible to expand studies of californium and prepare pure samples of the metal. This allowed important information to be obtained for californium; acquiring the enthalpy of solution (Fuger *et al.*, 1984) and the sublimation of californium metals (Ward *et al.*, 1980) are two such examples. These data then allowed thermodynamic cycles to be established for the element and many of its compounds.

Given the limited supplies of ^{249}Cf (i.e. perhaps a total of some 50–100 mg exist) as well as other experimental limitations (given its radioactive decay process, the accompanying heat, personnel radiation exposures, etc.) it may not be possible to perform all the desired experiments or to be able to carry them out to the degree of perfection that may be desired. However, californium is the element with the highest atomic number in the periodic table expected to be available in weighable amounts (milligrams) and that has a reasonably long half-life. This allows many studies with it that cannot be done with higher members of the actinide series or periodic table. The next element, einsteinium (see Chapter 12) is available in only multi-microgram amounts, but its very high specific radioactivity and the short half-lives of its isotopes severely limit the experiments can be performed with it. Therefore, data on californium can provide insights/extrapolations into the chemical/physical properties of the higher members of the actinide series, in addition to the importance of its own data in providing a better understanding of the architecture of the periodic table.

Oxidation states of 0, II, III, and IV have been established for Cf, with the III state being the most prevalent and the only state presently known to have a reasonable stability in aqueous solutions. The existence of Cf(V) has been suggested but needs confirmation. In may be more probable to generate this oxidation state in solids or nonaqueous solutions and/or molten salts than in aqueous solutions. Future investigations of californium may place emphasis on stabilizing oxidation states other than Cf(III).

Studies of californium in the gaseous state offer important new thrusts in californium chemistry. Using ion cyclotron resonance mass spectrometry, californium ions can be selected, held, and then reacted with a variety of materials to establish important parameters, thermodynamic properties, bond dissociation energies, reaction kinetics, etc.

Although a considerable amount of information has been acquired for californium metal, there are still unanswered questions about it, for example, concerning a potential divalent form of the metal under certain conditions. Recent high-pressure diffraction studies on the metals have provided important new aspects about the behavior of their 5f electrons under pressure and reduced interatomic distances. Indeed, under these very high pressures (i.e. 100 GPa or higher), the electronic nature of californium metal changes, and it adopts lower-symmetry structures normally displayed by the lighter actinide metals (Pa–Pu), which have itinerant 5f electrons at atmospheric pressure. These high pressures on californium metal forces the involvement of its 5f electrons into its bonding and changes its physical properties. Thus, pressure can bring about a form of modern alchemy in californium metal with regard to its structure and properties.

There is also a considerable amount of work that can be done on californium compounds, such as the monopnictides and chalcogenides – the mononitride and monosulfide both offer interesting compounds to study in detail. Investigations of its compounds under high pressure should also provide new findings about californium's chemistry. Applying modern tools (synchrotron-based, EXAFS, XANES, photon scattering, etc.) offers the potential to learn new facets about californium materials.

In short, there is a considerable amount of scientific work that needs to be done on californium, perhaps the highest atomic numbered element available for performing the usual actinide studies. The scope of such studies will be limited only by the imagination and skill of the investigators.

ACKNOWLEDGMENTS

The author gratefully acknowledges the assistance of several personnel at the Oak Ridge National Laboratory, as well as other institutions, for helpful discussions, references, comments, and in some cases collaborative studies on californium. The research reported herein was sponsored by the Division of Chemical Sciences, U.S. Department of Energy, under contract DE-AC05-00OR22725 with UT-Battelle, LLC.

CHAPTER TWELVE

EINSTEINIUM

Richard G. Haire

12.1 INTRODUCTION

The discovery of einsteinium, element 99, came about during the analyses of nuclear products produced in and then recovered from test debris following a thermonuclear explosion (weapon test device, 'Mike', November 1952) at Eniwetok Atoll in the Pacific Ocean. The uranium present in this device was subjected to a very intense neutron flux (integrated fluence of about 10^{24} neutrons) in an extremely short time frame (few nanoseconds), which allowed a large number of multiple neutron captures with a minimal degree of decay of the products formed. Nuclei were formed with usually high neutron/proton ratios (very 'heavy' uranium isotopes), which then rapidly beta-decayed into new, transuranium isotopes through element 100. Scientists from several U.S. Government laboratories separated and analyzed extensively the debris samplings in the following weeks. From these investigations came the discovery and identification of einsteinium and fermium. The first element was named in honor of Albert Einstein, and assigned the symbol, E (later changed to the current symbol, Es). Additional details and discussions about the discovery of this element and the scientists involved are given in several references (Thompson *et al.*, 1954; Ghiorso *et al.*, 1955; Fields *et al.*, 1956; Hyde *et al.*, 1964; Seaborg and Loveland, 1990).

Subsequently, einsteinium has been produced in accelerator targets, and in reactors via successive neutron captures, starting with targets of plutonium or higher actinides. The first macroscopic and weighable quantities of einsteinium (few hundredths of a microgram of ^{253}Es) were obtained in 1961. Today, up to $\sim$2 mg can be present in special high-flux isotope reactor targets at the time of release from a reactor.

The transplutonium elements, where einsteinium is the fifth, have chemistries similar to those of the lanthanide elements, especially in their ionic states and in compounds. In essence, elements in the series sequentially add one f-electron in progressing to higher atomic numbers. Einsteinium is therefore an f-electron element, and its 5f electrons are considered fully localized, as opposed to those in the protactinium through plutonium grouping.

Oxidation states of II, III, and IV have been reported for einsteinium, where the best-established state is III (state normally observed in solution) followed by divalent einsteinium, which can be obtained in solid compounds. The tetravalent state has been postulated from vapor transport studies using tracer levels of einsteinium, but this state has not been established fully. More remote is the potential for a hexavalent state, based on the conception that this state may acquire stability from attaining a half-filled, 5f shell (5f^{11} down to 5f^{7}), by losing a total of six electrons (Liebman, 1978).

An exception of this similarity of einsteinium to the regular lanthanide elements occurs with the elemental state of einsteinium, where its properties and bonding compare more closely to those for europium and ytterbium metals, rather than to the other lanthanide elements, or more specifically to its apparent lanthanide homolog, holmium. This difference in behavior for einsteinium is readily seen by examining the atomic volumes of the two f-series that are shown in Fig. 12.1. Einsteinium is therefore unique in that it is the first divalent

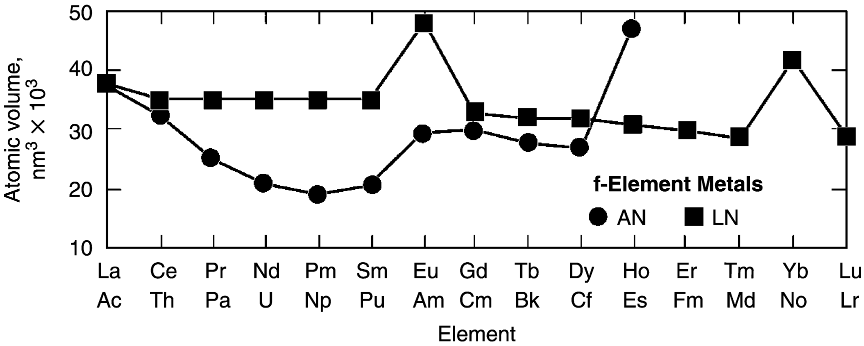

Fig. 12.1 *Atomic volumes of the two f-electron series of elements are shown. The behavior of einsteinium shows it is the first divalent actinide metal, with bonding similar to that for europium and ytterbium metals. This behavior for einsteinium metal is very different than that observed with Es(II) and Es(III) in compounds, which is similar to that for the lanthanides in these states.* (*Haire* et al., 2004).

actinide metal. In the lanthanide elements, europium and ytterbium are also divalent metals (two bonding electrons rather than three). The rationale for their metallic divalency is due to stabilization from a half-filled (Eu) or full (Yb) 4f-orbital arrangement. But this is not an appropriate explanation for the divalency of einsteinium metal. As discussed in Section 12.4, this situation for einsteinium is explained by its high 5f-electron promotion energy (energy to change an $f \rightarrow d$).

There are 16 established isotopes of einsteinium (with three isomers), with many having very short half-lives. The longest-lived isotope is ^{252}Es ($t_{1/2} = 471.7$ days), but the ^{253}Es ($t_{1/2} = 20.47$ days) isotope is available in the largest quantity and obtained primarily from nuclear reactors. The quantities of the latter isotope are normally limited to hundreds of micrograms, but frequently only a few micrograms are employed in studies at one time. Up to 2 mg can be discharged from special reactors (i.e. High Flux Isotope Reactor (HFIR) at Oak Ridge National Laboratory, ORNL) once every 6 months to 2 years, depending on the production schedule used. Even so, studies with it are also severely hindered by its half-life ($\sim$3% daughter 'impurity' ingrowth per day) and intense self-radiation (6.6 MeV alpha, self-heating of 1000 W g^{-1}), which are often detrimental to the studies being performed. A feeling for the magnitude of the energy released by the decaying einsteinium is obtained by looking at Fig. 12.2. The illumination is associated with the radioactive decay from 300 μg of ^{253}Es solid that is in the bottom of a 9 mm diameter quartz cone.

In essence, there are not many practical applications for einsteinium isotopes. Applications are found as target materials for producing elements with even higher atomic numbers, use of the self-irradiation fields of einsteinium for damage studies, and the use of its radiation for medical treatments. The latter application has been limited, but in principle would employ einsteinium chemically bound to biological agents that could deliver the radiation of einsteinium to biological sites for treatment of different disorders. In this regard, studies have been performed where beagles have been injected einsteinium citrate (Lloyd *et al.*, 1975). Other experiments along this line have been tried with the shorter-lived ($\sim$20 h) ^{255}Fm isotope, a daughter product of ^{255}Es; the latter is present in einsteinium products from reactors.

Einsteinium can also be useful in certain chemical studies, where its intense self-irradiation can be used for evaluating radiation damage and radiolysis effects both in solution and in the solid phase. One example of the latter would be to prepare a compound of einsteinium and then follow the chemistry of the daughter and granddaughter (i.e. from ^{253}Es one obtains ^{249}Bk, and ^{249}Cf, respectively) products as they grow into the einsteinium material (Young *et al.*, 1981). The main point is that knowing and understanding the science of einsteinium is important for actinide systematics and understanding the changing role of 5f electrons across the series.

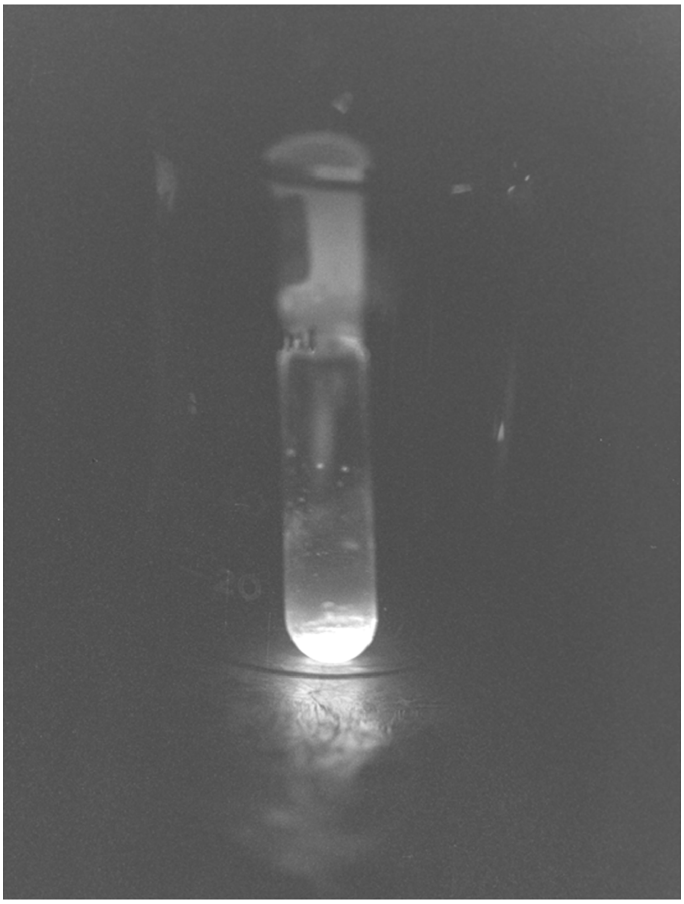

Fig. 12.2 *Self-luminescence arising from the intense radiation from* ~300 μg *of* ^{253}*Es in a quartz cone. The heat and radiation accompanying decay often generate detrimental effects in studies of Es.*

12.2 PRODUCTION AND NUCLEAR PROPERTIES

The primary nuclear properties and production schemes for einsteinium are outlined in Table 12.1 and in Appendix II. The reader is also directed in this regard to references discussing these isotopes (Hyde *et al*., 1964; Seaborg and Loveland, 1990). The nuclear levels of their daughters and the exact atomic mass of each isotope can be established by relating the total decay energies with the masses of the daughter products through studies of the decay processes.

The discovery of einsteinium in nuclear debris involved primarily the ^{253}Es and ^{255}Es isotopes, which have half-lives of 20.47 days and 39.8 h, respectively.

Table 12.1 *Nuclear properties of einsteinium isotopes.*[a]

EC = Electron capture

SF = Spontaneous fission

Both elution behavior during ion-exchange purification and the nuclear properties of these isotopes were used to establish the existence of this new element. These two isotopes together with ^{254g}Es ($t_{1/2}$ = 275.7 d) are produced by neutron-capture processes. All three isotopes are obtained in high-flux reactors designed to produce synthetic elements, but ^{253}Es and ^{254g}Es are the isotopes normally used for physicochemical studies other than for tracer work given their greater quantities.

The lighter isotopes of einsteinium are prepared in smaller quantities using accelerators and often other actinides as target materials (see Table 12.1). The synthesis of einsteinium isotopes using bombardment of targets with nitrogen isotopes has been discussed (Mikheev *et al.*, 1967), as has been the alpha decay properties of some lighter einsteinium isotopes (Ahmad and Wagner, 1977). The half-life of ^{252}Es is also addressed specifically in Ahmad *et al.* (1970). McHarris *et al.* (1966) have addressed the decay scheme of ^{254g}Es. Einsteinium isotopes have also been produced by bombardment of ^{209}Bi with ^{40}Ar ions (Ninov *et al.*, 1996). The electron-capture decay fission processes in neutron-deficient einsteinium isotopes have also been discussed (Shaugnessy *et al.*, 2000).

At the present time, einsteinium can be produced in the HFIR at the ORNL, Oak Ridge, Tennessee, and at the Research Institute of Atomic Reactors in Dimitrovgrad, Russia. At the HFIR, the targets for neutron irradiation consist mainly of curium isotopes (^{244}Cm through ^{248}Cm), which are irradiated in the reactor to produce the transcurium elements through fermium. The process involves successive neutron captures and beta decays to reach ^{253}Cf, which then β^- decays to ^{253}Es. The latter einsteinium isotope captures neutrons to reach ^{256}Es (possibility even ^{257}Es) but the einsteinium isotopes removed from the reactor targets consist of essentially ^{253}Es, ^{254g}Es, and ^{255}Es. The HFIR can produce einsteinium once every 12–24 months. The SM-2 loop reactor in Russia has similar power and flux levels, also giving it the potential for producing quantities of these transcurium isotopes.

The direct production in the HFIR in the U.S. is less than 2 mg of ^{253}Es, with the ^{254g}Es and ^{255}Es contents being ~0.3 and 0.06%, respectively, at discharge. However, ^{253}Cf is present in the californium isotope fraction that is chemically separated and it β^- decays to ^{253}Es. By subsequent chemical separation of the californium fraction of isotopes, it is possible to obtain chemically the ^{253}Es daughter from the californium fraction at a later time (weeks) and recover isotopically pure ^{253}Es at levels up to 200 μg.

From the mixed einsteinium isotope fraction received from the reactor there are two considerations to be addressed for using this einsteinium fraction. The first concerns the decay of the ^{255}Es present, which is a source of ^{255}Fm at the nanogram level (the longer-lived ^{257}Fm is produced directly in the reactor at only a 1 pg level). Chemical separations of the einsteinium fraction for multiple weeks (i.e. for about a total of four ^{255}Es half-lives) produces a repeated source of a few nanograms of ^{255}Fm. Another aspect is that after decay of —six to ten half-lives of ^{253}Es, the original einsteinium fraction is almost pure ^{254g}Es, and some 4 μg of it can be obtained essentially free of ^{253}Es. The latter isotope is highly desirable for nuclear syntheses but is of more limited value for physiochemical work, despite its longer half-life. This is due not only to the smaller amounts of it but also to the highly penetrating radiation field generated from its short-lived ^{250}Bk daughter ($t_{1/2} = 3.217$ h with β^- decay having a 45% branching ratio for a ~1 MeV gamma emission) in equilibrium with it. Thus, decisions must be made regarding the needs and the different choices available for the einsteinium products generated.

More detailed discussions on the nuclear properties, preparation of einsteinium isotopes, and their decay schemes are provided in the references. The K-series X-ray energies of einsteinium isotopes are discussed in Dittner and Bemis (1972). The electron-capture delayed fission processes of neutron-deficient isotopes, ^{242}Es and ^{244}Es, have also been reported, and highly asymmetric mass distributions have been noted (Kosyakov *et al.*, 1974). Average pre-neutron total kinetic energies of (183 ± 18) and (186 ± 9) MeV, respectively, were found. The probability of delayed fission was determined to be $(6 \pm 2) \times 10^{-3}$ and $(1.2 \pm 0.4) \times 10^{-4}$, respectively; smaller probabilities were given for the ^{246}Es and ^{248}Es isotopes.

12.3 PURIFICATION AND ISOLATION

The techniques used for the isolation, recovery, and purification of einsteinium isotopes are very dependent on the method of production. Accelerator production often involves thin foils or targets, where the einsteinium products are either recovered simply (washed off) from the target or from 'catcher' foils located behind a thin target. Recovery from 'catcher' foils can be straightforward, and recovery of products may only involve dissolution or washing of the foil followed by a minor purification of the einsteinium product.

In contrast, recovery of einsteinium following a neutron irradiation process can be rather complex. Larger quantities of very radioactive materials are involved in this process and it requires hot cell operations. The actinide targets are placed in some form of 'container' for the reactor irradiation (normally in aluminum rods), which must then be removed mechanically or chemically to reach the irradiated starting and product materials. At that point, one is faced with the starting material (i.e. curium oxide) and various fission products, in addition to the desired transcurium products (i.e. berkelium, californium, einsteinium, and some fermium). The purification and recovery of einsteinium then involves: (1) separation from lanthanide fission products; and (2) separation from curium, berkelium, and the adjacent actinides, californium and fermium. The major obstacle is the great similarity in the chemical properties of their trivalent actinide ions in solution, given their similar ionic radii.

There is only a small contraction in radii with increasing atomic number in the case of transplutonium elements, which provides a small increase in covalency and complexing ability, but these are sufficient to allow chromatographic methods to be used for separations. An advantage is acquired in the case of berkelium (which is also a daughter product of einsteinium), as this element can be oxidized to a tetravalent state and separated from the curium through fermium trivalent elements. Separation of einsteinium from its berkelium daughter product can be accomplished by solvent extraction. If solvent extraction is used to remove tetravalent berkelium, the extraction can then leave trivalent californium, einsteinium, and fermium ions together. These elements would have to be separated by subsequent ion exchange or chromatography techniques. A schematic for the separation of einsteinium is given in Fig. 12.3, parts A and B.

The details of various chemical separation processes have been published and presented as reviews. Two earlier reviews cover the approaches in the U.S. (Hulet and Bodé, 1972) and in Russia (Myasoedov *et al.*, 1974). A more general overview for separation of the transuranium elements is also available (Hyde *et al.*, 1964), and individual accounts of procedures used worldwide have been published (Müller, 1967; Bigelow, 1974; Ishimori, 1980; King *et al.*, 1981; Collins *et al.*, 1981). The early scheme used for products from the HFIR at ORNL has also been published in separate reports (Baybarz *et al.*, 1973; Benker *et al.*, 1981). Many of these procedures have not changed significantly over the years.

The removal of lanthanides from the actinides can be accomplished in different ways. An early method, suited for laboratory separations of smaller quantities, was through the use of alcoholic hydrochloric acid as an elutant for the

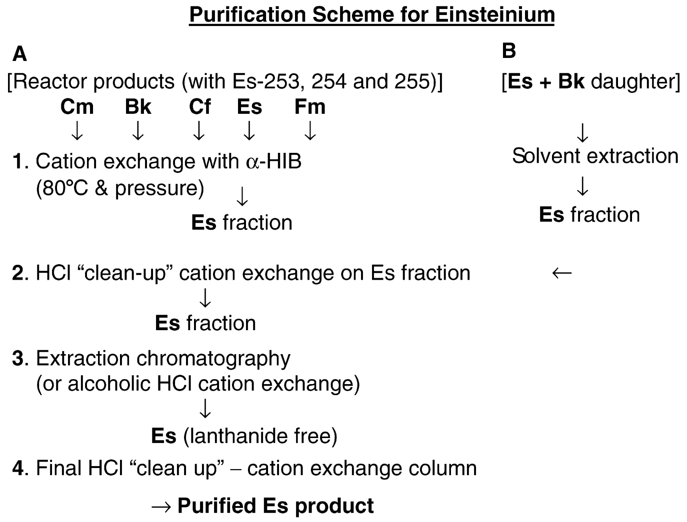

Fig. 12.3 *Einsteinium purification scheme.*

transcurium elements sorbed on cation resin (Street and Seaborg, 1950), where the greater complexing ability of the actinides allowed their desorption as chloride complexes ahead of the lanthanides. A preferred method for larger-scale operations is a lithium chloride anion-exchange process (Shoun and McDowell, 1980), which partitions the actinides from the lanthanides. For small amounts of lanthanides from einsteinium (i.e. the final removal of trace amounts of lanthanides of similar ionic radii) an extraction chromatography column employing ammonium thiocyanate and formic acid can be used (TEVA™ columns; see Horwitz *et al.*, 1994; Porter *et al.*, 1997). These special columns are also available commercially and give excellent separations between the lanthanide and actinide groups.

When the three elements californium, einsteinium, and fermium are considered, the individual elements can be separated by cation-exchange processes. One method that has been used for several decades is to sorb the three ions on a cation resin from dilute acids (i.e. 0.1 M hydrochloric acid) and selectively elute them with ammonium alpha-hydroxyisobutyrate (α-HIB) solutions at a pH in the range 3.8–4.2 (Choppin and Silva, 1956; Baybarz *et al.*, 1973; Bigelow *et al.*, 1980; Myasoedov *et al.*, 1980; Shoun and McDowell, 1980; Campbell, 1981). The elution order is fermium, einsteinium, and then californium; a high-pressure, ion-exchange column operated at 80°C gives the best results. Separation factors are not great but sufficient, ranging from 1 to 2 for different conditions. Details of using high-pressure columns for separation of f-elements have been given by Campbell (1981). However, even when working with only 10–20 μg of ^{253}Es, care must be exercised, as its radiation level is sufficient to char the resin upon standing and makes it difficult to recovery fully the einsteinium from the resin.

Another approach employs extraction chromatography, where either bis(2-ethylhexyl)phosphoric acid (HDEHP) or 2-ethylhexylphenylphosphonic acid (HEMΦP) are placed on an inert (i.e. fine glass particles) support. The actinides are loaded on this column and eluted with a dilute 0.3 M nitric acid solution (Hulet and Bodé, 1972). Separation factors for these actinide elements are again between 1 and 2. Ion-exchange separations of einsteinium from irradiated californium have also been discussed by Elesin *et al.* (1986).

The extraction chromatography behavior of einsteinium with a quaternary ammonium nitrate has been discussed (Horwitz *et al.*, 1966), and extraction of einsteinium with bis(2-ethylhexyl)phosphoric acid was also reported (Horwitz *et al.*, 1969). The extraction of einsteinium by bis(2-ethylhexyl)phosphoric acid and the stability constants for hydroxycarboxylic acids is reported by Aly and Latimer (1970a). The extraction of Es by dibutyl *N*,*N*,-diethyl carbamyl phosphate is also discussed (Aly and Latimer, 1970b). The current separation procedure for einsteinium from neutron-irradiated targets at ORNL dates back many years and has been summarized by Campbell (1970). Other separation methods for einsteinium have been provided by Horwitz *et al.* (1994).

12.4 ELECTRONIC PROPERTIES AND STRUCTURE

Chapter 16 is concerned with spectra and electronic structure of free actinide atoms and ions, and these topics are only touched upon here. As einsteinium belongs to the actinide series of elements it can be considered a 5f electron element, which has localized (non-bonding) 5f electrons, and potentially a 'dsp' or an 's^2' type of bonding. In addition, both non-relativistic and relativistic approaches (appropriate because of its high atomic number einsteinium) should be considered with regard to its behavior.

From non-relativistic considerations, the radial probability distributions of the 5f electrons are well within the principal confines of the 6d, 7s, and 7p orbitals, although there is some 'tailing' to the outer regions. This tailing or extension relative to the 7s and 7p orbitals lends itself to a slightly greater degree of covalency than found for the lanthanide's 4f electrons. With the transplutonium elements, the degree of covalency increases slightly when moving to elements with increased atomic number for a given ionic state.

For the relativistic situation, the binding of the electrons becomes greater with higher atomic numbers, which can affect the energies for the different electronic states. Also, potential effects may be found with regard to radii and energies of certain orbitals, spin–orbit splitting, and the expansion of the d- and f-orbitals, all of which can affect chemical behavior. An overview of this electronic picture has been given (Seaborg and Loveland, 1990).

The electronic configurations of einsteinium in neutral and singly ionized gaseous atoms have been analyzed via emission spectra (Gutmacher *et al.*, 1967; Conway, 1979), although full characterization of the ~20000 lines collected is still incomplete. Worden *et al.* (1974) have provided term assignments to a small number of these lines, and Brewer (1971a,b) had estimated energies for the lower spectroscopic terms. Brewer estimated that for a singly ionized atom the $f^{10}s^2$, f^{12}, and $f^{11}d$ levels should be lower in energy than the $f^{11}p$ level reported by Worden *et al.* (1974).

For the gaseous atom of einsteinium, a $5f^{11}7s^2$ ground state is assumed, and the successively ionized neutral gaseous atom loses first one, then two 7s electrons, while the third and even fourth electron lost are 5f electrons, to give a $5f^9$ configuration for the potential ion. It must be remembered that the gaseous atom configurations are different from those encountered in the metals, which are influenced by other factors including crystal energies.

Brewer (1971a,b) has calculated that for einsteinium metal the bonding configuration could be $5f^{10}dsp$, where the 6d and 7p orbitals play important roles. In this case, einsteinium would have three bonding electrons in its conduction band. Alternative configurations would be $5f^{11}sp$ or $5f^{11}s^2$, where only two bonding electrons are present, and in this case, einsteinium would be the first divalent actinide metal. The latter configuration appears to be the correct configuration for einsteinium metal. The reason for the divalency of einsteinium metal can be found in the promotion energy for changing an f-electron to a d-electron, which would then provide three electrons rather than two electrons for the metallic bonding.

A plot of promotion energies for the actinide is shown in Fig. 12.4 (Haire, 1994), which shows einsteinium's promotion energy as being just above the border between divalent and trivalent metal bonding. This 'borderline' energy relates to the crystal energy recovered when the metal atoms crystallize. Thus, when gaseous atomic einsteinium ($5f^{11}7s^2$) condenses to form a crystal, promotion of a 5f electron must occur to provide three rather than two bonding electrons in the solid if a trivalent metal (i.e. with a ds^2 configuration) is to form. For the earlier transplutonium metals, this promotion energy is provided from the greater crystal energy acquired, but with einsteinium, the promotion

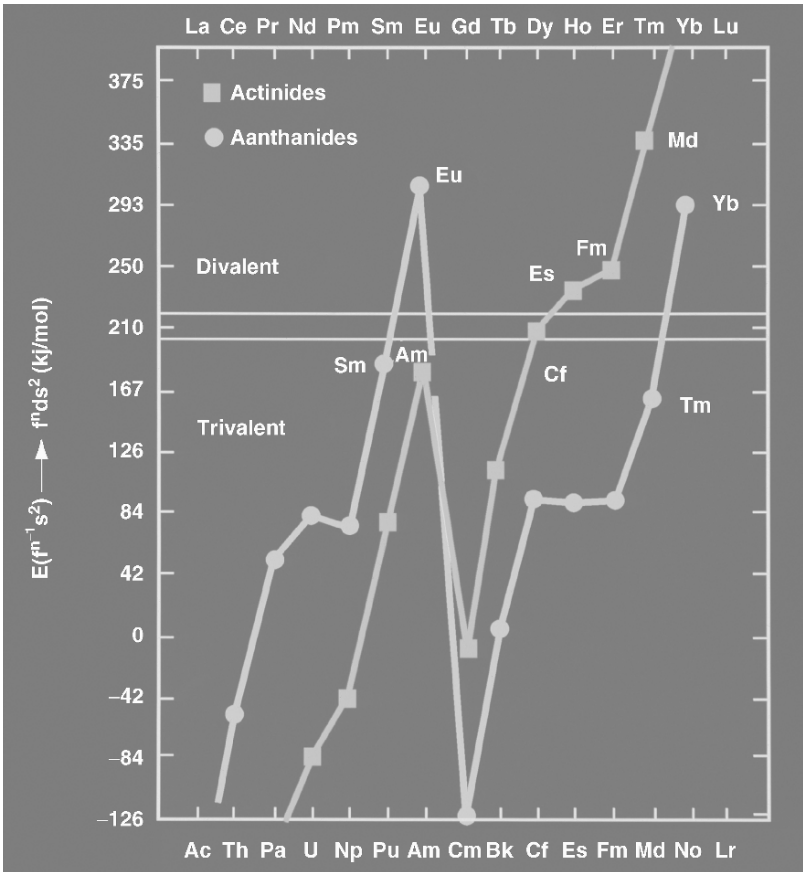

Fig. 12.4 *The f→d promotion energies for the f-elements (bar across figure is estimate of crystal energy needed to compensate for promotion of an electron from an f to a d level).*

energy needed exceeds the crystal energy recovered. Thus, einsteinium remains a divalent metal, as do the next three metals in the series.

Recent gas-phase studies of einsteinium have also provided important new insights into its chemistry. The behavior of einsteinium ions in the gas phase is discussed in Section 12.6.6 and the concept of f→d promotion energy again is seen as being important for the different gas species and their reactions.

Blaise and Wyart (1992) have provided tabulated values for einsteinium's energy levels and atomic spectra. Tabulated values for the newer values are given in Table 12.2 for Es(I). The reader is referred to Blaise and Wyart (1992) or Wyart *et al.* (2005) for more extensive data and values for Es(II). Some other atomic values for einsteinium and its ionization potentials are also given in Table 12.3. Estimations of the first ionization potential for einsteinium were earlier given to be 6.42(3) eV (Rajnak and Shore, 1978) but the ionization potential has now been determined accurately by resonance ionization mass spectroscopy using some 10^{12} atoms of ^{254g}Es in an atomic beam (Erdmann *et al.*, 1998; Peterson *et al.*, 1998). The method used is based on measuring photoionization thresholds as a function of an applied electric field, followed by an extrapolation to a zero electric field. The first ionization potential determined experimentally was found to be to be 6.367(5) eV (see Table 12.3). Goodman *et al.* (1975) also examined the nuclear and quadrupole moments of einsteinium. Table 12.3 provides some basic values for Es, but the reader may find more details in the references.

12.5 THE METALLIC STATE

The scarcity and the high specific radioactivity of einsteinium isotopes have in general impeded the investigation of its chemistry, but particularity so for its metallic state. The self-radiation and accompanying heat are imposing factors, and the former rapidly destroys the metal's crystal lattice. The transplutonium elements are all electropositive metals, and react with water and the oxygen in air, but einsteinium metal is even more reactive. Strong reducing agents are needed to convert einsteinium oxide or its halides to the metal. Einsteinium is the most volatile of all the actinides preceding it, which dictates the preparative methods that can be used. It has been concluded that einsteinium is the first divalent actinide metal, in the sense that there are two bonding electrons in its conduction band compared to three or higher for the preceding actinide metals (see Section 12.4). It is followed by divalent fermium metal, and presumably divalent mendelevium and nobelium metals. The last member of the series, lawrencium, is presumably again a trivalent metal. It is likely to have a filled 5f level and a single d-electron; therefore, the promotion of an f-electron is not necessary for it to become trivalent. Thus, einsteinium is divalent like europium and ytterbium metals, but not trivalent like its homolog holmium, the other lanthanide metals, or the americium through californium metals.

Small quantities of transplutonium metals have traditionally been prepared by different methods, two of which are mentioned here (Haire, 1982). The first is reduction of an actinide halide by an active metal (alkali or alkaline earth), and the desired actinide metal is left as a product. This is a suitable technique if the actinide has a lower volatility than the reductant or its halide product (i.e. lithium and lithium fluoride, which are both sufficiently volatile). The second approach is to reduce the actinide oxide with thorium or lanthanum metal and distill away the actinide product. The choice frequently depends on the volatility of the actinide metal. In the case of einsteinium, the latter technique is the most appropriate given its higher volatility. If einsteinium fluoride was reduced with lithium metal, it would be difficult to obtain the metal free of lithium fluoride in the distilled/condensed product.

The first reported attempt to prepare einsteinium metal (Cunningham and Parsons, 1971) used less than 1 μg of einsteinium, and involved distilling lithium metal onto EsF_3. The temperature was raised to 800°C and the sample than quench-cooled to give a material contaminated with lithium fluoride. Thin films of pure einsteinium were prepared subsequently by reducing Es_2O_3 with lanthanum metal followed by collecting the einsteinium metal distillate on electron microscopy grids (Haire and Baybarz, 1979). This reduction approach has become the normal preparative route for einsteinium metal, and has provided the first diffraction data from pure einsteinium metal.

Electron diffraction data for the metal prepared by oxide reduction consisted of over 14 diffraction lines and were obtained from 10–200 ng deposits. The very thin films reduced effects from both self-irradiation damage and self-heating in the metal from the ^{253}Es isotope, and they also allowed diffraction powder patterns to be obtained in a few seconds versus the 30–120 min often needed for X-ray powder analysis. The diffraction data obtained showed a face-centered cubic (fcc) (*Fm*3*m*) symmetry and generated a lattice parameter of 5.75(1) Å, which corresponds to a metallic radius of 2.03 Å. This radius compares with radii of 2.042 and 1.940 Å (Topp, 1965) for divalent europium and ytterbium metals, respectively, compared to much smaller radii (i.e. 1.734–1.877 Å) for the trivalent lanthanide metals and 1.691–1.725 Å for the trivalent americium through californium metals (Haire, 1990). The radii of Ba, Eu, Es, and Yb form a smooth curve, if radii are plotted versus atomic number (see Fig. 12.1 for the volume behavior of the latter three elements). These findings led to the conclusion that einsteinium is indeed the first divalent actinide metal, and this was subsequently supported by studies of the enthalpy of sublimation of einsteinium (see subsequent discussion) and thermochromatography studies with tracer levels of einsteinium. Selected data for einsteinium and selected f-element metals are given in Tables 12.4 and 12.5.

The elements americium through californium are trivalent metals and exhibit a double hexagonal close-packed (dhcp) room-temperature and an

elevated-temperature fcc structure. The densities of the four trivalent transplutonium metals range from 13.6 to 15.1 g cm^{-3}, while einsteinium has a density of 8.84 g cm^{-3} (Haire, 1990). The cubic structure of einsteinium should be considered as reflecting its electronic bonding configuration rather than being a high-temperature form, as are the room temperature structures of europium (body-centered cubic, bcc) and ytterbium (fcc) in the lanthanide series. Europium remains bcc down to 5 K, even with 'cold working' of the material. In contrast, ytterbium transforms from its fcc structure to a hcp form below 270 K, which can be retained at room temperature. Einsteinium metal has been examined at liquid nitrogen temperature (Haire, 1980), where evidence for a hexagonal structure was obtained. However, it was not resolved in that work whether this was a temperature-induced change (comparable to ytterbium metal) or reflected a change from the effects of radiation damage to the einsteinium lattice.

Alloys of einsteinium with europium and with ytterbium ($\sim$1 mol%) have also been prepared by co-distilling the metals (Haire, 1982) from mixed oxides (einsteinium–europium and einsteinium–ytterbium) after reacting the oxide mixtures with lanthanum metal. With 100 μg of ^{253}Es, the self-heating/radiation in an Es–Yb alloy was sufficient to give rise to partial sublimation of the einsteinium product when it was isolated in vacuum.

A value for the melting point of einsteinium was obtained by observing the heating of deposits in an electron microscope (Haire and Baybarz, 1979). The melting point was taken as the point where "micro-puddles" were formed, in conjunction with calibration studies with other known metals done in a similar fashion. A value of (1133 ± 50) K was reported for the melting point of einsteinium metal. This value can be compared to the melting points of 1099 and 1097 K for europium and ytterbium metals, respectively, while the values for the trivalent lanthanide and americium through californium metals are higher, being (1173–1620) K (Haire, 1990).

At the tracer level, einsteinium–calcium metal mixtures were prepared and studied via thermochromatographic metal columns, where their sorption/condensation behaviors were monitored (Hübener, 1980). Data from this work supported the divalency of einsteinium metal. It was determined that ytterbium, einsteinium, fermium, and mendelevium all condensed at the same column length ($\sim$700 K), but deviations were found for europium, samarium, and calcium, where their behaviors were intermediate to the divalent and trivalent metals. One aspect of this thermochromatographic technique has been variation in results when different metals are used for the sorbers or columns.

Volatilities of these metals are correlated with f-electron promotional energies and the number of bonding electrons – the fewer the bonding electrons the higher the volatility. Estimates have been given by Nugent *et al.* (1969a) for the enthalpy of sublimation of these metals via extrapolations. Kleinschmidt *et al.* (1984, 1985) and Haire and Gibson (1989) have also reported experimental data for the enthalpies of sublimation and entropies of einsteinium metal.

The enthalpy for einsteinium also supports that it is a divalent metal. The enthalpy of sublimation of einsteinium is given as 133 kJ $mol^{-1}$and was found to agree closely with that for fermium (143 kJ mol^{-1}) (Haire and Gibson, 1989), the second divalent actinide metal. In the latter work on fermium, the enthalpy for einsteinium was reevaluated, and a value of 134 kJ mol^{-1} was determined for einsteinium, this value being slightly lower than that for fermium. However, this difference is not significant, given that error bars were estimated at ± 12 kJ mol^{-1}. In essence, the two values for einsteinium and that for fermium can be considered the same.

Subsequent studies of heavy elements (including einsteinium) via thermochromatography have been performed (Hübener *et al.*, 1994; Taut *et al.*, 1997, 1998) and results varied significantly with the metal of the columns used – five different metals were used in the work. With iron columns, californium, einsteinium, and fermium behaved the same; with niobium columns, einsteinium was intermediate to positions for californium and fermium, and in titanium columns, einsteinium and fermium behaved similarly (Hübener *et al.*, 1994). It was concluded that einsteinium and fermium were acting as divalent actinide metals while californium was 'borderline' between divalent and trivalent. Subsequently, similar studies with californium, einsteinium, and fermium tracers estimated einsteinium's enthalpy of sublimation to be 167 kJ mol^{-1} (Taut *et al.*, 1997), a significantly higher value than reported earlier by more direct methods (134 kJ mol^{-1}) but still lower than the enthalpy for californium determined by this technique (close to 200 kJ mol^{-1}). It was stated in Taut *et al.*'s work (1997) that the value for einsteinium is still typical for a divalent metal, although it was higher than that for fermium. Additional discussions on einsteinium thermochromatography are given together with the work on nobelium, where the two models are discussed in conjunction with *ab initio* calculations for actinide adsorption enthalpies (Eichler *et al.*, 2002), and in diffusion studies into tantalum (Legoux and Merinis, 1986).

The crystal entropy of einsteinium has been calculated using a correlation (Ward and Hill, 1976; Ward *et al.*, 1980; Ward, 1986) based on ytterbium metal, and a value of (89.4 ± 0.8) J K^{-1} mol^{-1} at 298 K was determined. For the 1133 K melting point of einsteinium (Haire and Baybarz, 1979), the enthalpy of melting was calculated to be 9.40 kJ mol^{-1} and the entropy as 8.30 J K^{-1} mol^{-1} by Ward and Hill (1976). The magnetic entropy for a $5f^{11}$ configuration gives a total angular momentum of $J = 15/2$ for the divalent einsteinium. A boiling point of 1269 K was also calculated (Kleinschmidt *et al.*, 1984) for the metal. One additional piece of information has been reported for the metal; its thermal conductivity has been estimated to be 10 W m^{-1} K^{-1} at 300 K (Ho *et al.*, 1972). The bulk modulus of einsteinium was estimated to be similar to those for europium and ytterbium metals. See Tables 12.4 and 12.5 for selected properties and values of einsteinium.

More recent work on the preparation of einsteinium metal provided the first isolated piece of pure einsteinium metal (~100 μg) and a 60 μg deposit (~200 μm in diameter) on platinum. These efforts were in conjunction with attempts to study the high-pressure behavior of the metal (Haire and Heathman, 2000) by energy-dispersive X-ray diffraction using high-intensity tungsten radiation. The pressure behavior of einsteinium metal is very interesting, as it could become a trivalent metal under pressure, where pressure provides the energy necessary to promote an f-electron to a bonding state. In essence, the volume of einsteinium may be reduced under pressure to force additional bonding, similar to that found in the trivalent Am through Cf metals. It was anticipated that applying additional pressure on a potential trivalent einsteinium product could even lead to a further reduction in volume and result in the formation of an einsteinium metal product with itinerant 5f electrons (Haire *et al.*, 2004). This can be understood by examining the volume curves shown in Fig. 12.1, where the volume reduction induces greater bonding. However, the intended study of einsteinium under pressure was not successful, as the intense self-irradiation of einsteinium destroyed both its crystal lattice and the platinum pressure marker present within a few minutes. But the recent preparative effort with einsteinium allowed a new level to be reached in obtaining elemental einsteinium – namely, an einsteinium metal product free of a supporting substrate (i.e. a 100 μg 'bulk form' of pure einsteinium metal).

12.6 COMPOUNDS OF EINSTEINIUM

12.6.1 Crystal data

Once the existence of a new element has been established, scientists strive to determine its chemical and physical properties. The extent to which this is possible depends on the availability and nature of the material, and the techniques that are or can be established to study it. With the availability of multiple micrograms of einsteinium it became feasible to prepare and examine 'bulk forms' of its compounds, although not without perturbations and limitations caused by its short half-life, high self-radiation field, and the heat associated with the decay (^{253}Es alpha decay corresponds to 15312 kJ mol^{-1} min^{-1}). For the preparation of compounds, one normally uses the ^{253}Es isotope (see earlier discussion on isotopes), given its greater availability. Some of the techniques used for microgram-sized samples of einsteinium have been discussed (Haire, 1981, 1982).

Only a few compounds of einsteinium have been prepared and have had their crystal structures identified. In this realm, there are induced changes or destruction of crystal lattices by the isotope's self-irradiation (alpha emission plus nucleus recoil) and the rapid ingrowth of the berkelium daughter (~3% per day, berkelium 'impurity'). For diffraction studies, the accompanying penetrating radiation (L, M and N X-rays, the gamma emissions from ^{254g}Es and its short-lived daughter, ^{250}Bk, also have serious effects on both X-ray detectors and/or X-ray film in a short time frame (the film is often used for small 1–2 μg sized samples).

Even with rotating anode-type generators with higher X-ray intensities, these difficulties with einsteinium are not overcome. Electron diffraction techniques do afford major advantages, as only small, very thin samples (which can be smaller than the alpha particle's range, where a minimum amount of its energy is transferred) are needed. This technique requires very short exposure times (seconds) and that the detection mode is located approximately 1 m from the sample, which avoids film or detector problems from the einsteinium radiations.

Although synchrotron radiation can supply more intense radiation for diffraction studies with einsteinium samples, two difficulties are encountered: (1) the destruction of the crystal lattice during the time of 'transportation' to the synchrotron beamline; (2) the difficulty of obtaining approvals to use the activity levels from the einsteinium at the synchrotron, or for setting up an apparatus for *in situ* preparation of the compounds on the beamline. Yet, the latter remains an option for dealing with some of the experimental problems with einsteinium's rapid radioactive decay.

As with many of the transuranium compounds, halides and oxides were among the first compounds of einsteinium to be prepared and studied, which is in accord with the fact that these have frequently been among the first to be prepared for new elements. These are also used often as a starting platform for synthesizing other materials. To overcome the experimental difficulties encountered with diffraction analysis of ^{253}Es or ^{254g}Es compounds, three approaches have been successful. One has been constant resynthesis of the compound during X-ray analysis, while another has been the use of very thin films, especially in conjunction with electron diffraction. The third has been to use very short exposures as can be accomplished by electron diffraction. Crystal data have been collected for the following materials: $EsCl_3$, EsOCl, Es_2O_3, $EsBr_3$, and EsI_3 (See Table 12.6). A discussion of X-ray diffraction techniques for einsteinium compounds is also available (Haire and Peterson, 1979).

The first crystal data for einsteinium compounds were obtained for the trichloride and the oxychoride via the constant synthesis technique (Fujita *et al.*, 1969a,b). The approach was to resynthesize these materials *in situ* at ~430°C. The trichloride was found to be hexagonal, isostructural with the actinium through californium trichlorides and the lanthanum through gadolinium trichlorides (UCl_3-type, space group $C^2_{6h}-C6_3/m$). The oxychloride was found to crystallize in the tetragonal PbFCl structure (space group $D^7_{4h}-P4/nmm$) and is isostructural with the trivalent lanthanum through erbium oxychlorides and the known actinium through californium oxychlorides. The lattice parameters, corrected to 298 K, are given in Table 12.6.

Einsteinium sesquioxide was the next compound for which diffraction data were acquired, and this involved the use of the electron diffraction technique. The samples were prepared by calcining an einsteinium nitrate salt *in situ* on

0.928 Å) for this oxide were intermediate to those for Gd_2O_3 and Tb_2O_3, and just smaller than those for Cf_2O_3 (see Table 12.7).

Lattice parameters and ionic radii for the cubic sesquioxides of the f-elements are shown in Fig. 12.6, where a smooth relationship can be seen. These behaviors differ from the volume behaviors of the metals (see Fig. 12.1). The properties of einsteinium oxide and a comparison of its properties are also discussed in reviews (Baybarz and Haire, 1976; Haire and Eyring, 1994). As opposed to the metal, compounds of einsteinium (i.e. the oxide here) display lattice parameters and ionic radii similar to the comparable transplutonium and lanthanide compounds. All of the first five transplutonium sesquioxides form this cubic crystal form, but some may also exist in a monoclinic structure (Sm_2O_3-type, space group *C*2/*m*) or a hexagonal form (La_2O_3-type, space group *P*3*m*1), depending on the thermal history and the particular element in question (see Haire and Eyring, 1994).

Self-irradiation may also convert one structural form of the sesquioxide to another; this radiation effect has been discussed in an earlier review (Fuger, 1975). For einsteinium sesquioxide, both a monoclinic and a hexagonal form have been recorded (Haire *et al.*, 1985; Haire and Eyring, 1994). The monoclinic form was observed during oxidation of metal films below 1273 K, and this effect has also been observed with gadolinium metal films. The hexagonal oxide was observed in 'aged' cubic einsteinium sesquioxide. It could not be ascertained whether the monoclinic and/or hexagonal forms of Es_2O_3 resulted from being heated, from self-heating, or from self-irradiation damage. It is probable that the hexagonal form resulted from one of both of the latter two consequences; the hexagonal form of Es_2O_3 would be expected from systematics to be formed

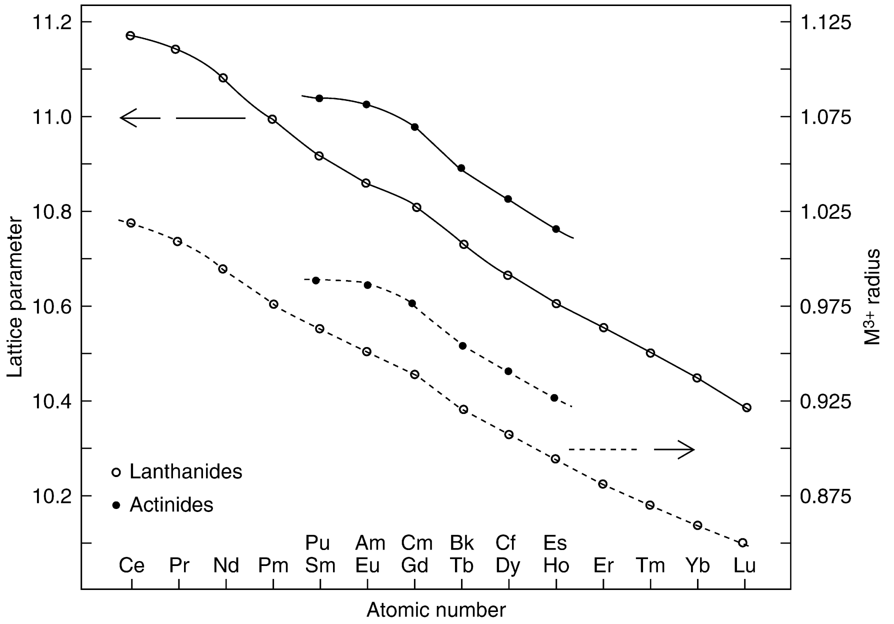

Fig. 12.6 *Lattice parameters and calculated radii for the cubic sesquioxides. A regular trend is observed with Es(*III*), as opposed to the different behavior observed with Es metal* (*Haire and Eyring*, 1994). *Parameters and radii are given in Å.*

only near its melting point (Baybarz and Haire, 1976; Haire and Eyring, 1994). Lattice parameters for the monoclinic and/or hexagonal structural forms of einsteinium sesquioxide must also be considered in this context. The monoclinic form of einsteinium sesquioxide was obtained after heating at temperatures lower than would be expected to bring about the thermal transformation from its cubic form. The values for the lattice parameters of the monoclinic and hexagonal forms of Es_2O_3 are however reasonable, based on ionic systematics for the lanthanide and first four transplutonium sesquioxides (Haire and Eyring, 1994), and allowing for some lattice expansion due to self-irradiation.

X-ray data were also obtained for $EsBr_3$ (Fellows *et al.*, 1975, 1977) and EsI_3 (Peterson, 1979; Haire, 1980). The $EsBr_3$ data were acquired from very small (~1 μg) pieces immediately after annealing at 400°C. Fifteen diffraction lines were obtained and indexed as a monoclinic $AlCl_3$-type structure, which is isostructural with $BkBr_3$ and $CfBr_3$ (Burns *et al.*, 1975). The information for EsI_3 was obtained from freshly sublimed films formed in a quartz capillary. The diffraction lines were indexed as belonging to a hexagonal BiI_3-type structure, which is also formed by the transneodymium triiodides and the five transplutonium triiodides. The first four lanthanide triiodides form a $PuBr_3$-type structure (Brown, 1968). Important factors in obtaining these diffraction data were the very small samples or thin films and some luck.

12.6.2 Spectrometry – solids

Another important technique for characterizing einsteinium compounds was the use of absorption spectrometry of solids (as well as for actinides in solution, see Section 12.6.3). Divalent compounds of einsteinium were characterized entirely by this technique, given the difficulties in obtaining diffraction data. A great aid in this technique was incorporation of a 'fingerprint' approach, where correlations between spectra and short-range local environment ('crystal environment'; X-ray diffraction requires 'longer-range order') allowed important conclusions to be drawn for the einsteinium compounds. This technique depends partly on the changes in metal ion coordination in the structures. One advantage of this technique is it allows samples to be prepared, annealed, and/or chemically converted in quartz capillaries, while permitting spectral analyses of intermediate products to follow the completeness of the changes being sought (i.e. reduction of a trihalide with hydrogen) in the same system. This approach was particularly suited to halides, as they had modest melting points, and with care, the melts can be solidified to transparent solids or even single crystals. The technique employed a microscope–spectrometer system, which has been described (Young *et al.*, 1976, 1978, 1981). The einsteinium solid-state absorption spectra are characterized normally by sharp electronic f–f transitions. In addition, luminescence spectra have been obtained but the self-radiation of einsteinium also excites trace amounts of impurities and the quartz envelopes containing it, producing an additional source of luminescence that must be considered. Some of the solid-state absorption spectra for einsteinium compounds are shown in Fig. 12.7.

As discussed in Section 12.6.5, potentials ranging from –1.6 to –1.2 V are reported for the Es^{3+}–Es^{2+} couple in aqueous solutions; a value of –1.3V is adopted in Chapter 19. This potential offers an explanation for the ability to reduce einsteinium trihalides with hydrogen at elevated temperatures. This potential for einsteinium contrasts with the more negative $Am^{3+}-Am^{2+}$ through $Bk^{3+}-Bk^{2+}$ potentials, whose trihalides cannot be reduced by hydrogen. This smaller potential is in accord with the greater tendency for obtaining divalency with einsteinium (also see Section 12.6.5).

Several halide materials have been prepared and their solid-state absorption spectra obtained: $EsCl_2$ (Fellows *et al.*, 1975, 1977; Peterson *et al.*, 1977, 1979; Peterson, 1979; Young *et al.*, 1981); $EsBr_2$ and EsI_2 (Young *et al.*, 1976, 1978; Peterson *et al.*, 1979); for EsF_3 (Ensor *et al.*, 1981); and $EsBr_3$ and $EsCl_3$ (Fellows *et al.*, 1975, 1977; Peterson *et al.*, 1979; Young *et al.*, 1981). Efforts to prepare EsF_2 have not been successful and attempts to prepare EsI_3 have encountered difficulties involving the thermal reduction to EsI_2. The spectra obtained for the three divalent halides of einsteinium and that for $EsBr_3$ are shown in Fig. 12.7 (Peterson *et al.*, 1979). The distinct differences between the spectra of $EsBr_2$ and $EsBr_3$ are obvious, while the similarities in the spectra for the three dihalides are also evident. The cutoff in the near UV for the diiodide reflects charge transfer occurring in this sample. The absorption spectrum of

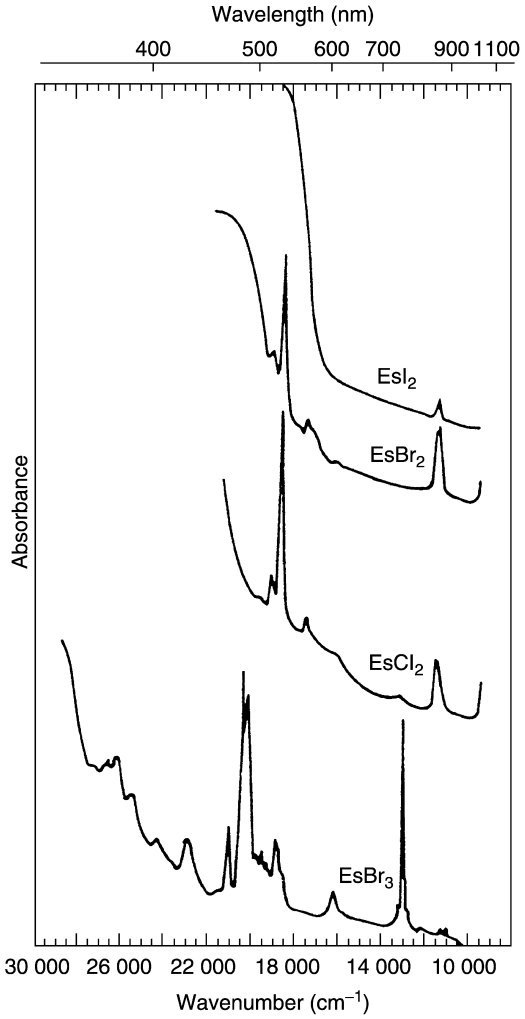

Fig. 12.7 *Solid-state absorption spectra for Es halides* (*Peterson* et al., 1979).

EsOBr is similar to that of $EsBr_3$, but it is sufficiently different to differentiate between the spectra of the two compounds and identify them.

Absorption spectrometry has also been used to study EsF_3 (Ensor *et al.*, 1981) and to then follow the decay products (^{249}Bk and ^{249}Cf, daughter and granddaughter) as they formed in the solid-state sample. From the spectrometric data, it was concluded that EsF_3 initially formed as a LaF_3-type trigonal phase.

Silicate matrices containing ^{253}Es have also been prepared. Results of recent spectroscopic investigations of their properties have been reported (Assefa *et al.*, 1999; Assefa and Haire, 2000, 2001). These studies concentrated on

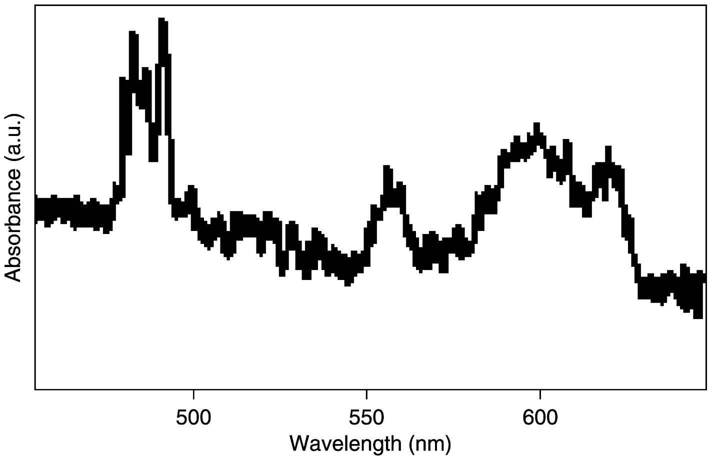

Fig. 12.8 *Absorption spectrum of Es in a borosilicate glass: absorption bands correspond to Es(*III*) (Assefa and Haire,* 2001).

self-luminescence from the materials, and examined the effects of the excitation source used, power of excitation, sample age, and nature of the sample matrix. Also obtained in that work were the absorption spectra of the einsteinium in this host matrix. The self-luminescence arising from einsteinium in these matrices was attributed to defect centers within the Si–O–Si network, nonbonding oxygen holes and Si cluster sites. It was determined that Es(III) was present; evidence for Es(II) was not found. The different spectra obtained for einsteinium in silicate matrices are shown in Figs. 12.8 and 12.9.

12.6.3 Other results – solids

Electron paramagnetic resonance spectra have been obtained for einsteinium placed in single-crystal hosts of CaF_2 (Edelstein *et al.*, 1970; Edelstein, 1971), in BaF_2 and SrF_2 (Bouissières *et al.*, 1980), and in BaF_2 and $SrCl_2$ (Boatner *et al.*, 1976). The spectra of Es^{2+} were similar in CaF_2 and BaF_2. The immediate reduction of Es(III) to Es(II) in the matrix from electron displacement via the alpha radiation field was suggested as the cause of the einsteinium reduction observed in these efforts. A $5f^{11}$ configuration with a ground state close to the $^4I_{15/2}$ (with a small admixture of a $^2K_{15/2}$ state) state was assigned to einsteinium. This indicated that only a minor perturbation of the inner 5f orbitals occurred from the crystal fields in the solids. A value of $\mu_n = 3.62(50)$ nm was reported for einsteinium.

Some information has also been acquired for the magnetism of einsteinium compounds. Preliminary magnetic measurements on einsteinium metal did not show a low temperature transition (Huray *et al.*, 1983). Studies on Es_2O_3 and EsF_3 indicated moments of 10.2(1) and 10.5(1) Bohr magetons, respectively. When corrected for the berkelium ingrowth present in the oxide sample, a value

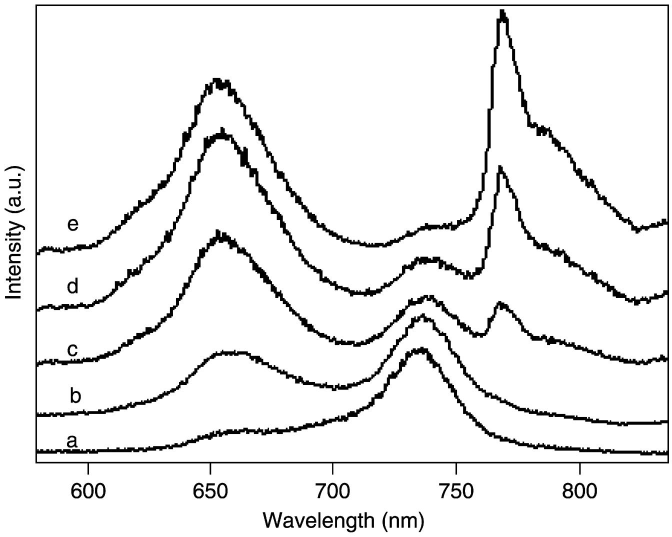

Fig. 12.9 *Photoluminescence spectra from a borosilicate glass doped with Es: excitation was with* 488 nm. *Spectra were recorded at laser powers of* (*a*) 100; (*b*) 310; (*c*) 600; (*d*) 800; *and* (*e*) 1000 mW (*Assefa and Haire*, 2001).

of 10.6(1) is obtained, which is in excellent agreement with a calculated $5f^{10}$ free-ion value (Huray *et al.*, 1983; Huray and Nave, 1987).

Preliminary information for the vaporization behavior of Es_2O_3 has been reported (Haire, 1994). The primary mode of vaporization for this oxide is the generation of atomic metal vapor, rather than via a monoxide (Es/EsO in the vapor was greater than 10:1). This situation arises as a result of the lower dissociation energy of EsO, which was estimated to be 460 kJ mol^{-1}. More recent calculations and work (Gibson, 2003; Gibson and Haire, 2003) discuss the electronic states, dissociation energies, and gaseous behavior of einsteinium. A brief discussion on these topics is given in Section 12.6.6.

The thermal behavior of einsteinium sesquioxide and the reduced formation of EsO(g) compares closely to the behaviors of europium and ytterbium oxides. The sesquioxides of europium and ytterbium also decompose mainly to atomic europium and ytterbium rather than form monoxides. A calculated estimate for the standard Gibbs energy of formation of Es_2O_3 at 298 K has been given as –1605 kJ mol^{-1}, and that for EsO_2 as –701 kJ mol^{-1} (Chapter 19). A tentative value for the Gibbs energy of formation for Es_2O_3 based on experimental behavior was given to be between –1650 and –1700 kJ mol^{-1} (Haire, 1994). Attempts to form EsO_2 or other compounds containing Es(IV) (i.e. $BaEsO_3$ or other materials that might help stabilize Es(IV)) have produced negative results (Haire and Bourges, 1980). Several estimated values for thermodynamics of formation of Es_2O_3, EsO_2, EsF_3, EsF_4, $EsCl_2$, and $EsCl_3$ are also given in Chapter 19.

12.6.4 Spectrometry – solutions

Spectrometry of einsteinium in solution has also been pursued, but only its trivalent state has been observed. The solution properties of the trivalent state are similar to those of the previous four transplutonium elements, and coordination number is an important variable. Given that the trivalent ion is present, bonding with ligands is often due to electrostatic effects. But as covalence for a given oxidation state increases across the series, second-order contributions from covalent interactions are possible. The ionic radius of einsteinium in solution should be only slightly smaller than that of californium(III). The free-ion energy levels for trivalent actinides have been given by Blaise and Wyart (1992) and Wyart *et al.* (2005). The ground state of einsteinium (Es(I)) is given as $^5I_8$, with the first excited state appearing at $\sim 10 \times 10^3$ cm^{-1} higher in energy (see Table 12.2).

The first observation of a solution spectrum was for $EsCl_3$ in hydrochloric acid by Cunningham *et al.* (1967), which was obtained by a special technique, where the micro-sized volume of the solution was kept constant by 'pumping' in liquid to overcome evaporation/radiolysis effects. Superior results were obtained subsequently with larger amounts of einsteinium, and 18 peaks between 370 and 1060 nm were obtained in a later work (Fujita *et al.*, 1969b). Electronic energy level and intensity correlations have also been made for Es(III) aquo ion, using data from dilute perchloric acid solutions (Carnall *et al.*, 1973). The absorption spectrum of Es(III) in solution, as demonstrated by Carnall *et al.*, is shown in Fig. 12.10. The band structure and intensities of einsteinium have also been discussed (Nugent *et al.*, 1969b, 1970; Varga *et al.*, 1973a,b).

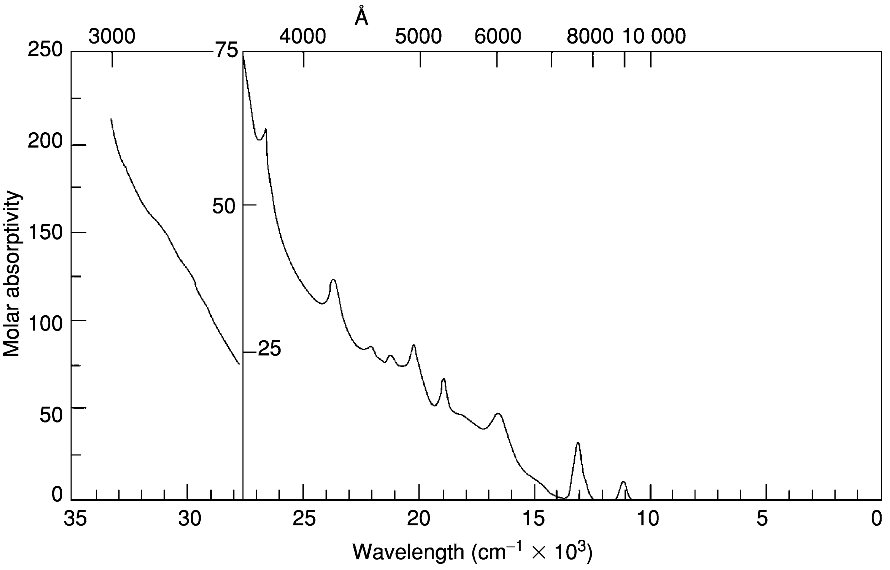

Fig. 12.10 *Solution spectrum of Es(III) in dilute perchloric acid (Carnall* et al., 1973).

The spectra fit the behavior expected for an Es(III) free ion, where the f–f transitions were believed to arise from mixed eigenstates, due to coupling that was intermediate between LS and jj.

Photoelectron spectrometry of einsteinium oxide provided spectra of the 4f lines obtained with MgKα excitation (Krause *et al.*, 1988). Binding energies for $4f_{5/2}$ (569.3(4) eV) and $4f_{7/2}$ (550.8(3) eV) of einsteinium were reported and compared to values for other actinides. These values compared well (within –1.0 and –0.1 eV, respectively) with theoretical binding energies The spin–orbit splitting for the 4f level was also measured and compared to the values obtained from theory. Beitz *et al.* (1992, 1998) have reported on the spectrometry and dynamics of the 5f electron states in Es(III) placed in a LaF_3 matrix.

The consequences of self-irradiation from einsteinium on selected clay minerals for waste isolation have also been probed employing ^{253}Es in solution. The einsteinium was sorbed from aqueous solution using two different clay minerals (kaolin and attapugite) and the morphology of the clay was followed with time using electron microscopy (Haire and Beall, 1979). The conclusion reached was that although the clay structure became damaged, einsteinium was still retained by the clay debris and not released to the solution.

12.6.5 Related studies in solution

The complex-ion chemistry of einsteinium has often been studied in conjunction with an examination of the stabilities of other trivalent actinide ions in solution, and often at the tracer level. Although einsteinium exhibits oxidation states of II, III with a potential for IV in the solid state, its solution chemistry is essentially that of a trivalent ion, and is often comparable to the actinide and lanthanide ions having similar radii. A list of the reported stability constants for einsteinium is given in Table 12.8. It has been concluded that chloride and possibly some thiocyanate complexes are the only outer-sphere complexes (water of hydration found between the ligand and the metal ion). The majority of the complexes are instead the inner-sphere type, which has been inferred from an increased stability constant as a function of increased atomic number, and from the enthalpy and entropy values for the formation of the complexes. Several different complexes have been studied, and these are shown in Table 12.8.

The radii and hydration numbers for actinide(III) ions have been derived from the Stokes' law approach using migration rates in electric fields or diffusion coefficients of tracers in electrolytes (Lundqvist *et al.*, 1981; Latrous *et al.*, 1982; Fourest *et al.*, 1983). David (1986) have also discussed the radii of actinides. In line with an expected greater covalent nature when progressing across the series, the Es(III) and Fm(III) hydrated ions are larger than those for earlier members of the series. A value of 0.492 nm (with up to ~16 molecules of water in the hydration sphere) has been estimated for the radius of einsteinium(III).

Several thermodynamic values have also been reported for einsteinium: (1) the molar activity coefficient in sodium nitrate solutions (Chudinov and Pirozhkov,

1973); and (2) the Gibbs energy, enthalpy, and entropy of formation (Nugent, 1975; David *et al.*, 1978, 1986; Lebedev, 1978). The following values given were: enthalpy of formation, $\Delta_f H^0 = -603\,\text{kJ mol}^{-1}$; the entropy of formation, $\Delta_f S^0 = -100\,\text{J K}^{-1}\,\text{mol}^{-1}$; and the Gibbs energy, $\Delta_f G^0 = -573\,\text{kJ mol}^{-1}$.

Morss (1986) has provided estimates for several thermodynamic properties of einsteinium, ranging from the formation of aqueous ions, the activity products for the trihydroxide and dioxide, hydration enthalpies and ionization energies, and the enthalpies of formation and solution for the sesquioxide and dioxide. Also given are the calculated enthalpies of formation and solution for the dichlorides and trihalides (fluoride, chloride, bromide, and iodide) and the enthalpy of formation of the four tetrahalides.

Electrode potentials and diffusion coefficients for einsteinium were measured by radiopolarography using solutions and a dropping mercury cathode (Samhoun and David, 1979). A single half-wave for the III to 0 standard potential for reduction/amalgamation was reported as –1.460(5) V and a diffusion coefficient of $6 \times 10^{-6}\,\text{cm}^2\,\text{s}^{-1}$. Nugent (1975) suggested a corrected, more negative value (−1.98(7) V; after correcting for the amalgamation energy) as given in

Chapter 19. David (1986) discussed other values and gave selected ionic radii for several actinides, including einsteinium.

The amalgamation behavior of einsteinium and other actinide elements had been investigated earlier, where it was noted that amalgams of californium, einsteinium, and fermium displayed an anomalous behavior (Maly, 1969). This work suggested that these three elements may display a divalent state, given their preference to form amalgams in comparison to other actinides. Radiopolarography frequently employs mercury as one phase but phase diagrams for mercury alloys or dilute amalgams are not available for many of the transplutonium elements. One report (Guminski, 1996) has tabulated information from pre-1970 publications that contained incorrect data, which makes this publication of limited value.

Although einsteinium is the first element in the series to be divalent, the divalent ionic states of americium and californium have also been reported (see Chapters 8 and 11). The III → II reduction potential for einsteinium was initially estimated to be –1.6V, based on the lowest state for electron transfer (Nugent *et al.*, 1969b; Nugent, 1975), but was later suggested to be –1.21 V (from work with chloroaluminate salts (Duyckaerts and Gilbert, 1977)) and –1.18 V from radiopolarographic experiments (David *et al.*, 1978). Using a method of cocrystallization of einsteinium tracer with $SmCl_2$, Mikheev *et al.* (1972a,b) and Mikheev and Rumer (1972) had suggested einsteinium's reduction potential should be close to that for samarium ($-1.55(6)$ V). A value of -1.3 V is adopted in Chapter 19 for the standard potential of the Es^{3+}–Es^{2+} couple.

A series of papers over several years have dealt with Es^{2+} in selected solutions. These have been tracer-level studies involving different facets of the co-crystallization technique and of complexation studies. One of these papers (Mikheev *et al.*, 1986) investigated the cocrystallization of divalent ions of californium, einsteinium, fermium, samarium, europium, and ytterbium with SrI_2 (18-crown-6) using tetrahydrofuran as a solvent. The Tm^{2+} ion controlled the oxidation potential of the solution. Cocrystallization coefficients relative to strontium were given as close to 1, where the coefficients of the three actinides fell between values of 1.10 for samarium and 0.83 for ytterbium.

The behavior of einsteinium (together with other Am, Cf, and Fm) in $LiCl$–$NdCl_2$–$NdCl_3$ and in LiI–PrI_2 systems was examined (Kulyukhin *et al.*, 1997a,b). In the first molten salt, Nd(II) reduced Cf and Fm to a divalent state. In the second salt system, it was not clear if these actinides were reduced to their divalent or monovalent states. Ratios of the actinide distribution coefficients to those of samarium were reported for both salt systems. Mikheev *et al.* (2004) have reviewed the lower oxidation states of actinides with regard to cocrystallization coefficients in melts, and provided a distribution coefficient for einsteinium versus strontium ($D_{Es/Sm} = 0.94$).

Complexation and cocrystallization of einsteinium with 18-crown-6 in water and water–ethanol mixtures were reported by Mikheev *et al.* (1993a,b). Log K values measured for water and the water–ethanol mixtures were 2.64

and 4.70, respectively. The solvent effects on cocrystallization of Es^{2+} with $SrCl_2$ were reported by Mikheev *et al.* in the 1993b reference. Mikheev *et al.* (1986) had also looked at cocrystallization of Es^{2+} with SrI_2–18-crown-6 complexes, and the effects of water on the cocrystallization and solubility of einsteinium in $Sr(Sm)SO_4$ systems (Mikheev *et al.*, 1987). In the latter work, hydration values could be estimated for Es^{2+} from radii considerations of the different ions. Solubility products for einsteinium complexes with 18-crown-6, boron tetrafluoride, and boron tetraphenyl in tetrahydrofuran were discussed by Kulyukin and Mikheev (1997a,b). The distribution of einsteinium in molten salts containing reductants was described by Kulyukin *et al.* (1997). Veleshko *et al.* (1993) discussed the complexation of Es^{2+} with tetraphenylborate in acetonitrile, and Mikheev *et al.* (1988b) reported the data for the latter with water–ethanol mixtures.

Another study examined the effects of water on the cocrystallization of divalent europium, ytterbium, and einsteinium ions in the $Sr(Sm)SO_4$–ethanol system (Mikheev *et al.*, 1988a,b). Water affected the Es^{2+} coefficients up to 10 M water. The Gibbs energies of hydration were given for Eu^{2+}, Yb^{2+}, and Sr^{2+} ions and were assumed to extend to Es^{2+}. Values ranged from 1361 to 1461 kJ mol^{-1}. The coordination of these three ions was also examined with sodium tetraphenylborate in water–ethanol solutions (Mikheev *et al.*, 1988b). The coordination constants, β_1 and β_2, were determined and the observed trend suggested that the hydrated Es^{2+} ion was smaller than the two divalent lanthanide ions. The β_1 and β_2 values were given as log values: 6.2 and 106.4 for Es^{2+}; 1.7 and 52.7 for Eu^{2+}; and 6.5 and 25.7 for Yb^{2+}.

The effect of the solvent on the cocrystallization of Es^{2+} complexed with tetraphenylborate in acetonitrile and tetrahydrofuran was reported (Mikheev *et al.*, 1993a,b), where the einsteinium was complexed in the acetonitrile but not in the other solvent. The stability constants of the Es^{2+} complexes in acetonitrile were given as $\log \beta_1 = 6.6$ and $\log \beta_2 = 16.0$. Additional work on the complexation of Eu^{2+}, Yb^{2+}, and Es^{2+} with this reagent in different solvents suggested that outer sphere complexes are formed due to electron tunneling from the cation into the unsaturated π-bonds of the anion to form a single-electron bond (Mikheev *et al.*, 1993). The β_1 and β_2 values were given for the three divalent ions in water–ethanol mixtures, acetonitrile, and tetrahydrofuran. From the complexation of Es^{2+} in ethanol–water, acetonitrile, and tetrahydrofuran with the tetraphenylborate ion, it was concluded that complexes are not formed in tetrahydrofuran, as the solvent molecule is too large (Veleshko *et al.*, 1993). In the other two solvents, the smaller solvent molecule is inner sphere and complexes are formed.

The complexation of Es^{2+} with 18-crown-6 in aqueous ethanol and in water was studied, and the stability constants of the complex were determined (Mikheev *et al.*, 1993a,b). The log *K* values for einsteinium were given as 2.70 in water and 4.70 in ethanol–water (10 M). In both solvents, the log *k* varied in the order: $Eu^{2+} > Es^{2+} > Yb^{2+}$. The effect of perchlorate, tetrafluoroborate, and tetraphenylborate ions on the crystallization behavior of Es^{2+} with Sr–10-crown-6)I in tetrahydrofuran was reported (Kulyukhin and Mikheev, 1997a,b). The first two ions affected the cocrystallization constants but the tetraphenylborate ion did not, as it did not form complexes with the metal ion in this solvent. The stability constants were found to increase in going from the tetrafluoroborate to the perchlorate ions.

12.6.6 Compounds in the vapor state

The chemistry of elemental einsteinium in the vapor state was covered in Section 12.5. Elemental einsteinium vapor was generated by direct vaporization of it while ions as Es^+ or EsO^+ were produced by laser ablation of solid matrices or by heating oxides.

Recent gas-phase studies of einsteinium have provided important new insights into its chemistry. The concept of f→d promotion energy is also very important for different gas species and their reactions. The promotion energies for einsteinium's 5f electrons in the elemental state and in different ions are given in Figs. 12.11–12.13, which are taken from Gibson and Haire (2003). One plot is for the promotion energies for An^+ and Ln^+ ions from their ground state electronic configuration to the lowest-lying configurations that have two unpaired non-f valence electrons (i.e. $5f^{n-2}6d7s$), where the value for einsteinium requires some 150 kJ mol^{-1} more energy than its homolog, holmium. The second plot in Fig. 12.12 compares promotion energies for an An^+ ion from the ground state to a configuration having two non-5f valence electrons, a $5f^{n-2}6d7s$ versus a $5f^{n-2}7s^2$ state. The promotion energy for an einsteinium ion having two unpaired 7s electrons is lower. The third comparison in

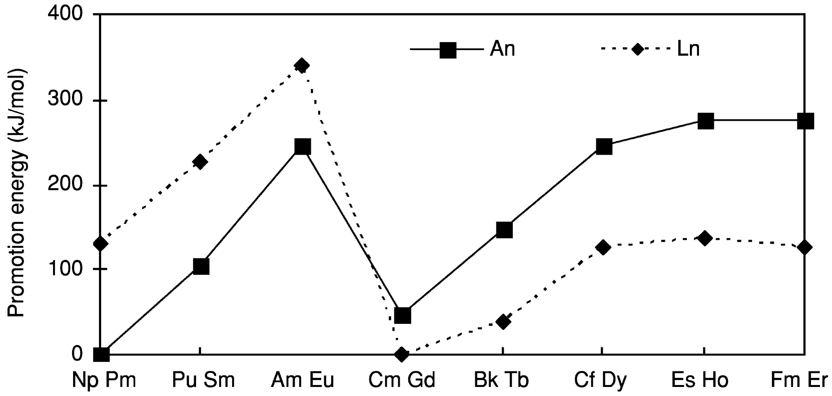

Fig. 12.11 *Promotion energies for An^+ and Ln^+ from ground states to the reactive lowest lying onfiguration having two unpaired, non-f electrons.* (*Gibson and Haire*, 2003). *Note the different trend with the higher members of each series.*

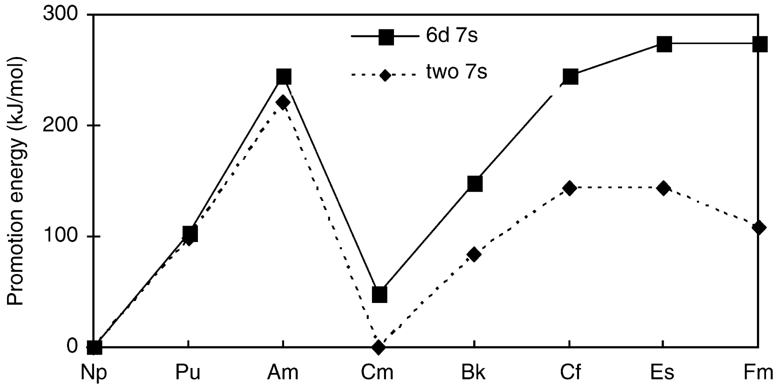

Fig. 12.12 *Promotion energies for An$^+$ ground state to produce a reactive state with two unpaired f electrons and a* 6d7s state (*solid line*) *versus a paired* 7s^2 *state* (*dashed line*). *Additional energy is needed to acquire the* 6d7s *reactive state.* (*Gibson and Haire*, 2003).

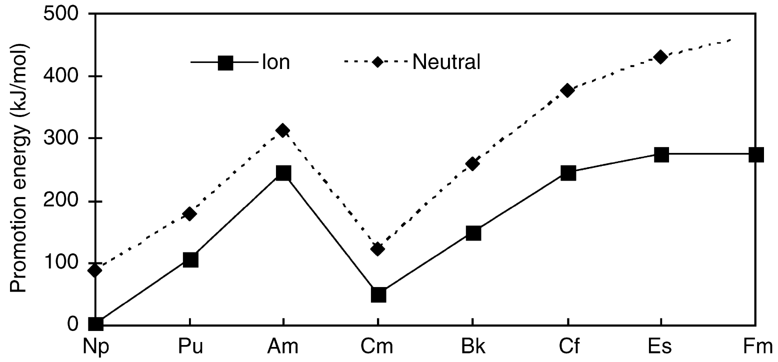

Fig. 12.13 *Promotion energies for An$^+$ for atomic ions and for An neutral atoms. The energies are for excitation from the ground states to* 6d7s *"divalent" configurations for An$^+$ and for* 6d7s *"trivalent" configurations for the atoms.* (*Gibson and Haire*, 2003).

Fig. 12.13 is made for the promotion energies from the ground state to the neutral atom ('trivalent' configuration, 5f^{n-3} 6d^{2}7s) and the Es$^+$ ion ('divalent' configuration, 5f^{n-2}6d7s), where the neutral atom has a promotion energy twice that for forming the An$^+$ ion.

Important information has been acquired from gas-phase studies of einsteinium, where laser ablations were used in conjunction with mass spectrometry (Gibson and Haire, 2003). The small yields of EsO$^+$ obtained relative to Es$^+$ ions indicated that the Es$^+$–O bond is significantly weaker than that for the earlier actinides.

Fluorination of Es^+ by extraction of fluorine atoms from hexafluoropropene demonstrated the stability of the divalent state of einsteinium. Using this technique, the first organometallic complex of einsteinium was observed ($EsC_4H_8^+$) in the gas phase. From this work the bond dissociation energy for EsO^+ was established and it was found to be smaller than those for EuO^+ and YbO^+, being more similar to that for TmO^+.

Systematic trends of einsteinium's chemistry terms of electronic structure and the energetics of the actinides and lanthanides were developed in this work (Gibson and Haire, 2003). The bond dissociation energy for Es^+–O was estimated to be (470 ± 60) kJ mol^{-1}, higher than the values for Eu^+–O (389 kJ mol^{-1}) and Yb^+–O (372 kJ mol^{-1}), but similar to that for Tm^+–O (478 kJ mol^{-1}) (Gibson and Haire, 2003). The dissociation energy for EsO was earlier reported to be 443 kJ mol^{-1} (Haire, 1994), smaller than dissociation energies for the americium through californium monoxides but similar to those for europium and ytterbium. Thus, einsteinium sesquioxide at high temperatures produces mainly elemental einsteinium rather than a monoxide, where the latter is found when heating curium sesquioxide to very high temperatures.

An important finding was that for einsteinium to become a reactive species, it was necessary to promote the Es^+ ion's ground state electronic configuration to the lowest-lying configuration having two unpaired non-5f valence electrons (i.e. 6d7s rather than $7s^2$). The Es^+ ion was found to be the least efficient of the Th^+ through Cf^+ ions at the dehydrogenation of organic materials, although it was only slightly less efficient than Am^+ and Cf^+ ions (Gibson and Haire, 2003).

In conjunction with the proposal that a hexavalent state of einsteinium could exist based on the added stability acquired from formation of a half-filled 5f orbital (i.e. $[Rn]5f^{11}7s^2 \rightarrow [Rn]5f^7$ for Es(VI)); Liebman, 1978), a potential compound could be the hypothetical EsF_6. As a molecular material, it would be expected to be volatile like UF_6 and PuF_6. From limited attempts to make this material, there is no experimental evidence to support its existence. Attempts to prepare AmF_6 have also proven it to be an elusive material, and far less stable than UF_6 or PuF_6. Therefore, it is unlikely that EsF_6 would be stable.

Studies have also been performed on the formation of volatile molecules using the concepts of thermochromatography (see Section 12.5), and the idea that a molecule in an unusual oxidation state may have a greater potential to form or to exist in the vapor state. From tracer experiments with ^{254}Es, evidence was claimed to support the existence of EsF_4 (Bouissières *et al.*, 1980). The technique consisted of treating EsF_3 with flowing fluorine and determining the temperature where the einsteinium's activity was deposited. This temperature was correlated with deposition temperatures for five other (Pu–Cf) actinide materials, also assumed to be transported as tetrafluorides. The volatility of fluorides should increase with higher oxidation states, so that the order of volatility would be expected to be hexafluoride > tetrafluoride > trifluoride. A point of concern with einsteinium may be the ability to form a tetrafluoride from its trifluoride at temperatures above the expected decomposition temperature of the tetrafluoride, as estimated from the behaviors of other actinide tetrafluorides.

Thermochromatography of ^{254g}Es in chlorinating carrier gas was used to estimate the adsorption of $EsCl_3$, and was found to be in agreement with a Monte Carlo model for its behavior (Eichler *et al.*, 2002). Volatile einsteinium hexafluoroacetylacetonate (HHFA) complexes have also been reported (Fedoseev *et al.*, 1987a,b). At the tracer level, these materials can form by passing vapors of the HHFA over einsteinium chloride solids at 200°C. A thermochromatographic study was then used to follow the reaction products. Mixed ligand complexes and lanthanide complexes were also studied. Solvated complexes of HHFA (as well as other organic materials) and the oxychlorides were found to be less volatile in the system. It was concluded that the complexes contained Es(III) rather than Es(II), the latter having a lower volatility.

The gas-phase chemistry of Es^+ and EsO^+ ions has been studied by a laser ablation technique (Gibson and Haire, 2003). The behavior of the Es^+ ion was found to be comparable to that of other actinide ions. The yield of EsO^+ ions suggests that the Es^+–O bond energy is significantly lesser that that of other such actinide ions (i.e. Bk^+–O). By performing chemical reactions in the gas phase between these einsteinium ions and other materials (halogenated organics, alkenes, etc.), it was possible to ascertain important aspects of the chemical behavior of einsteinium in the gas phase, and the ability to form organometallic compounds of einsteinium.

12.7 ATOMIC AND IONIC RADII, AND PROMOTION ENERGIES – THEIR IMPORTANCE IN EINSTEINIUM'S OVERALL SCIENCE

The radii of ions, molecules, and atoms are important in the chemistry and physics of materials as well as for estimation/interpolation of their behaviors. For einsteinium there is a considerable difference in its atomic radius compared to the four previous transplutonium elements, and this is reflected in its properties and science. For divalent and trivalent einsteinium ions, much of their solid and solution behaviors reflect their radii, and in these states einsteinium often behaves similarly to the comparable oxidation states of the other transplutonium and lanthanide ions. In the gas state, bonding energies and potentials (oxidation and promotion) are also of major chemical importance.

The atomic and ionic radii for a given number of bonding electrons or for an oxidation state of the f-elements, in principle, should decrease in a uniform manner across each series (well-established f-element contraction phenomena). This contraction with atomic number has been found to be is in good agreement with multidimensional Dirac–Fock calculations (Desclaux and Freeman, 1984). Ionova *et al.* (1978) have also calculated einsteinium's radius via Hartree–Fock approximations. Thus, these radii are often useful for extrapolations of behavior and properties.

In the case of atomic radii, one observes that einsteinium's radius compares well with radii of europium and ytterbium; as a result of it being a divalent rather than a trivalent metal (see Section 12.5 and Fig. 12.1). The divalent atomic radii of these elements are considerably larger than the trivalent atomic radii of these f-elements, as expected from one less bonding electron. This comes about in part due to the larger promotion energy for changing an f-electron in einsteinium to a 'd' state to enable additional bonding. As a result, einsteinium is the first divalent actinide metal.

With ionic compounds, many are found to form similar, isostructural phases, which is well established in oxide systems (Haire and Eyring, 1994). The ion-exchange behavior of the trivalent ions in solution also shows this correlation (Seaborg and Loveland, 1990). The ionic radius of Es(III), which varies with the coordination number, has been determined from different compounds. From sesquioxide lattice parameters for the actinides and lanthanides (Haire and Eyring, 1994), the ionic radius of Es^{3+} (0.928 Å) is slightly smaller than that of Cf^{3+}, and midway between the radii for Tb^{3+} (0.920 Å) and Gd^{3+} (0.938 Å). Another set of ionic radii has been given by David (1986), which shows a similar relationship. Thus, similar oxide-phase behavior is expected for these ions. The relative behaviors of the sesquioxide lattice parameters and the ionic radii are shown in Fig. 12.6 and Table 12.7, including calculated radii for Es(II) ions. Values are also given for potential Es(IV) ions; these ions would have different coordination numbers and show somewhat different behaviors than the Es(II) and Es(III) ions.

Einsteinium's sesquioxide and trivalent halide-phase behaviors in several solid compounds are found to be comparable to the lanthanides discussed above. In the case of cation-exchange behavior, the elution behavior from ion-exchange columns for a given oxidation state is generally in the order of the radii of the hydrated ions, with the largest or more readily complexed ions eluting first (einsteinium before californium). With elution from a cation column using α-HIB, einsteinium is found at a position between dysprosium and holmium (einsteinium's lanthanide homolog; Seaborg and Loveland, 1990).

Thus, einsteinium's atomic and ionic radii are important factors in the science of einsteinium. They often serve as useful information to understand, predict, and/or extrapolate the behavior of einsteinium. And the $f \rightarrow d$ electron promotion energy is also very important to understanding elemental einsteinium, as well as several facets of einsteinium's gas-phase chemistry.

ACKNOWLEDGMENTS

Research was sponsored by the Division of Chemical Sciences, Geosciences and Biosciences, Office of Basic Energy Sciences, U.S. Department of Energy, under contract DE-ACO5-00OR22725 with Oak Ridge National Laboratory, managed and operated by UT-Battelle, LLC.

CHAPTER THIRTEEN

FERMIUM, MENDELEVIUM, NOBELIUM, AND LAWRENCIUM

Robert J. Silva

13.1 GENERAL

Because of conflicting claims, the International Union of Pure and Applied Chemistry (IUPAC) recently reviewed the names of all the trans-fermium elements; Münzenberg (1999) has published a detailed discussion of the problems and the resolution. First, a Transfermium Working Group decided the priority of discoveries. Next, the discoverers proposed names to the IUPAC and names were officially accepted by that body. The names for the elements mendelevium, nobelium, and lawrencium were retained as originally proposed at the time of their discoveries.

As of this writing, the number of known isotopes of Fm, Md, No, and Lr is 58, ranging in half-life from as short as 0.25 ms for ^{250}No to as long as 100.5 days for ^{257}Fm. Relativistic effects have been predicted to affect ground state electronic configurations, ionic radii, and oxidation state for the heavier actinides. While the 3+ oxidation state remains a dominant feature of the heavier actinides, a tendency toward the formation of lower oxidation states has emerged. Divalency had been observed in solution for fermium through nobelium, in fact, the elements Fm, Md, and No are divalent in the metallic state. Due to increased 5f electron binding of the filled 5f^{14} shell, the 2+ oxidation state is the most stable in aqueous solution for nobelium. However, lawrencium, the last member of the actinide series, returns to the 3+ oxidation state as the most stable in aqueous solution, as predicted (Seaborg, 1949).

Due to the short half-lives and low production yields of Fm–Lr, all available chemical information has been obtained from experiments with tracer quantities. In fact, in many cases, chemical experiments were performed with only a few atoms or even one atom at a time. These experiments have necessarily been rather simple in principle, aimed primarily at making comparative studies with elements of known chemical properties. Nevertheless, all available experimental and theoretical evidence supports the original prediction of an actinide series (Seaborg, 1945) involving filling of the 5f electron shell, analogous to the lanthanide series resulting from the filling of the 4f electron shell, and that element 103 is the last member of this series of elements (Seaborg, 1949). The next element, atomic number 104, would be expected to fall into the next chemical group, i.e. Group IVB, of the periodic table.

13.2 FERMIUM

13.2.1 Introduction

The first isotope of element 100 was discovered in heavy-element samples obtained after the ‘Mike’ thermonuclear explosion of 1952, during the same set of experiments that resulted in the discovery of element 99. A joint effort by the researchers from the Lawrence Berkeley National Laboratory, the Argonne National Laboratory, and the Los Alamos National Laboratory resulted in the chemical isolation and identification of the 20 h half-life isotope ^{255}Fm (Ghiorso *et al.*, 1955a). The production involved rapid, multiple neutron capture by uranium nuclei in the nuclear device to form neutron-rich uranium isotopes of heavy mass followed by beta decay to elements of higher atomic number. The ^{255}Fm in the samples, produced from the beta decay of the longer-lived ^{255}Es, was purified and chemically identified by cation-exchange chromatography and detected through the use of alpha particle energy analysis. The name, fermium, was proposed in 1955 in honor of the leader in nuclear science, Enrico Fermi, and the name was subsequently accepted by the IUPAC.

13.2.2 Isotopes of fermium

As can be seen in Table 13.1, there are 19 known isotopes of element 100, ranging from atomic masses 242 through 260. Isotopes with masses 254 through 257 have been identified in samples of plutonium or elements of higher atomic number following neutron irradiation in nuclear reactors. All the other isotopes can only be produced by charged-particle bombardments of targets of elements of lower atomic number at charged-particle accelerators, e.g. cyclotrons, linear accelerators, etc.

The isotope that can be produced in largest quantities on an atomic basis is ^{257}Fm. This isotope is also the nuclide of highest atomic and mass number ever

isolated from either reactor or thermonuclear-produced materials. The neutron capture production chain essentially terminates at mass 257 owing to the very short spontaneous fission half-lives of the heavier isotopes. The current annual reactor production rate is in the picogram range (Porter *et al.*, 1997). However, in the thermonuclear explosion of 1969 called ‘Hutch,’ about 10^8 higher production was achieved (Hoff and Hulet, 1970), but only one part in 10 million of the total number of atoms of ^{257}Fm imbedded in tons of geologic debris was recovered, i.e. a 10 kg sample of debris yielded about 10^{10} atoms.

Though ^{257}Fm is produced in larger amounts, ^{255}Fm has been more available on a regular basis from the beta decay of reactor-produced ^{255}Es ($t_{1/2} = 38.3$ days) and is more frequently used for chemical studies at the tracer level. Radioactivity levels in excess of 10^8 alpha disintegrations per minute of ^{255}Fm can be obtained from periodic chemical separations of Fm, 'milkings,' from purified Es samples.

13.2.3 Preparation and purification

Because of their strong chemical similarity, the only satisfactory methods of separation of the trivalent actinides are by cation exchange or solvent extraction chromatography. The procedure most often selected is separation by elution from a cation-exchange resin column, e.g. Dowex 50 × 8 or × 12 resin, using an aqueous solution of the chelating agent ammonium α-hydroxyisobutyrate (α-HIB) as eluant. This combination, developed in 1956 (Choppin *et al.*, 1956) primarily for the isolation and identification of new actinide elements, remains the main process method for the separation of trivalent actinides (Porter *et al.*, 1997). The actinides exhibit increasing complexation strength with the organic ligand with increasing atomic number, attributed to the decreasing ionic radii due to the actinide contraction (Katz *et al.*, 1986) and are eluted from the column in a regular sequence with the higher atomic number elements eluting first. Fig. 13.1 shows a typical separation of trace amounts of trivalent actinides using this method.

Vobecký *et al.* (1991) have obtained similar sequential elution and separation of 3+ actinides from a column of the spheroidal cation exchanger OSTION using a solution of ammonium α-hydroxy-α-methylbutyrate as the eluant.

Porter *et al.* (1997) have described a process method for the isolation and purification of fermium from other actinides and from rare earth fission produce from reactor target material. In addition to the standard series of transcurium actinide separations through the use of ammonium α-HIB eluant and cation-exchange resin, final purification of the fermium from small amounts of rare earth impurities that could contribute to the mass of the sample was accomplished using a solvent extraction chromatographic resin (the quaternary amine, Aliquat-336, impregnated into Amberchrom CG-71 ms support resin) that is marketed under the trade name TEVA.

Mikheev *et al.* (1983) have developed a rapid method for the separation of fermium from californium, einsteinium, and lanthanide elements based on the cocrystallization of reduced ^{254}Fm(II) with sodium chloride in aqueous ethanol solutions containing Yb(II). The coefficient of separation of Fm

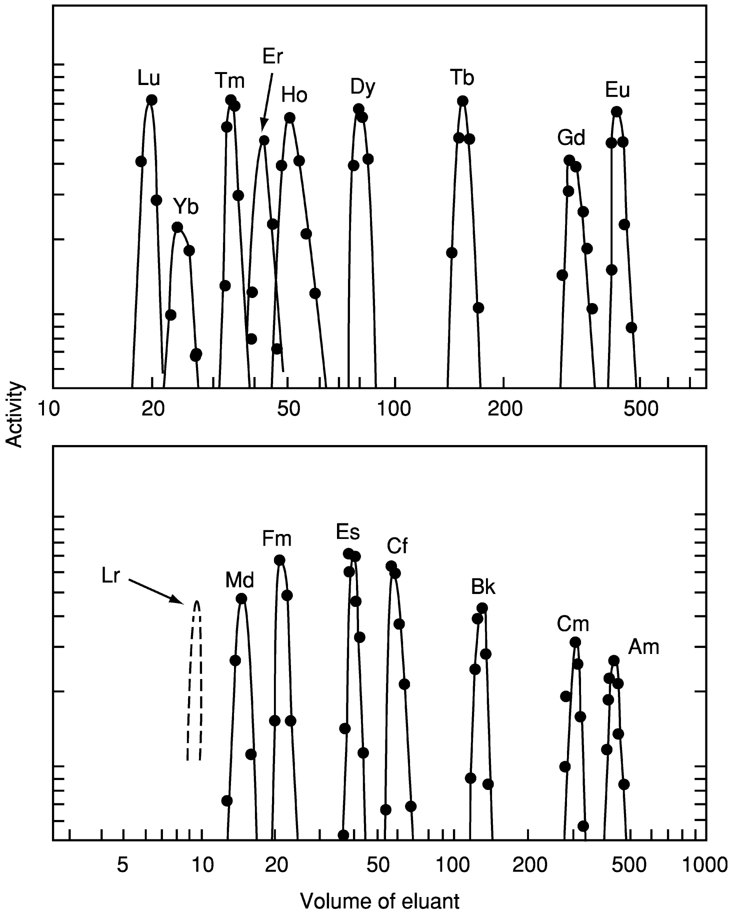

Fig. 13.1 *Elution of homologous trivalent actinides and lanthanides from a Dowex* 50 *cation-exchange resin column at* 87°C *with ammonium α-hydroxyisobutyrate as eluant. The broken curve for element* 103 (*Lr*) *is an estimate based on its predicted radius.*

from its elemental analogs in one cocrystallization step is 10^3 to 10^4 and the separation takes about 10 min.

Fermium has also been separated rapidly from the other transplutonium elements via chromatography using strongly basic anion-exchange resin and mixtures of nitric acid and methyl alcohol at elevated temperatures for the elutions (Usuda *et al.*, 1987).

Volatile hexafluoroacetylacetonates of Md and Fm have been prepared and could be the bases for chemical isolation by thermochromatography (Fedoseev *et al.*, 1990).

13.2.4 Atomic properties

Goodman *et al.* (1971) have used the atomic-beam magnetic resonance technique, adapted to the measurement of radioactive samples, to determine the magnetic moment, g_j, of the atomic ground state of neutral atoms of ^{254}Fm to be 1.16052 ± 0.00014. A comparison of the experimentally measured value with values obtained from intermediate coupling calculations for several likely electron configurations was made. The measured value of g_j was found to be in close agreement only with that calculated for the $^3H_6$ level of the $5f^{12}7s^2$ electronic configuration. This agreement was taken as a conclusive evidence for the assignment of this configuration to the ground state of fermium.

The inner-shell binding energies and X-ray energies for the heavy elements have been estimated from total energies obtained from a Dirac–Fock computer code of Desclaux by Carlson and Nestor (1977). In these calculations, small empirical corrections were added as a result of comparing calculations with experimentally determined binding energies for elements of $Z > 95$. Where comparisons have been made for higher Z elements, the results of the calculations have agreed well with the experimentally measured values. Fricke *et al.* (1972) have also published electron binding energies in fermium obtained from Dirac–Fock calculations and compared them to the values of Porter and Freedman (1971) measured experimentally via spectroscopic measurements of internal conversion electrons emitted following the beta decay of ^{254m}Es to ^{254}Fm. Das (1981) calculated the binding energies in fermium by using a relativistic local density functional theory. Porter and Freedman (1978) have recommended atomic binding energies of the K, L, M, N, O, and P shells for heavy elements from $Z = 84$ to 103. A table of electron binding energies based on the latter is given by Firestone *et al.* (1996). The values for Fm differ slightly from their earlier experimental values (Porter and Freedman, 1971). The results of the three theoretical calculations are compared with the recommended values of Porter and Freedman in Table 13.2. The agreement is quite good and demonstrates that these types of theoretical calculations are consistent and quite useful for predictive purposes.

Dittner *et al.* (1971) have measured the K-series X-rays of ^{251}Fm emitted following the alpha decay of ^{255}No. The K-series X-ray energies derived experimentally from these studies are compared with the values calculated using the binding energies of Porter and Freedman (1978) in Table 13.2.

13.2.5 The metallic state

Fermium metal has not been prepared, however, measurements have been performed on alloys with rare earth metals and a number of predictions about it have been made.

Johansson and Rosengren (1975) have correlated the measured and predicted cohesive energies of the lanthanide and actinide elements in both the divalent and trivalent metallic states. They concluded that the gain in energy of binding

[f] Dittner *et al.* (1971).

of the $5f^n6d^17s^2$ (trivalent) configuration over the $5f^{n+1}7s^2$ (divalent configuration) is less than the energy necessary to promote one 5f electron to the 6d state in the final members of the actinide series. Therefore, Es, Fm, Md, and No prefer a divalent metallic state similar to Eu and Yb rather than a trivalent one. However the energy difference is small for Es and Fm and, at modest compression, the divalent metallic state may convert to the trivalent one.

The sublimation enthalpy, a fundamental metallic property, is connected directly with the valence electronic structure of the metal. The enthalpy of sublimation of fermium has been determined directly by measuring the partial pressure of Fm over Fm–Sm and Fm, Es–Yb alloys for the temperature range 642–905 K (Haire and Gibson, 1989). Based on their combined second law and third law measured values for the enthalpy of sublimation of Fm, they reported a value of (142 ± 13) kJ mol^{-1} for ΔH_{298}. Because the enthalpy of sublimation of Fm was similar to those of divalent Es, Eu, and Yb, it was concluded that Fm is divalent in the metallic state. Comparisons with radii and melting points of Eu, Yb, and Es metals have yielded estimated values of 0.198 nm and 1125 K for Fm by these authors. David *et al.* (1978) have estimated a divalent metallic radius of 0.194 nm for Fm, in close agreement.

Because the heaviest actinides are available only in trace amounts, innovative experimental approaches must be used in order to characterize their elemental state properties. Zvara and coworkers (Zvara *et al.*, 1976) compared the evaporation rates of trace amounts of Es, Fm, and Md from molten La with those of Ce, Eu, Yb, Am, and Cf to obtain information on their metallic states. Hübener (1980) compared the thermochromatographic behavior of Es, Fm, and Md evaporated from molten La in titanium columns with those of Na, Sc, Sm, Eu, Yb, Bk, and Cf. The conclusion reported in both of these papers supported the idea that Es, Fm, and Md prefer the divalent metallic state. The adsorption behavior of Cf, Es, Fm, and Md on titanium and molybdenum thermochromatographic columns was compared to a number of monovalent, divalent, and trivalent elements and enthalpies of adsorption determined (Hübener and Zvara, 1982). From the data, the authors also concluded that Es, Fm, and Md are divalent in the metallic state and that the position of the f-energy levels relative to the Fermi-energy is lower than in the cases of Cf and Yb. A nearly linear correlation was found between the experimental enthalpies of adsorption of the heavy actinides and their predicted enthalpies of sublimation.

Thermochromatographic studies of the adsorption of Cf, Es, and Fm on several metals were conducted by Taut *et al.* (1997) and enthalpies of sublimation inferred from the measured enthalpies of adsorption. The results support the value of the enthalpy of sublimation of Fm published by Haire and Gibson (1989).

13.2.6 Solution chemistry

The chemical properties of fermium have been studied only with trace quantities. The chemical properties of Fm have been discussed by Thompson *et al.* (1954). Under conditions not strongly reducing, fermium behaves in aqueous solution as expected for a trivalent actinide ion. Fermium coprecipitates with rare earth fluorides and hydroxides. The elution of fermium just before einsteinium from cation-exchange resin columns with hydrogen ion and the complexing ligands citric acid, lactic acid, and α-HIB is consistent with the existence of a trivalent ion (Katz and Seaborg, 1957). In concentrated hydrochloric acid, nitric acid, and ammonium thiocyanate solutions, fermium forms anion complexes with these ligands that can be adsorbed onto and subsequently eluted from anion-exchange columns (Thompson *et al.*, 1954). In this case, fermium follows einsteinium in the elution sequence. Both types of column results indicate that Fm forms a slightly stronger complex with the ligands than Es, which is due to the slightly smaller ionic radius of Fm as a result of the actinide contraction

(Katz *et al.*, 1986). Fermium also exhibits a more acidic behavior than the preceding actinides in aqueous solution, having a first hydrolysis constant of 1.6×10^{-4} (Hussonnois *et al.*, 1972).

David *et al.* (1978) have estimated some thermodynamic properties of the 5f elements obtained from theoretical considerations and empirical correlations drawn from observed trends in the 4f series. They proposed an ionic radius of 0.0922 nm for Fm^{3+}. From the linear correlation of log distribution coefficients with ionic radius obtained from elution positions from α-HIB/cation-exchange column separations, a value of 0.0911 nm was calculated for the ionic radius of Fm^{3+} (Brüchle *et al.*, 1988). Lundqvist *et al.* (1981) have studied the migration rates of Fm^{3+} in an electrical potential gradient using paper electrophoresis and reported a hydrated radius of 0.495 nm and a hydration number of 16.9 in aqueous perchlorate solutions.

Fermium readily forms complexes with a variety of organic ligands, e.g., β-diketones (Hussonnois *et al.*, 1972), hydroxycarboxylic acids (Thompson *et al.*, 1954; Choppin *et al.*, 1956; Baybarz, 1965, 1966; Ermakovl and Stary, 1967; Hubert *et al.*, 1974), organophosphorus esters (Baybarz, 1963; Stary, 1966; Horwitz *et al.*, 1969), and alkylamines (Müller, 1967). α-HIB has long been used as the eluant for inner series separation of trivalent actinides by cation-exchange chromatography as stated above. However, bis(2-ethylhexyl)phosphoric acid (HDEHP) (Horwitz and Bloomquist, 1973) and Alamine 336 (a mixed *n*-octyl and *n*-decyl tertiary amine) (Leuze *et al.*, 1963) have also been used for similar separations of Fm by solvent extraction column chromatography. Gorski *et al.* (1990) have investigated the complex formation of several transplutonium elements, including Fm, with 1,2-diaminocyclohexane tetraacetic acid (DCTA) and shown the correlation of ionic radii with the values of the log of the complex stability constants. A linear dependence is observed for lanthanides while it deviates from linearity for the heavy actinides. The author's postulate that, since the stability of chelate complexes are determined by the positive change of entropy of the reaction, the change in stability constants of the heavy actinides is due to an entropy effect rather than to the change in the ionic radii.

The behavior of Sr, Y, Sm, Eu, Am, Cf, Es, and Fm in the molten salt mixtures $LiCl–NdCl_2–NdCl_3$ and $LiI–PrI_2$ have been studied (Kulyukhin, 1997). In the presence of Nd^{2+}, Cf, Es, and Fm are reduced to the 2+ oxidation state. The results obtained in the $LiI–PrI_2$ system were ambiguous as to whether the actinides Cf–Fm were reduced to the 1+ or 2+ oxidation states.

The tendency of Fm to form a divalent ion under strong reducing conditions was first suggested by the work of Maly (1967). Mikheev *et al.* (1972) reported the reduction of Fm^{3+} to Fm^{2+} in 1972 from the results of reduction/cocrystallization experiments with $SmCl_2$. The reduction of Fm^{3+} to Fm^{2+} with $SmCl_2$ has also been observed by Hulet *et al.* (1979). Mikheev *et al.* (1977) were able to estimate the reduction potential to be very nearly the same as the $Yb^{3+} \rightarrow Yb^{2+}$ couple or −1.15 V. This value is in reasonably good agreement with the value of –(1.1 ± 0.2) V calculated by Nugent (1975) using refined electron-spin-pairing theory.

Using a refined radiopolarographic technique, Samhoun and David (1976) measured the half-wave potential for the $Fm^{2+} \rightarrow Fm(Hg)$ reduction at a dropping mercury electrode as –(1.47 ± 0.01) V. By applying an estimated amalgamation potential correction of 0.90 V obtained from correlations of other divalent ions, a value for E° ($Fm^{2+} \rightarrow Fm^0$) of –(2.37 ± 0.1) V was reported. Using this latter value of Samhoun and David, combined with Mikheev's value of –1.15 V for the $Fm^{3+} \rightarrow Fm^{2+}$ couple, a value of –(1.96 ± 0.13) V can be calculated for E° ($Fm^{3+} \rightarrow Fm^0$). Nugent (1975) has estimated $E^\circ(Fm^{4+} \rightarrow Fm^{3+})$ to be +4.9 V. These values (Table 13.8) are consistent within uncertainties with those in Chapter 19 (Fig. 19.9).

Unless otherwise indicated, all electrode potentials in this chapter are with reference to the normal hydrogen electrode (NHE) and the 1969 IUPAC convention, i.e. the more positive the potential the more stable the reduced form (McGlashan, 1970).

13.3 MENDELEVIUM

13.3.1 Introduction

The first isotope of element 101 was produced in 1955 by Ghiorso *et al.* (1955b). It was synthesized in the bombardment of approximately one billion atoms of ^{253}Es with 41 MeV alpha particles and produced at a rate of only about two atoms per 3 h bombardment. A chemical identification was made on the basis of its elution position just before Fm from a cation-exchange resin column using ammonium α-HIB as eluant in a series of repetitive experiments. It was not detected directly but by the observation of spontaneous fission events arising from its electron-capture daughter ^{256}Fm. Additional analysis of the data, coupled with further experimentation, showed the isotope to have mass 256 and to decay by electron capture with a half-life of 1.5 h. The name mendelevium was proposed for the element in honor of Dimitri Mendeleev, in recognition of his contributions to the development of the chemical periodic system, and it was accepted by IUPAC.

13.3.2 Isotopes of mendelevium

Sixteen isotopes of mendelevium from mass 245 to 260 are known (see Table 13.3) . All of its isotopes can only be produced through charged-particle irradiations at accelerators. Although ^{258}Md, with a half-life of 51 days, is the longest-lived isotope, ^{256}Md remains the isotope most often used in chemical experiments because it can be produced in relatively larger quantities. Using microgram amounts of ^{253}Es presently available, more than a million

atoms per hour of ^{256}Md can be produced by alpha-particle bombardments (Hulet *et al.*, 1967).

13.3.3 Preparation and purification

The isotope ^{256}Md can best be produced for chemical study by the ^{253}Es(α,n) or ^{254}Es(α,2n) reactions at cyclotrons or linear accelerators. The isotope ^{254}Es would be the target material of choice if available. It has a half-life of 276 days compared to only 20.5 days for ^{253}Es and thus it would have a longer usable target lifetime.

The discovery experiments on mendelevium were the first in which the recoil momentum imparted by the bombarding ion to a product atom during its formation was used to carry out an instantaneous physical separation of the product atom from the target material (Seaborg, 1963). The recoil atoms were collected on a thin metal foil placed behind the target in an evacuated reaction chamber. This eliminated the time needed to separate the product atoms from the target atoms, previously accomplished by chemical means, and made it possible to use the same valuable target in repeated bombardments. A few years later, it was found that the recoil atoms could be slowed down and stopped in a gaseous atmosphere, frequently helium. The gas could be pumped out of the reaction chamber through a small orifice to form a 'gas-jet.' If this jet was impinged onto the surface of a foil, some fraction (frequently 75% or more) of the nonvolatile product atoms carried along with the gas were deposited permanently on the foil surface (Ghiorso, 1959; Macfarlane and Griffioen, 1963). The foil could be removed periodically for processing and a new foil installed. A good description of this system has been giving by Hoffman (1994).

After removal of the Md atoms from the collector foil by acid etching or following total dissolution of the thin metal foil, they can be purified and isolated from other product activities by several other techniques.

Md can be separated from the dissolved 'catcher' foil material, e.g. Be, Al, Pt, or Au, and most fission-product activities by coprecipitation with lanthanum fluoride. Subsequent separation of trivalent actinides from lanthanide fission products and La carrier can be accomplished with a cation-exchange resin column using a 90% water/10% ethanol solution saturated with HCl as eluant (Thompson *et al.*, 1954). When a very thin gold foil is used as the 'catcher' foil, after dissolution with aqua regia, a rapid separation of the Md from the Au can be made by anion-exchange chromatography using 6 M HCl as eluant. The gold remains on the column while the Md and other actinides pass through.

Final isolation of Md^{3+} from other trivalent actinides can be accomplished by selective elution from a cation-exchange resin column using ammonium α-HIB (Choppin *et al.*, 1956). When using the gas-jet system, the first two steps can frequently be eliminated.

In more recent years, it was found that, using the 'gas-jet' method, the recoil product atoms could be transported many meters with the stopping gas through a long capillary tube to the chemistry/counting area (Macfarlane and McHarris, 1974). In this case, effective transport over long distances requires the presence of large clusters, frequently KCl aerosols, in the 'carrier' gas. By this method, it is possible to transport and collect individual product atoms in a fraction of a second some tens of meters away from the target area. This method is quite generally used nowadays in the production and isolation of transeinsteinium elements.

A good separation of Md and Fm has been performed on a spheroidal cation-exchanger OSTIN using ammonium α-hydroxy-α-methylbutyrate (Vobecký *et al.*, 1991). The isotope ^{256}Md is most easily detected through the measurement of the spontaneous fission activity of its daughter ^{256}Fm; however, in the presence of other fissioning nuclides, the detection of alpha particles of the characteristic energy of ^{256}Md associated with the 10% alpha decay branch can be used for identification.

Intragroup separation of the 3+ actinides has also been achieved by solvent extraction chromatography using HDEHP as the stationary organic phase and HNO_3 as the mobile aqueous phase (Horwitz and Bloomquist, 1969). Here, the actinide elution sequence is reversed from that of the cation-exchange resin column. This method gives a somewhat better final separation of Md from Fm than the cation-exchange resin column. It has the advantage that the final solution containing the Md is free of organic complexing agents compared to the resin column but has the disadvantage that Md elutes after Fm late in the sequence.

Following the discovery that Md can form a divalent state, extraction chromatography using HDEHP was used to show that the elution behavior of Md^{2+} is dissimilar to that of Es^{3+} and Fm^{3+} (Hulet *et al.*, 1967). This became the basis for a rapid separation method for the isolation of Md (Hulet *et al.*, 1979; Lundqvist *et al.*, 1981). After the initial steps of dissolution from the 'catcher' foil and coprecipitation with terbium fluoride, the mendelevium and 50 mg of Cr (added as a holding reductant) in 0.1 M HCl are co-reduced with Zn(Hg). The solution is passed through a solvent extraction column containing HDEHP on an inert support as the stationary organic phase. The actinides in the trivalent and tetravalent states as well as the trivalent lanthanides are extracted by the HDEHP and are retained on the column while the divalent Md is not appreciably extracted and appears in the 0.1 M HCl washes of the column. After reoxidation of the Md and Cr to the trivalent states with H_2O_2, the residual impurities, including the Cr, are separated from the Md by selective elution with 2 M (to remove the impurities) and 6 M HCl (to remove the Md) from a small column of Dowex 50 × 12 colloidal resin. Guseva *et al.* (1988) have reported a similar method for isolating Md where, using one column with cationite and zinc amalgam and a solution of 1 M HCl as the eluant, Md is reduced and washes through the column with the alkaline earth elements.

Volatile hexafluoroacetylacetonates of Md and Fm have been prepared and could be the bases for chemical isolation by thermochromatography (Fedoseev *et al.*, 1990).

13.3.4 Atomic properties

The electronic structure of the ground state of gaseous mendelevium atoms has been predicted to be the $^2F_{7/2}$ level of the $5f^{13}7s^2$ configuration (Martin *et al.*, 1974). An experimental confirmation has not yet been made. No experimental measurements of inner-shell binding energies or X-ray energies have been reported but estimated values have been reported by Firestone *et al.* (1996)

Table 13.4 *Estimated electron binding and X-ray energies for mendelevium, nobelium, and lawrencium.*

based on the values recommended by Porter and Freedman (1978). The results are given in Table 13.4.

13.3.5 The metallic state

While mendelevium metal has not been prepared, Johansson and Rosengren (1975) predicted that, for the same reasons as discussed above for Fm, Md would prefer a divalent metallic state similar to Eu and Yb rather than a trivalent one.

As was the case with Fm, thermochromatographic studies conducted with trace amounts of Md by Zvara *et al.* (1976), Hübener (1980), and Hübener and Zvara (1982) led to the conclusion that Md forms a divalent metal. If the enthalpies of sublimation determined for Es and Fm from alloys are accepted, then, using the measured enthalpies of adsorption and the established correlation between the sublimation and adsorption enthalpies, Haire and Gibson (1990) estimated that Md has an enthalpy of sublimation in the range of

134–142 kJ mol^{-1}. Using empirical correlation methods, David *et al.* (1978) have estimated a divalent metallic radius of (0.194 ± 0.010) nm.

13.3.6 Solution chemistry

Before mendelevium was discovered, the trivalent state was predicted to be the most stable in aqueous solution and, therefore, it was expected to exhibit a chemical behavior similar to the other 3+ actinides and lanthanides (Seaborg and Katz, 1954). The elution of Md just before Fm in the elution sequence of trivalent actinides from a cation-exchange resin column observed in the discovery experiments appeared to confirm this prediction. Later, Md was indeed found to form insoluble hydroxides and fluorides that are quantitatively coprecipitated with trivalent lanthanides (Hulet *et al.*, 1967). Both the cation-exchange resin column (Choppin *et al.*, 1956) and HDEHP solvent extraction column (Horwitz and Bloomquist, 1969) elution data are consistent with a trivalent state for Md and an ionic radius slightly smaller than Fm.

Using empirical correlations, David *et al.* (1978) have estimated an ionic radius of 0.0912 nm (coordination number (CN) 6) for Md^{3+}. In addition to the ionic radius, a number of enthalpies and entropies of formation and sublimation were also estimated for Md. Hoffman *et al.* (1988) and Brüchle *et al.* (1988) compared the distribution coefficients for Lr, Md, and Fm with those of Tm, Er, and Ho obtained from ammonium α-HIB elutions from cation-exchange resin columns. Using the known ionic radii for the trivalent rare earths and the linear correlation of log distribution coefficient with ionic radius (for the same coordination number), an average ionic radius of 0.0896 nm was estimated for Md^{3+} and a heat of hydration of −(3654 ± 12) kJ mol^{-1} calculated using empirical models and the Born–Haber cycle.

Gorski *et al.* (1990) have studied the extraction behavior of Md with trioctylphosphine oxide in the presence of complexing agents and compared it to other transplutonium elements. They have also investigated the complex formation of several transplutonium elements, including Md, with DCTA and shown the correlation of ionic radii with the values of the log of the complex stability constants. The observed deviation from linearity by the heavy actinides is discussed in Section 13.2.5.

Hulet *et al.* (1967) first observed an anomalous chemical behavior for Md in certain chemical systems involving reducing conditions. With 10^5 to 10^6 atoms per experiment, coprecipitation with $\mathrm{BaSO_4}$ and solvent extraction chromatography experiments using HDEHP were carried out in the presence of a number of different reducing agents. These experiments showed that Md^{3+} could be easily reduced to a stable Md^{2+} in aqueous solution. An estimate was made for the standard potential of the half-reaction $E^\circ(\mathrm{Md}^{3+} \rightarrow \mathrm{Md}^{2+})$ of approximately −0.2 V. Maly and Cunningham (1967) also produced the divalent state of Md and, from experiments similar to Hulet *et al.*, estimated $E^\circ(\mathrm{Md}^{3+} \rightarrow \mathrm{Md}^{2+})$ at −0.1 V. David (1986a) estimated $E^\circ(\mathrm{Md}^{3+} \rightarrow \mathrm{Md}^{0})$ to be −1.74 V. David *et al.* (1981, 1990a) measured $-(1.51 \pm 0.01)$ V for the polarographic $E_{1/2}$ of the couple $Md^{2+} \rightarrow Md^0$ which (with correction for amalgamation potential of 1.0 V) yields an estimated $E°(Md^{2+} \rightarrow Md^0) = -2.5$ V (SHE). These values (Table 13.8) are consistent with those in Chapter 19 (Fig. 19.9).

Guseva *et al.* (1988) compared the elution behavior of Md^{2+} with Sr^{2+} and Eu^{2+} from a cationite and zinc amalgam ion-exchange column using 1 M HCl. On the basis of the elution peak position of Md relative to the Sr and Eu and the known ionic radii of the latter two elements, a value for the ionic radius of Md^{2+} was estimated to be 0.115 nm. Using this value for the radius, the enthalpy of hydration of Md^{2+} was calculated to be -1413 kJ mol^{-1}.

In 1973, Mikheev *et al.* reported that a stable monovalent Md ion could be produced in neutral water–ethanol solutions and that it cocrystallized with CsCl (Mikheev *et al.*, 1973). However, studies of the overall reduction of Md^{3+} to Md^0 (Hg) using controlled potential radiocoulometry (Samhoun *et al.*, 1979) and radiopolarography (David *et al.*, 1981) led to the conclusion that Md could not be considered as a cesium-like element and no evidence was obtained consistent with the formation of a monovalent state. Electrode reduction proceeded in two steps, $3+ \rightarrow 2+$ and $2+ \rightarrow 0$. Hulet *et al.* (1979) repeated some of the cocrystallization experiments of Mikheev and performed a series of new experiments in an attempt to prepare Md^+ by reduction with Sm^{2+} in ethanol solutions and also in fused KCl. In these experiments, the coprecipitation behavior of Md was compared to tracer quantities of Es, Fm, Eu, Sr, Y, and Cs. Md consistently followed the behavior of Fm^{2+}, Eu^{2+}, and Sr^{2+} rather than Cs^+. They concluded that Md could not be reduced to a monovalent state with Sm^{2+} as claimed by Mikheev. However, on the basis of the results of further thermodynamic studies of the cocrystallization process of mendelevium with chlorides of alkali metals, the Russian investigators maintain that Md can be reduced to the monovalent state in water–ethanol solutions and that the cocrystallization of Md^+ with salts of divalent ions can be explained as being due to the formation of mixed crystals (Mikheev *et al.*, 1980, 1981a; Spitsyn *et al.*, 1982). An ionic radius of 0.117 nm was calculated for Md^+ from the results of the cocrystallization studies (Mikheev *et al.*, 1981b, 1982).

Unsuccessful attempts have been made to oxidize Md^{3+} to Md^{4+} using the strong oxidant sodium bismuthate (Hulet *et al.*, 1967). Thus, Md^{3+} is not readily oxidized as would be expected from the value of +5.4 V predicted by Nugent (1975) for the $E°(Md^{4+} \rightarrow Md^{3+})$ couple.

13.4 NOBELIUM

13.4.1 Introduction

The discovery of element 102 was first reported in 1957 by an international research team working at the Nobel Institute in Stockholm, Sweden (Fields *et al.*, 1957). During the bombardment of a ^{244}Cm target with ^{13}C ions from the

Nobel Institute cyclotron, an 8.5 MeV alpha particle activity was produced which decayed with a half-life of approximately 10 min. The alpha activity eluted just before Es and Fm from a cation-exchange resin column using ammonium α-HIB as eluant and also appeared in the trivalent actinide fraction along with Cf and Fm, also produced in the irradiations, from a cation-exchange resin column using 6 M HCl as eluant. This behavior was taken as chemical evidence for the production of an isotope of element 102. From half-life systematics and reaction energetics, an isotope with a mass number of 253 or 255 was thought to have been produced. The name, nobelium, was proposed in honor of Alfred Nobel, in recognition of his support of the natural sciences, and in honor of the Nobel Institute where the experiments were conducted.

During the following 10 years, researchers at both the Lawrence Berkeley National Laboratory and the Dubna Research Center, Russia, attempted to repeat the Nobel Institute experiments, but were unsuccessful. However, the Berkeley group did succeed in identifying an alpha-emitting isotope of element 102 in 1958 using a newly developed method called the ‘double recoil technique’ (Ghiorso *et al.*, 1958) and assigned a mass of 254. Where the same isotopes have been studied, the Dubna and Berkeley groups are in substantial agreement (Ghiorso and Sikkeland, 1967). The results of the efforts of both groups exclude the likelihood of any isotope of element 102 having a half-life of 10 min with the emission of 8.5 MeV alpha particles. Further, chemical studies by Maly *et al.* (1968) showed that, because of its divalency in aqueous solutions, element 102 could not have exhibited the trivalent cation-exchange column elution behavior attributed to the 10 min activity. On the basis of their 1958 and later work, the Berkeley group claimed discovery of element 102 and, because of the wide use of the name over many years, suggested that nobelium be retained as the name of element 102 (Ghiorso and Sikkeland, 1967).

Because No is normally a divalent ion in aqueous solution and is difficult to oxidize and hold in the trivalent state, it has not been possible to make a chemical identification of the atomic number in the same manner as the preceding 3+ actinides, i.e. identification by their unique positions in the elution sequence from a cation-exchange resin column. However, in 1971, the atomic number of ^{255}No was unequivocally determined through the observance of characteristic K-series X-rays from the daughter isotope ^{251}Fm in coincidence with the alpha particles from the decay of the parent, ^{255}No (Dittner *et al.*, 1971).

13.4.2 Isotopes of nobelium

The known isotopes of nobelium range from mass 250 through 262, with the exception of 261 (Table 13.5) . The isotope ^{259}No is the longest-lived with a half-life of 58 min. However, the isotope ^{255}No has a considerably higher production rate and is most often used for chemical studies.

Table 13.5 *Nuclear properties of nobelium isotopes.*

Mass number	*Half-life*	*Mode of decay*	*Main radiations* (MeV)	*Method of production*
250	0.25 ms	SF		^{233}U(^{22}Ne,5n)
251	0.8 s	α	α 8.68 (20%) 8.60 (80%)	^{244}Cm(^{12}C,5n)
252	2.27 s	α 73% SF 27%	α 8.415 (~ 75%) 8.372 (~ 25%)	^{244}Cm(^{12}C,4n) ^{239}Pu(^{18}O,5n)

262	5 ms	SF		^{262}Lr daughter

13.4.3 Preparation and purification

The isotope ^{255}No can be produced for chemical study via the ^{249}Cf (^{12}C,α2n) reaction; about 1200 atoms were produced in a 10 min irradiation of a 350 μg cm^{-2} target of ^{249}Cf with 3 × 10^{12} particles per second of 73 MeV ^{12}C ions (Dittner *et al.*, 1971).

As with Md, the physical separation of the nobelium atoms from the target material can be made using the recoil-atom catcher foil technique. It is preferable to combine this with the 'gas-jet' technique since the product atoms can be deposited on the 'catcher' foil in a chemistry area separate from the bombardment area. The nearly monolayer of collected atoms can then be easily rinsed off the surface of the foil with dilute acid without dissolution of the foil. Isolation of the No from other actinides produced in the bombardment and from any target material transferred to the foil can be readily made using schemes based on the separation of divalent ions from trivalent ones, e.g. selective elution by solvent extraction chromatography using HDEHP as the stationary organic phase and 0.05 M HCl as the mobile aqueous phase (Silva *et al.*, 1969). Under these conditions, No passes through the column in the first few column volumes while the trivalent actinides are strongly adsorbed on the column. Selective elution from a cation-exchange resin column, e.g. Dowex 50 × 4, can also be made using 3 M HCl as eluant. Here, No again elutes in a few column volumes and the trivalent actinides remain on the column (Silva *et al.*, 1973). When using a direct 'catcher' foil, e.g. gold, a more elaborate scheme involving separation of the gold by anion-exchange chromatography is necessary (David *et al.*, 1990b). This can be followed by selective isolation of the No from contaminants by elution from a chromatographic extraction column using HDEHP.

13.4.4 Atomic properties

The electronic ground state of gaseous nobelium atoms has been predicted to be the $^1S_0$ level of the $5f^{14}7s^2$ configuration (Martin *et al.*, 1974). No experimental information is available. No experimental measurements of inner-shell binding energies have been reported but estimated values have been published by Firestone *et al.* (1996), along with X-ray energies, based on the values recommended by Porter and Freedman (1978). The results are given in Table 13.4.

The characteristic K-series X-rays of ^{253}No emitted following the alpha decay of ^{257}Rf have been measured in alpha/X-ray coincidence experiments by Bemis *et al.* (1973). Values for $K_{\alpha 2}$ and $K_{\alpha 1}$ were reported as (120.9 ± 0.3) and (127.2 ± 0.3) keV, respectively.

13.4.5 The metallic state

Nobelium metal has not been prepared; however Johansson and Rosengren (1975) predicted that, for the same reasons as discussed above for Fm, No would prefer a divalent metallic state similar to Eu and Yb rather than a trivalent one. An estimate of 126 kJ mol^{-1} for the enthalpy of sublimation of No has been reported (David, 1986a). This value is similar to that of Es, Fm, and Md and supports the suggestion that No would form a divalent metal (Haire and Gibson, 1990). David (1986a) estimated a divalent metallic radius of 0.197 nm.

13.4.6 Solution chemistry

Before discovery, nobelium was expected to be a trivalent ion in aqueous solution and to exhibit a chemical behavior similar to the elements preceding it in the actinides series. However, in 1949, Seaborg (1949) predicted that a relatively stable 2+ state might exist for element 102 due to the special stability of the filled $5f^{14}$ shell in the $5f^{14}7s^2$ electronic configuration. Twenty years later, this prediction was confirmed.

In over 600 experiments, Maly *et al.* (1968) subjected about 50000 atoms of ^{255}No to cation-exchange chromatography and coprecipitation experiments. These tracer experiments showed that nobelium exhibits a chemical behavior substantially different from the trivalent actinides but similar to the divalent alkaline earth elements, Sr, Ba, and Ra. Thus, the divalent ion of nobelium was shown to be the most stable species in aqueous solution in the absence of strong oxidizing agents.

Chuburkov *et al.* (1967) have compared the behavior of nobelium to those of Tb, Cf, and Fm during experiments where the atoms were first chlorinated and subsequently were carried by gas along a tube with a thermal gradient. From the position of deposition of atoms along the tube, they concluded that the chloride of No undergoes strong adsorption on solid surfaces and therefore is not very volatile; its volatility is close to the chlorides of Tb, Cf, and Fm. The chloride of either divalent or trivalent nobelium would be expected to exhibit a low volatility.

Silva *et al.* (1974) have conducted solvent extraction and cation-exchange chromatography studies of nobelium. Its complexing ability with chloride ions were compared with that of divalent mercury, cadmium, copper, cobalt, and barium in a tri-*n*-octylamine chloride/HCl liquid extraction system, and it was found to be most similar to the relatively weakly complexed alkaline earth element. The elution behavior of nobelium was also compared with that of Be, Mg, Ca, Sr, Ba, and Ra in a cation-exchange resin column/4 M HCl system and found to elute with Ca^{2+}. Further, comparison with these alkaline earth elements in an HDEHP/HCl liquid chromatography system showed nobelium to elute between Ca^{2+} and Sr^{2+}. The ionic radius of No^{2+} was estimated as 0.11 nm from a linear correlation of ionic radius with log distribution coefficient for several divalent ions obtained using an HDEHP/HNO_3 liquid–liquid extraction system. Using a similar correlation, a value of 0.10 nm was obtained from the cation-exchange chromatography data. From the results of relativistic Hartree–Foch–Slater calculations (Lu *et al.*, 1971), a value of 0.11 nm was suggested for the ionic radius of No^{2+}. The single-ion heat of hydration, calculated using an empirical form of the Born equation (Phillips and Williams, 1966) was 1486 kJ mol^{-1}. From correlations of ionic radii of actinides and lanthanides with atomic number, an ionic radius for No^{3+} of 0.90 and 1.02 Å for CNs 6 and 8, respectively, have been estimated. (David *et al.*, 1978; David, 1986b).

The formation of divalent nobelium complexes with citrate, oxalate, and acetate ions in aqueous solution of 0.5 M NH_4NO_3 have been studied by McDowell *et al.* (1976) using solvent extraction techniques. In general, the complexing tendency of nobelium with these ligands is between that of Ca and Sr, being somewhat more like Sr.

Silva *et al.* (1969) have studied the reduction potential of the No(III)–No(II) couple in aqueous solution with 50–100 atoms per experiment using HDEHP extraction column chromatography to distinguish between No^{2+} and No^{3+}. By comparing the extraction of nobelium from dilute acid solutions containing oxidants of differing potentials with the extraction behavior of tracer quantities of Cf, Cm, Ra, Tl, and Ce, the standard potential $E^\circ(No^{3+} \rightarrow No^{2+})$ was estimated to be between +1.4 and +1.5 V.

Meyer *et al.* (1976) used a modified radiopolarographic technique and ^{255}No to measure the half-wave potential for the reduction of nobelium at a mercury electrode and reported a value for $E^\circ(No^{2+} \rightarrow No^0(Hg))$ of −1.6 V. After applying an estimated amalgamation potential correction, a value of -2.6 V was calculated for the standard potential of the $\mathrm{No}^{2+} \rightarrow \mathrm{No}^0$ couple. More recently David *et al.* (1990b) have measured amalgamation potentials of nobelium using radiocoulometry with the isotope ^{259}No. From the data, they estimated the $\mathrm{No}^{2+} \rightarrow \mathrm{No}^0$ couple standard potential as $-(2.49 \pm 0.06)$ V. This couple, combined with the measured $3+ \rightarrow 2+$ potential of 1.45 V (Silva *et al.*, 1969) resulted in an estimated value for E° ($\mathrm{No}^{3+} \rightarrow \mathrm{No}^0$) of -1.18 V by David *et al.* (1990b). David (1986a, 1986b) estimated E° ($\mathrm{No}^{3+} \rightarrow \mathrm{No}^0$) to be -1.26 V, which leads to a calculated E° ($\mathrm{No}^{2+} \rightarrow \mathrm{No}^0$) $= -2.61$ V; these values were selected for Table 13.8 and Fig. 19.9 because of the consistent systematics (David, 1986a, 1986b) among many actinide species. David *et al.* (1990b) also estimated Gibbs energies of formation of -480 and -342 kJ mol^{-1} for No^{2+} (aq) and No^{3+} (aq), respectively. From a semiempirical technique for the linearization of actinide and lanthanide electrode potentials, Nugent (1975) has calculated a value of $+6.5$ V for $E^\circ(\mathrm{No}^{4+} \rightarrow \mathrm{No}^{3+})$.

13.5 LAWRENCIUM

13.5.1 Introduction

In 1961, Ghiorso, Sikkeland, Larsh, and Latimer of the Lawrence Berkeley National Laboratory reported the discovery of element 103 (Ghiorso *et al.*, 1961). An alpha particle activity of 8.5 MeV energy with a half-life of 8 s was produced in bombardments of a Cf target with both ^{10}B and ^{11}B ions. Owing to the short half-life, a chemical identification was not possible but the alpha activity was attributed to an isotope of element 103 on the basis of convincing nuclear evidence, i.e. the results of cross-bombardments with other targets and projectiles. However, because the target consisted of a mixture of californium isotopes, masses 249 through 252, an unambiguous mass assignment was not possible. Though isotopes of masses 255–259 could have been produced, based on cross-section considerations, the highest yield was expected for mass 257. The discoverers suggested the name lawrencium, symbol Lw, for the new element in honor of E. O. Lawrence, inventor of the cyclotron and founder of the Lawrence Berkeley National Laboratory. The name was accepted by IUPAC, but the symbol was changed to Lr.

The results of subsequent studies on the production and identification of ^{255}Lr, ^{256}Lr, and ^{257}Lr by researchers at the Joint Institute for Nuclear Research (JINR) at Dubna, Russia, appeared to conflict with the Berkeley mass assignment because none of the above isotopes had the decay properties of the original Berkeley alpha activity (Druin, 1971). However, in 1971, six alpha particle emitting isotopes of lawrencium, masses 255–260, were identified at Berkeley in bombardments of nearly isotopically pure targets of ^{248}Cm with ^{14}N and ^{15}N and ^{249}Cf with ^{10}B and ^{11}B ions, respectively, and an explanation for the discrepancy was suggested (Eskola *et al.*, 1971). From the Berkeley experiments, ^{257}Lr was found to emit alpha particles of 8.8 MeV with a half-life of only 0.6, but ^{258}Lr was found to have a half-life of 4.2 s with the emission of 8.62 MeV alpha particles. Thus, Ghiorso and associates considered that the mass assignment made in 1961 should have been 258. The difference in the new half-life value compared to the 1961 value was attributed to relatively poor counting statistics resulting from the small number of alpha particle events observed in the earlier work.

13.5.2 Isotopes of lawrencium

Twelve isotopes of lawrencium are known with masses ranging from 252 through 262 (Table 13.6). The longest-lived isotope is ^{262}Lr, with a half-life of 3.6 h. The isotope ^{256}Lr, half-life of 26 s, was used in the early chemical studies; however, the longer-lived isotope ^{260}Lr ($t_{1/2} = 3$ min) has been used in more recent experiments.

13.5.3 Preparation and purification

The production of ^{256}Lr is best accomplished through the ^{249}Cf(^{11}B,4n) reaction using 70 MeV boron ions while ^{260}Lr is produced via the ^{249}Bk(^{18}O, α3n) reaction using 117 MeV oxygen ions.

As with Md and No, the physical separation of the Lr atoms from the target material and subsequent rapid collection is best accomplished using a recoil-atom gas-jet system coupled to a capillary transport system of some type (Hoffman *et al.*, 1988).

Because of their short half-lives, there is insufficient time to obtain a rigorous chemical purification of ^{256}Lr or ^{260}Lr. The isotope, ^{256}Lr was first isolated from

Table 13.6 *Nuclear properties of lawrencium isotopes.*

Mass number	*Half-life*	*Mode of decay*	*Main radiations* (MeV)	*Method of production*
252	0.36 s	α	α 9.018 (75%)	^{256}Db daughter
253 m	1.5 s	α	α 8.722	^{257}Db daughter

reaction products by a rapid solvent extraction technique using the chelating agent thenoyltrifluoroacetone (TTA) dissolved in methyl isobutyl ketone (MIBK) as the organic phase and buffered acetate solutions as the aqueous phase (Silva *et al.*, 1970). This method did not separate individual trivalent actinides so identification of Lr was made on the basis of its unique alpha particle energy of 8.24 MeV.

When the capillary transport system is used, the longer-lived isotope, ^{260}Lr, can be washed from the 'catcher' foil along with the small amount of aerosol carrier particles with 0.05 M HCl. Kept to a few drops of volume, this solution can be placed on the top of a cation-exchange resin column and isolation of Lr^{3+} from other trivalent actinides can be accomplished by selective elution with ammonium α-HIB (Hoffman *et al.*, 1988). An automated system called Automated Rapid Chemistry Apparatus (ARCA) has been developed and used to carry out this separation (Brüchle *et al.*, 1988).

13.5.4 Atomic properties

The electronic structure of the ground state of neutral atoms of Lr was predicted in 1970 as the $^2D_{3/2}$ level of the $5f^{14}6d^{1}7s^{2}$ configuration (Moeller, 1970) similar to the rare earth homolog Lu, $4f^{14}5d^{1}6s^{2}$, as one would expect from a simple extrapolation from the chemical periodic table. This prediction was brought into question in 1971 by Brewer who calculated, by a semiempirical method, a configuration of $5f^{14}7s7p^{1}$ (Brewer, 1971). Later the results of relativistic Dirac–Hartree–Fock calculations by Nugent *et al.* (1974) concluded that the energy difference between these two configurations was quite small and either configuration could be the ground state. On the basis of the results of multiconfiguration Dirac–Fock calculations, Desclaux and Fricke (1980) predicted the $5f^{14}7s^{2}7p^{1}$ configuration as the ground state. Later, multiconfiguration Dirac–Hartree–Fock calculations by Wijesundera *et al.* (1995) and relativistic Fock-space coupled-cluster method by Eliav *et al.* (1995) led to a similar conclusion, i.e. the s^2p $J = 1/2$ is energetically favored over the s^2d $J = 3/2$ state. This result is due to the relativistic mass increase of the electrons that are strongly accelerated near the highly charged nucleus. This effect is strongest for the spherical s and $p_{1/2}$ orbitals that have high densities near the nucleus.

In 1988, Eichler and coworkers proposed gas adsorption chromatography experiments to distinguish between the two ground state configurations s^2d and s^2p. They calculated that there should be a measurable difference in the enthalpies of adsorption on metal surfaces for the two different configurations (Eichler *et al.*, 1988). The s^2p was predicted to be less volatile, perhaps similar to the p-element Pb, than the s^2d configuration with estimated sublimation energies of about 134 and 400 kJ mol^{-1}, respectively. Online gas chromatography was applied to study the volatility of Lr by Jost *et al.* (1988) and to determine the enthalpy of adsorption. No evidence for Lr as a volatile element was found under reducing conditions at a temperature of about 1000°C. Their

Table 13.7 *Comparison of calculated and measured L-series X-rays for Lr.*

	X-ray energy (keV)	
Transition	*Calculated*[a]	*Measured*[b]
$L_{\gamma 1}$ ($4d_{3/2} \rightarrow 2p_{1/2}$)	27.91	27.97 (15)[c]
$L_{\beta 1}$ ($3d_{3/2} \rightarrow 2p_{1/2}$)	23.93	24.03 (14)

[a] Firestone *et al.* (1996).
[b] Bemis *et al.* (1977).
[c] Error in last two digits.

results gave a lower limit for the adsorption enthalpy for Lr on quartz and Pt surfaces at 290 kJ mol^{-1}, significantly higher than the estimated values for Lr (s^2p). The configuration of the ground state of lawrencium is still in doubt.

No experimental measurements of inner-shell binding energies have been reported but estimated values have been published by Firestone *et al.* (1996), along with X-ray energies, based on the values recommended by Porter and Freedman (1978). The results are given in Table 13.4.

The characteristic L-series X-rays of ^{256}Lr have been observed in coincidence with alpha particles of the parent ^{260}Db by Bemis *et al.* (1977). The results are presented in Table 13.7. They agree very well with those given by Firestone *et al.* (1996).

13.5.5 Metallic state

Lawrencium metal has not been prepared. An estimate of 352 kJ mol^{-1} for the enthalpy of sublimation of Lr has been reported (David *et al.*, 1978). This value is similar to that of Lu and supports the suggestion that Lr would prefer the formation of a trivalent metal as expected for the last member of the actinide series. Systematic properties of heats of vaporization, bulk modulus, and atomic volumes suggest that Lr would be a trivalent metal with a volume similar to that of Lu (Haire and Gibson, 1990). David *et al.* (1978) estimated a trivalent metallic radius of 0.171 nm.

13.5.6 Solution chemistry

In 1949, element 103 was predicted by Seaborg (1949) to be the last member of the proposed actinide or 5f series of elements and to be similar to lutetium with respect to the stability of the 3+ oxidation state in aqueous solution. It required nearly 20 years to finally synthesize this element and to conduct chemical experiments to confirm this prediction.

Silva *et al.* (1970) employed a fast solvent extraction procedure using MIBK containing the chelating agent TTA as the organic phase and buffered acetate solutions of differing pH as the aqueous phase to distinguish between the 2+, 3+, and 4+ oxidation states. In over 200 separate experiments, approximately 1500 atoms of ^{256}Lr were produced for study and the extraction behavior of Lr was compared with a number of tetravalent (Th, Pu), trivalent (Fm, Cf, Cm, Am, Ac), and divalent ions (No, Ba, Ra). In these experiments, lawrencium was found to extract into the organic phase over the pH range of 3+ ions along with Fm and Cf. Thus, it was concluded that the 3+ oxidation state is the most stable oxidation state for Lr in aqueous solution. Unfortunately, because of the short half-life, there was insufficient time to perform a cation-exchange resin column separation to confirm its predicted elution position just ahead of Md^{3+}.

From studies comparing the retention times of chlorinated atoms of several different actinides and transactinides as they passed through a heated glass column, Chuburkov *et al.* (1969) concluded that the chloride of element 103 has an adsorbability on solid surfaces, and hence volatility, similar to the chlorides of Cm, Fm, and No and to be much less volatile than the chlorides of element 104, Rf.

Because Lr is a trivalent ion in aqueous solution, it should exhibit a chemical behavior similar to the other 3+ actinides and lanthanides, e.g. insoluble fluoride and hydroxide. One would expect Lr^{3+} to have a slightly smaller ionic radius than Md^{3+}, due to the actinide contraction, and to elute just before Md from a cation-exchange resin column using ammonium α-HIB as eluant (see Fig. 13.1). From correlations of ionic radius with atomic number for actinide and lanthanide elements, David *et al.* (1978) estimated an ionic radius of 0.0893 nm for Lr^{3+}.

By 1987, a longer-lived isotope of lawrencium, ^{260}Lr, with a half-life of 3 months and alpha particle energy of 8.03 MeV, was available for chemical studies. Hoffman *et al.* (1988) repeated the solvent extraction experiments of Silva *et al.* (1970) and confirmed the trivalent nature of Lr in aqueous solution. Further, elutions of Lr from a cation-exchange resin columns using ammonium α-HIB as eluant were conducted and compared with the elution behavior of Md and the rare earths Tm, Er, and Ho (Hoffman *et al.*, 1988). Lr was found to elute between Ho and Tm, and approximately with the Er tracer. Seven alpha events attributable to Lr^{260} were detected. The distribution coefficients were determined from the elution positions and, using the linear correlation of ionic radius with log distribution coefficient, an ionic radius was calculated for each Lr event. The average Lr^{3+} radius was found to be 0.0886 ± 0.0003 nm assuming an ionic radius of 0.0881 nm for Er for CN 6 (Templeton and Dauben, 1954). This result was surprising to the authors because it gave a difference of only 0.0015 nm for the step of 2 in atomic number between Md, with an ionic radius of 0.0896 nm, and Lr. This is substantially smaller than the 2Z difference of 0.0021 for the analogous trivalent rare earth ions Tm and Lu and indicates an ionic radius for Lr larger than expected. Therefore, Lr elutes later than predicted in Fig. 13.1.

In later experiments, a German–American collaboration (Brüchle *et al.*, 1988) used the ARCA (Automated Rapid Chemistry Apparatus) system to check the earlier results of Hoffman *et al.* (1988) and to increase the number of Lr atoms studies and thus the statistical significance. The earlier work was confirmed and a value of 0.0881 ± 0.0001 nm was obtained from the elution data for Lr. A heat of hydration of $-(3685 \pm 13)$ kJ mol^{-1} was calculated from the radius using empirical models and the Born–Haber cycle. Brüchle *et al.* (1988) pointed out that the difference between the radii of $\mathrm{Md^{3+}}$, $\mathrm{Fm^{3+}}$, and $\mathrm{Es^{3+}}$ is 0.0016 nm while this difference is 0.0012 nm for the analogous lanthanide ions. This suggests that the contraction at the end of the actinides series is larger than the analogous lanthanide contraction, perhaps due to relativistic effects (Seth *et al.*, 1994), with the exception of the last member of the actinide series, Lr.

It is possible that relativistic effects could stabilize the $7s^2$ closed shell so that only the $7p_{1/2}$ or 6d electron would be ionized under reducing conditions to give a monovalent Lr. Several attempts have been made to reduce $\mathrm{Lr^{3+}}$ to a divalent or monovalent ion in aqueous solution. Hoffman *et al.* (1988) used a solvent extraction column with HDEHP as the stationary organic phase and dilute HCl as the mobile aqueous phase to separate 1+ and 2+ ions from 3+ and 4+ ions, the former passing through the column while the latter remain fixed. Solutions containing $^{260}\mathrm{Lr^{3+}}$ were passed through the column where the Lr remained fixed. The reducing agent hydroxylamine hydrochloride was added to the HCl and the resulting solution passed through the column for 20 s at 80°C in an attempt to reduce and elute any Lr. The attempt was unsuccessful, however, as the authors noted, the kinetics of the reduction are slow. In companion experiments, Scherer *et al.* (1988) used the HDEHP solvent extraction column

Table 13.8 *Summary of chemical properties of elements* 100–103.

Element	100	101	102	103
electronic configuration[a]	$5f^{12}7s^2$	$5f^{13}7s^2$	$5f^{14}7s^2$	$5f^{14}6d^1(7p^1)7s^2$
stable oxidation states[b]	$\underline{3}$, 2	$\underline{3}$, 2	3, $\underline{2}$	$\underline{3}$
ionic radius of indicated ion (nm)	0.0911(3+)	0.0896(3+)	0.105(2+)	0.0886(3+)
standard electrode potentials (V)[c]				
3+ → 2+	−1.15	−0.15	+1.45	<−0.44
3+ → 0	−1.96	*−1.74*	*−1.26*	*−2.06*
2+ → 0	−2.37	*−2.5*	*−2.61*	
first ionization potential (V)[d]	6.50	6.58	6.65	

[a] Free neutral atom + Rn core.

[b] Most stable state in aqueous solution underlined.

[c] Values in italics are estimates.

[d] From Martin *et al.* (1974).

method, with the ARCA system, to attempt reductions of Lr to di- or monovalent ions (Scherer *et al.*, 1988). In a series of experiments using the reducing agents V^{2+} and Cr^{2+} in the dilute HCl-eluting solutions, there was no evidence for the reduction of Lr^{3+} to either the 2+ or 1+ oxidation state. From the results, a limit of <-0.44 V was estimated for the $Lr^{3+} \rightarrow Lr^{2+,\,1+}$ reduction potential. Using the newly discovered Lr^{262} ($t_{1/2} = 3.6$ h), Lougheed *et al.* (1988) attempted to reduce Lr with Sm^{2+}, $E°(Sm^{3+} \rightarrow Sm^{2+}) = -1.55$ V, and coprecipitate Lr^{1+} with Rb using sodium tetraphenylborate or chloroplatinic acid but were unsuccessful. The 2+ and 3+ actinide ions do not coprecipitate under these conditions. On the basis of 20 Lr events, they calculated an upper limit of -1.56 V for $E°(Lr^{3+} \rightarrow Lr^{1+})$ and concluded that it is unlikely that Lr^{1+} can exist in aqueous solutions. Nugent (1975) has calculated values of -2.06 V for $E°(Lr^{3+} \rightarrow Lr^{0})$ and $+7.9$ V for $E°(Lr^{4+} \rightarrow Lr^{3+})$.

A summary of some of the chemical properties of fermium, mendelevium, nobelium, and lawrencium is given in Table 13.8.

CHAPTER FOURTEEN

TRANSACTINIDE ELEMENTS AND FUTURE ELEMENTS

Darleane C. Hoffman, Diana M. Lee, and Valeria Pershina

14.1 INTRODUCTION

This chapter gives a brief summary of the reported discoveries, confirmation, and nuclear properties of the claimed and confirmed transactinide elements through the year 2004. However, the primary emphasis is on the chemical properties – experimental, theoretical, and predicted – of the transactinides and a comparison of measured properties with theoretical predictions. The experimental studies of chemical properties are especially challenging because of the low production rates and the short half-lives and the need for very special facilities and the use of atom-at-a-time chemistry. The discovery of a new element must furnish evidence that its atomic number is different from those of all the currently known elements and first claims to discovery often lacked such positive identification. As a result, there were uncertainties and controversies over priority of discovery, nuclear and chemical properties, and assignment of names. The first *positive identification* of the atomic number of all these elements was accomplished using 'physical' rather than chemical techniques.

The authors of this chapter have made a conscientious effort to present a balanced view of research on the properties of the transactinides. The chapter also includes predictions of the nuclear and chemical properties of the

SuperHeavy Elements (SHEs). The term originally referred to an 'island of nuclear stability' around the predicted closed spherical shells at 112 to 114 protons and 184 neutrons. Revisions due to recent experiments and theoretical calculations are discussed.

As of 1997, discoveries of the transactinide elements 104 through 109 had been recognized by the International Union of Pure and Applied Chemistry (IUPAC) and the International Union of Pure and Applied Physics (IUPAP). The names and symbols for these elements as finally approved by IUPAC in 1997 (CNIC, 1997) and the year of discovery are given in Table 14.1.

Claims to the discovery of element 110 were made by researchers at the Lawrence Berkeley National Laboratory (LBNL) (Ghiorso *et al.*, 1995a,b), by researchers at the Gesellschaft für Schwerionenforschung (GSI) in Darmstadt, Germany (Hofmann *et al.*, 1995a), and by a Dubna/Livermore group working at the Joint Institute for Nuclear Research (JINR) in Dubna, Russia (Lazarev *et al.*, 1996).

The published analysis of these claims by a Joint Working Party (JWP) of IUPAC/IUPAP (Karol *et al.*, 2001) gave credit for the synthesis of element 110 to the GSI group and invited them to propose a name. They proposed the name 'Darmstadtium' with the symbol Ds after the place in Germany where the element 110 discovery experiments were conducted. The IUPAC Commission on Nomenclature of Inorganic Chemistry (CNIC) considered the proposal and in March 2003 (Corish and Rosenblatt, 2003) recommended to the IUPAC Bureau that it be accepted. It was officially approved by the IUPAC Council at the 42nd General Assembly in Ottawa, Canada, on August 16, 2003.

The discovery of elements 111 and 112 was reported by the GSI group in 1995 (Hofmann *et al.*, 1995b, 1996) and confirmatory experiments were reported in 2002 (Hofmann *et al.*, 2002). In mid-2003 the JWP assigned credit for discovery of element 111 to the GSI group and asked them to propose a name (Corish and Rosenblatt, 2003; Karol *et al.*, 2003), but judged that the evidence for assigning

Table 14.1 *CNIC/IUPAC compromise recommendation for names of transactinide elements. Approved by IUPAC, August* 30, 1997, *Geneva, Switzerland.*

Element	*Name*	*Symbol*	*Discovery year*
104	Rutherfordium	Rf	1969
105	Dubnium (Hahnium)[a]	Db (Ha)[a]	1970
106	Seaborgium	Sg	1974
107	Bohrium	Bh	1981
108	Hassium	Hs	1984
109	Meitnerium	Mt	1982

[a] Many publications of chemical studies before 1997 use hahnium (Ha) for element 105.

credit for the discovery of element 112 was insufficient. The element 111 discovery team proposed the name 'Roentgenium' with symbol Rg after Wilhelm Conrad Roentgen, the discoverer of X-rays. A provisional recommendation for approval of the proposal was sent (Corish and Rosenblatt, 2004) to the IUPAC Bureau and Council and was approved in late 2004. A modern periodic table showing elements through $Z = 154$ is given in Fig. 14.1.

Evidence for elements 112 through 116 has been reported from 1999 to early 2004 by groups working at Dubna (Oganessian, 1999a–c, 2001, 2002; Lougheed *et al.*, 2000; Oganessian *et al.*, 2000a,b, 2002, 2004a–c). However, it should be emphasized that as yet there is no confirmation by other groups of the isotopes of these elements and their decay products. Nuclear properties of the transactinide elements including half-life, mode of decay, main radiations, and method of production based on reports published through early 2004 are given in Table 14.2 and in Appendix II. Nuclides for which only one decay chain has been reported are not listed. Charts of the isotopes of Lr (the last of the actinides) through 109 and for 110 through 116 are shown in Fig. 14.2(a) and (b).

The transactinide elements begin with element 104 (rutherfordium) and include all the elements beyond lawrencium, the element that ends the actinide series with the filling of the 5f electron shell. According to results of atomic relativistic calculations (Fricke, 1975), the filling of the 6d shell takes place in the

first nine of the transactinide elements (Z = 104 through 112). In elements 113 through 118 the 7p shell is being filled and element 118 is the heaviest member of the noble gas group. Filling of the 8s shell is expected to occur with elements 119 and 120, making them homologs of elements in groups 1 and 2. Accurate relativistic calculations (Eliav *et al.*, 1998a) show that element 121 will have an 8p electron in its ground state configuration in contrast to the 7d electron expected from simple extrapolation of the members of group 3 in the periodic table. A 7d electron will be added in element 122 to give it the [118] $8s^27d8p$ configuration (Eliav *et al.*, 2002), in contrast to thorium, which has the configuration $[Rn]7s^26d^2$.

No accurate calculations exist beyond element 122 (Eliav *et al.*, 1992), where the situation becomes more complicated because the energy spacings for the 7d, 6f, and 5g levels and later on for the 9s, $9p_{1/2}$, and $8p_{3/2}$ become so close that in the region of $Z = 160$ the usual classification on the basis of a simple electronic configuration may become invalid. Clear structures on the basis of pure p-, d-, f-, and g-blocks are no longer distinguishable. Chemical properties of the elements influenced by these mixed electronic shells will then be so different from anything currently known that classification on the basis of the known periodic table will be impossible.

In order to positively identify a new element and place it in its proper position in the periodic table, its atomic number (proton number) must be determined or deduced in some way. For transactinide elements it became necessary to develop new methods for positive identification of atomic number. One widely used technique is that of correlation of the unknown element's decay to a known daughter and/or granddaughter, which can be identified either chemically or by its decay characteristics. The method of $\alpha-\alpha$ correlations has been widely used for elements that decay by alpha emission to subsequent known α emitters. Another definitive method is measurement of the characteristic X-rays of the new element. This technique was used by Bemis *et al.* (1973, 1977) to confirm the discovery and reported properties of elements 104 and 105, but it requires considerably larger samples than the α–α correlation method. Although detection of spontaneous fission (SF) is a very sensitive technique, determination of the Z of the parent fissioning nuclide is extremely difficult and depends on some other indirect method such as excitation functions, half-life systematics, production in other reactions, or determination of the atomic number of *both primary fragments* from the same SF event in order to add them together to get the Z of the fissioning new element. Detection of only SF decay has led to many controversies concerning discoveries of the transactinide elements.

In 1974, IUPAC and IUPAP appointed an *ad hoc* committee of neutral experts, consisting of three members from the USA, three from the USSR, and three from other countries (including the chairman), to consider the claims of priority to discovery of elements 104 and 105 and attempt to get agreement between the research groups at Berkeley (USA) and Dubna (USSR). The committee was finally disbanded without finishing the report, but the American members eventually published their own in-depth report (Hyde *et al.*, 1987) that summarized the claims and counterclaims together with a critical assessment of both the physical and the chemical evidence relating to discovery of these elements during the period 1960–77. Reference tables with all the known information for each element, a comprehensive bibliography including internal laboratory reports from Dubna and Berkeley, and all articles published in refereed journals related to the first synthesis and identification of the isotopes of elements 104 and 105, and a summary and conclusions were presented. They concluded that the information published for element 104 (Ghiorso *et al.*, 1969) and element 105 (Ghiorso *et al.*, 1970, 1971) was correct and fully met the criteria for discovery of new elements stated by Harvey *et al.* (1976) and Flerov and Zvara (1971) and that priority for discovery of elements 104 and 105 clearly belonged to the Berkeley group and endorsed their proposal that they be named rutherfordium (Rf) and hahnium (Ha).

However, the combined IUPAC and IUPAP Transfermium Working Group (TWG) came to different conclusions in their reports (Barber *et al.*, 1991, 1992, 1993) on the final assignment of credit for discovery of elements 101 through 109. An immediate rebuttal to the initial assignments of credit for discovery (Barber *et al.*, 1991) of element 102 to Dubna, and assignment of shared credit to Berkeley/Dubna for elements 104 and 105, and to GSI/Dubna for element 107 was sent in 1991 in a message from Ghiorso and Seaborg to the chairman of the joint IUPAC/IUPAP TWG. A longer response is found in Ghiorso and Seaborg (1993a), as part of the responses invited from Berkeley, Dubna (Oganessian and Zvara, 1993), and GSI (Armbruster *et al.*, 1993). These were published immediately following the TWG report (Barber *et al.*, 1993). The response from Ghiorso and Seaborg (1993b) was also published in *Progress in Particle and Nuclear Physics* because IUPAP had given them no opportunity to respond to the companion 'discovery' article published there (Barber *et al.*, 1992). A long period of dissent ensued after the CNIC resolved that 'an element could not be named after a living person' and, therefore, the name seaborgium for element 106 already approved by the American Chemical Society could not be accepted. The names for elements 101 through 103 were accepted as mendelevium, nobelium, and lawrencium, but dubnium (Db), joliotium (Jl), rutherfordium (Rf), bohrium (Bh), hahnium (Ha), and meitnerium (Mt) were recommended for elements 104 through 109 by IUPAC/CNIC and approved by the IUPAC Bureau in September 1994. This resulted in protest and criticism from around the world as names that had been in common use were scrambled and the historical right of discoverers of a new element to name it was ignored. A long period of negotiation ensued and resulted in 1995 in the suggestion of still another 'compromise' set of names. This time nobelium (102) was replaced with the name flerovium (Fl), and dubnium, joliotium, seaborgium, nielsbohrium, hahnium, and meitnerium were suggested for elements 104 through 109. This slate did not meet with any more approval than the previous one and in an unprecedented step the IUPAC Bureau rescinded the previously approved names and solicited comments over a 5-month period. Finally, the CNIC/IUPAC compromise recommendation shown in Table 14.1 was approved by the IUPAC Bureau on August 30, 1997. The long negotiations and final compromise that resulted in the naming of elements 104 through 106 as rutherfordium, dubnium, and seaborgium, and elements 107 through 109 as bohrium, hassium, and meitnerium have been described in detail in the book *The Transuranium People* (Hoffman *et al.*, 2000a).

14.2 NUCLEAR PROPERTIES OF THE TRANSACTINIDE ELEMENTS

All known isotopes of the transactinides are radioactive. The longest known confirmed half-life for these elements ranges from 75 s for ^{261}Rf to only 42.7 ms for ^{268}Mt, the daughter of ^{272}111 (see Fig. 14.2). No transactinide elements have been found in nature although early predictions (Myers and Swiatecki, 1966; Meldner, 1967) that an ‘island of SHEs’ well beyond uranium might exist around elements with atomic numbers 114 or 126 raised the tantalizing possibility that very long-lived SHEs might still exist on Earth after having been formed during the last nucleosynthesis in our solar system some 5 billion years ago. Later theoretical studies based on new theories of nuclear structure (Strutinsky, 1966; Nilsson *et al.*, 1969a,b; Fiset and Nix, 1972; Randrup *et al.*, 1974) confirmed that an island of nuclear stability stabilized by spherical nuclear shells should be centered around 110 to 114 protons and 184 neutrons. Some calculations even indicated that element 110 with 184 neutrons (^{294}110) should be the longest-lived, with a half-life in the range of hundreds of thousands to a billion years. These predictions sparked a host of experimental investigations to try to detect SHEs in a wide variety of natural sources, but by 1987 no credible evidence for SHEs in nature remained (Hoffman *et al.*, 2000b).

14.3 ONE-ATOM-AT-A-TIME CHEMISTRY

14.3.1 Challenges

Special challenges are involved in studying the chemical properties of the transactinide elements because of their short half-lives, low production rates, the presence of many other unwanted activities, the necessity for producing them in accelerators with high-intensity beams, and the need to build special radiochemistry laboratory and detection facilities nearby. In addition, it is often necessary to prepare and use highly radioactive and rare targets, e.g. ^{248}Cm, ^{249}Bk, ^{249}Cf. Techniques have been developed for detection of a single atom at a time, usually by measuring its radioactive decay. Often the longest-lived known isotope of the element that is used for chemical studies is not the isotope first discovered. Knowledge of the nuclear decay properties and a measurement technique that positively shows that the detected decay arises from the element in question are required. The technique of α–α correlation to known daughter or granddaughter activities can provide such positive identification and has been widely used because many of the transactinide isotopes decay by alpha emission to known alpha-decaying daughter isotopes. Measurement of characteristic X-rays associated with the decay can also provide positive identification of atomic number, but the technique is difficult to apply when only a few atoms can be detected.

14.3.2 Production methods and facilities required

Chemical studies require use of an isotope with a half-life long enough to permit chemical separation and a reasonable production and detection rate, which for the transactinide elements may range from a few atoms per minute for Rf to only an atom per week in the case of Hs. In addition, the isotope must have unique decay characteristics so that it can be positively identified even on an atom-at-a-time basis in order to prove that it belongs to the element whose chemistry is being studied. The isotopes of elements Rf through Hs that were used in the first definitive chemical studies for each element, their production modes, approximate cross sections, and approximate detection rates for the initial experiments that had different overall efficiencies and transport times are listed in Table 14.3, together with those for Lr, the last of the actinides.

14.3.3 Chemical procedures

The chemical procedures used in atom-at-a-time studies must be fast enough to be accomplished in times comparable to the half-lives of the isotopes used in those studies and must give the same results for a few atoms as for macro

Table 14.3 *Isotopes used in first definitive chemical studies of Lr through Hs.*

Nuclide (*half-life*)	*Reaction*	*Cross section*	*Estimated rate*	*Year*

amounts. Chemical methods in which a single atom rapidly participates in many identical chemical interactions in two-phase systems with fast kinetics that reach equilibrium quickly have proven to be valid. Adloff and Guillaumont (1993) have given a thorough discussion of the validity of conclusions about chemical behavior obtained from very small numbers of atoms. An equilibrium constant was defined for such reactions in terms of the probabilities of finding the species in one phase or the other. Adloff and Guillaumont concluded that it is valid to combine the results of many separate one-atom-at-a-time experiments in order to get statistically significant results. Thus the results obtained from many identical experiments, each performed with only a single atom, can be added together to obtain statistically significant information about chemical behavior (Guillaumont *et al.*, 1989, 1991).

In early studies, activities recoiling from the target were deposited on a thin 'catcher' foil placed directly behind the target in the production chamber of the accelerator. The foil was then removed manually or remotely shuttled to a detection system without disturbing the accelerator vacuum, and its alpha and SF activity measured with appropriate radiation detectors. Alternatively, the collector foil was removed and chemically processed. In either case, the valuable target is not destroyed, and considerable decontamination from all of the activity remaining in the target itself is achieved. Later, gas transport systems using a variety of gases and aerosols were developed to rapidly and efficiently transport reaction products to collection sites outside the radiation field where chemistry can be carried out within a few seconds, either manually or with computer-controlled automated systems that have been developed for both aqueous- and gas-phase chemistry. Although the automated systems are not necessarily faster, they usually give more reproducible results and are more appropriate for carrying out the many repetitive, around the clock experiments lasting weeks at a time that are required to get statistically significant information. Several detailed reviews (Gäggeler, 1990; Hoffman, 1994; Wierczinski and Hoffman, 1996; Hoffman and Lee, 1999; Kratz, 1999a) of these methods have been given.

(a) Gas-phase chemistry

Both thermochromatographic and isothermal methods have been used to study gas-phase properties of the heaviest elements. These methods are particularly useful for short-lived isotopes because the lengthy process of evaporating liquid samples that is required in most aqueous chemistry experiments is avoided. Gas-phase chromatographic methods permit determination of the adsorption enthalpy, ΔH_{ads}, by using correlations between measured properties such as temperature of adsorption and ΔH_{ads}. The latter were shown to be linearly related to the sublimation enthalpy, ΔH_{sub} (Zvara *et al.*, 1970), which is used to compare the volatilities with lighter homologs.

Pioneering studies of the volatilities of the halides of elements 104 and 105 were carried out in the late 1960s and 1970s by Zvara *et al.* (1974, 1976) using thermochromatographic separations. In this method, a longitudinal, negative temperature gradient is established along a chromatographic column through which a gas stream is conducted. It contains the volatile species of interest that deposit on the surface of the column according to their volatilities. Later, the deposition zones are determined from fission tracks registered in detectors positioned along the column. These fissions are associated with specific deposition temperatures, which are then correlated with ΔH_{ads}. The advantage of this method is that production and separation of the detected species takes place very rapidly and species with half-lives as short as a few seconds can be measured. It also has some disadvantages. Positions of the deposition zones are determined only after the experiments are finished. This makes the interpretation of the results very difficult because it is necessary to correct for the half-lives of the various species involved before their volatilities can be compared. Furthermore, real-time observation of the nuclear decay and the determination of the half-lives of the detected species are not possible. Another difficulty is that if only SF activity is measured in the experiments, it is difficult to prove what the atomic number of the detected species actually was because only the fission fragments are detected (see discussion in Section 14.1).

Improved gas thermochromatographic systems have now been developed in which volatile species are transported through a thermochromatographic column (TC) where they are deposited directly on the surface of the pairs of opposing (Si) photodiode detectors that form the column. Both the radiations from the radioactive species and their deposition positions as a function of temperature along the column can be determined simultaneously and recorded. In this way, the isotope (and element) being studied can be positively identified and its deposition temperature at various positions along the TC (Si) (subjected to an appropriate negative temperature gradient) can be determined. Such a cryogenic on-line TC system was used (Düllmann *et al.*, 2002b) to perform the first successful chemical studies of element 108 (Hs) using the alpha-emitting isotopes ^{269,270}Hs and compare the behavior of Hs with Os, its lighter group 8 homolog. These investigations are described in detail in Section 14.6.4b.

Recent studies of gas-phase chemistry have utilized isothermal chromatographic systems such as the On-Line Gas Analyzer (OLGA) developed by Gäggeler (1994) and the Heavy Element Volatility Instrument (HEVI) developed by Kadkhodayan *et al.* (1996) and the alpha-emitting isotopes shown in Table 14.3 to compare the behavior of the halides and oxyhalides of elements 104 through 107 with those of their lighter homologs in groups 4 through 7 of the periodic table. In such systems the entire chromatographic column (usually quartz) is kept at a constant temperature. Volatile species pass through the column and undergo numerous sorption/desorption steps. Chromatographic experiments are carried out at a series of temperatures and the chemical yield of the volatile, short-lived species is studied as a function of temperature. Retention time is indicative of the volatility at each isothermal temperature and can be deduced from the observed changes in the yield from low to high values. The half-life of the nuclide under investigation serves as an 'internal' clock for the process. Just half of the atoms introduced into the isothermal gas chromatographic column will exit from the other end when the time it takes for an atom to pass through the column (the retention time) corresponds to its half-life. That is, the retention time in the chromatographic column at the temperature where the yield is 50% ($T_{50\%}$) of this maximum value is equal to the half-life of the short-lived nuclide (Gäggeler, 1997) and can be used as a relative measure of volatility. If the retention time is very short compared to the known half-life, the yield through the column will approach 100%. A Monte Carlo program taking account of all the experimental conditions is used to deduce the ΔH_{ads} for the measured species. Examples of these studies are discussed in Section 14.6.

(b) Solution chemistry

The Automated Rapid Chemistry Apparatus (ARCA) and the microcentrifuge system SISAK (Special Isotopes Studied by the AKUFE, Swedish acronym for the centrifuge liquid–liquid extraction technique) are examples of automated, computer-controlled systems that have been used in studies of solution chemistry of the heaviest elements.

(*i*) *ARCA*

ARCA can be used to perform rapid, repeated, high-pressure liquid chromatography column experiments on a timescale of seconds. The separations usually are carried out using microscale ion-exchange resin columns. After sorption on the column, the absorbed species are eluted and distribution coefficients are determined from the retention times of the species on the column. The collected liquid samples must then be dried before measurement of alpha emission and/or SF decay with high-resolution solid-state detectors, thus limiting detection to nuclides with half-lives longer than ~30 s. However, longer-lived daughter products can be detected in subsequent steps and used to infer properties of the parent element. The ARCA system has been used successfully for separations of elements 104 through 106, as described in detail in several reviews (Hoffman, 1994; Schädel, 1995; Hoffman and Lee, 1999; Kratz, 1999a,b).

(*ii*) *SISAK*

SISAK is a well-established on-line technique that has been used for studies of gamma-emitting nuclides with half-lives as short as 0.8 s, e.g., ^{109,110}Tc (Alzitzoglou *et al.*, 1990) and was later adapted for use with alpha emitters (Alstad *et al.*, 1995). The SISAK system can be used to perform liquid–liquid extractions on the timescale of a few seconds and has been coupled to a flowing liquid scintillation system to provide continuous separation and measurement of α–α correlations and SFs for nuclides as short as a few seconds (Omtvedt *et al.*, 1998). This permits chemical studies of shorter-lived nuclides, but the detection energy resolution is not as good. However, a recent experiment by Omtvedt *et al.* (2002) showed that rapid pre-separation by the Berkeley Gas-filled Separator (BGS) furnished sufficient decontamination from the extremely high background of unwanted activities so that the SISAK system could be used to obtain more detailed information about the chemical properties of Rf using 4.7-s ^{257}Rf produced in the ^{208}Pb(^{50}Ti,n) reaction. The same technique can be extended to studies of 4.4-s ^{258}Db produced via ^{208}Pb(^{51}V,n) or ^{209}Bi(^{50}Ti,n) reactions as well as to still heavier elements although the production rates are steadily decreasing as Z increases. Additional developments to increase production rates will be required. Another limitation will be the requirement to choose extraction systems with fast enough kinetics to achieve equilibrium.

14.4 RELATIVISTIC EFFECTS ON CHEMICAL PROPERTIES

14.4.1 Relativistic effects on atomic electronic shells

The relativistic mass increase can be expressed as $m = m_0\sqrt{1-(v/c)^2}$ where m_0 is the rest mass and v is the velocity of an electron. As the Z of the heavy elements increases, the stronger attraction to the core causes the electrons to move faster, and the resultant mass increase leads to a decrease in the Bohr radius of the hydrogen-like s and $p_{1/2}$ electrons: $a_{\mathrm{B}} = \hbar^2/mc^2 = a_{\mathrm{B}}^0\sqrt{1-(v/c)^2}$. The contraction and stabilization of these orbitals is the direct relativistic effect; it was shown to originate from the region of the inner K- and L-shells (Schwarz *et al.*, 1989; Baerends *et al.*, 1990). This effect was originally thought to be large only for the 'fast' electrons in inner core shells of heavy atoms. Later, it was also found to be large for the outer s and $p_{1/2}$ valence electrons. For example, the relativistic contraction for the 7s orbital in Db is $\Delta_{\mathrm{R}}\langle r\rangle_{ns} = (\langle r\rangle^{nr} - \langle r\rangle^{\mathrm{rel}}/\langle r\rangle^{nr}) = 25\%$, as shown in Fig. 14.3. As a consequence, the relativistic stabilization of this 7s orbital is 2.6 eV, as shown in Fig. 14.4.

The effect of the *n*s orbital contraction reaches its maximum in the 6th period with Au (17.3%) and in the 7th period with element 112 (31%); the phenomenon has been called the relativistic effect gold maximum and group 12 maximum, respectively (Pyykkö, 1988; Schwerdtfeger and Seth, 1998). The same maximum is, consequently, observed with the relativistic stabilization of the 6s and 7s orbitals (Fig. 14.5). The shift of the maximum to element 112 in the 7th period in contrast to gold in the 6th period is due to the fact that in both elements 111 and 112 the ground state electronic configuration is d^qs^2, while the electronic configuration changes from Au ($d^{10}s^1$) to Hg ($d^{10}s^2$). (See the discussion of relativistic effects in relation to electronic configurations by Autschbach *et al.* (2002).)

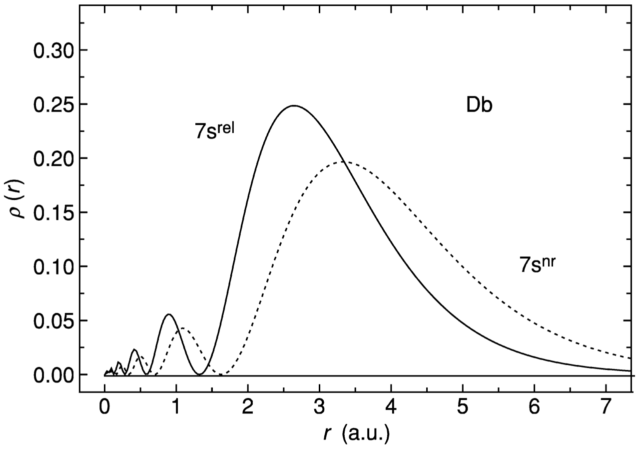

Fig. 14.3 *Relativistic (solid line) and nonrelativistic (dashed line) radial distribution of the 7s valence electrons in Element* 105, *Db.*

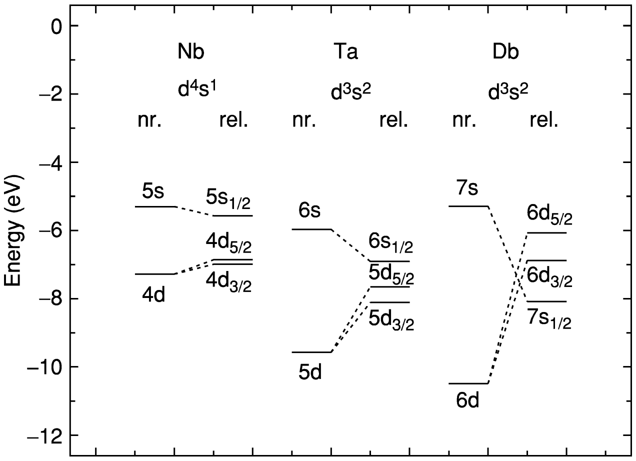

Fig. 14.4 *Relativistic stabilization of the* n*s orbitals, the destabilization of the* (n − 1)*d orbitals and their SO splitting for the group* 5 *elements. Dirac–Fock values are from Desclaux* (1973).

The contraction of the outer s and $p_{1/2}$ orbitals was recently explained as due to the admixture of higher bound and (partially) continuum orbitals due to relativistic perturbations (Schwarz *et al.*, 1989; Baerends *et al.*, 1990).

The relativistic contraction of the s and $p_{1/2}$ shells results in a more efficient screening of the nuclear charge so that orbitals of the outer d- and f-electrons, which never come close to the core, become more expanded and energetically destabilized. This is called the second or indirect relativistic effect. It was

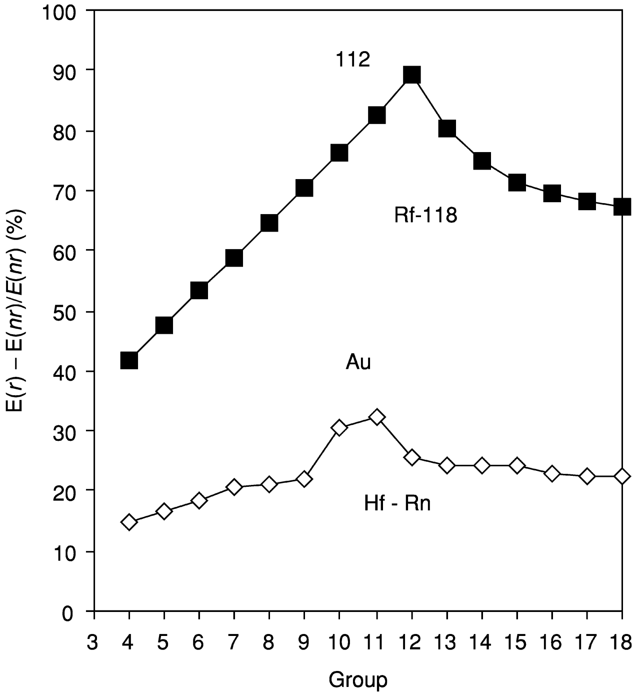

Fig. 14.5 *Relativistic stabilization of the* 6*s and* 7*s orbitals in the* 6*th and* 7*th periods of the periodic table. Redrawn from the data of Schwerdtfeger and Seth* (1998). *Relativistic Dirac–Fock data are from Desclaux* (1973). E(r) *is the relativistic orbital energy and* E(nr) *is the nonrelativistic orbital energy.* (*Figure from Pershina,* 2003).

realized that though contracted s and $p_{1/2}$ core (innermost) orbitals cause indirect destabilization of the outer orbitals, relativistically expanded d- and f-orbitals cause the indirect stabilization of the outer valence s- and p-orbitals. That partially explains the very large relativistic stabilization of the 6s and 7s orbitals in Au and in element 112, respectively (Fig. 14.5). Since both d-shells and f-shells become fully populated at the end of the d- and f-series, respectively, a maximum of indirect stabilization of the valence s- and p-orbitals will occur (Schwarz *et al.*, 1989) there. An example of the relativistic destabilization of the $(n - 1)$d orbitals is shown in Fig. 14.4 for the group 5 elements. This figure shows that trends in the relativistic and nonrelativistic energies of the valence electrons are opposite in going from the 5d to the 6d elements. Their spatial distributions show a similar effect (Fig. 14.3). Thus, only the relativistic description of the wave function can give the appropriate predictions of trends in properties within the chemical groups.

The third relativistic effect is the well-known spin–orbit (SO) splitting of levels with $l > 0$ (p-, d-, f-electrons, etc.) into $j = l \pm 1/2$. It also originates in the vicinity of the nucleus. The SO splitting decreases with increasing *l* quantum number: SO(np$_{1/2}$ – np$_{3/2}$) > SO(nd$_{3/2}$ – nd$_{5/2}$) > SO(nf$_{5/2}$ – nf$_{7/2}$). All three of these effects are of the same order of magnitude and increase roughly as Z^2. The effects can be seen from the energies of one-electron levels of the 7th series of the elements shown in Fig. 14.6.

Breit effects (accounting for magnetostatic interactions) on energies of the valence orbitals and on ionization potentials (IPs) are usually small, e.g. 0.02 eV for element 121 (Eliav *et al.*, 1998a). They can, however, reach a few percent for the fine structure level splitting, e.g. 3.6% of the total amount of the Tl ^{2}P splitting. Quantum electrodynamic (QED) effects are known to be very important for the inner shells, e.g. in accurate calculations of x-ray spectra. The effects were shown to be small, but not negligible for the valence electron shells, and are of the order of 1–2% of the kinetic relativistic effects. That means that existing studies of relativistic effects have uncertainties of no more than 2% (Pyykkö *et al.*, 1998). Recent monographs are recommended for a discussion of relativistic effects on chemical properties (Schwarz, 1990; Wilson *et al.*, 1991).

14.4.2 Current relativistic quantum-chemical methods

Early predictions of chemical properties of the heaviest elements were made in the 1970s on the basis of relativistic atomic electronic structure calculations and extrapolations of properties from the lighter elements (Keller *et al.*, 1970, 1973; Fricke and Waber, 1971; Fricke, 1975; Penneman and Mann, 1976). Influenced by the success of chemical experiments on the heaviest elements and due to the further development of the quantum-mechanical theory, a new wave of predictions of chemical properties based on relativistic molecular calculations

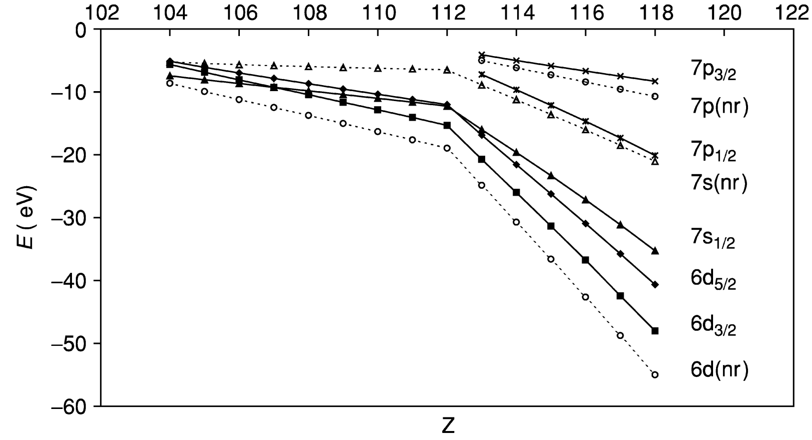

Fig. 14.6 *Relativistic* (*Dirac–Fock, solid lines*) *and nonrelativistic* (*Hartree–Fock, dashed lines*) *orbital energies for elements* 104 *through* 118. *The Dirac–Fock data are from Desclaux* (1973); *Hartree–Fock data are from Schwerdtfeger and Seth* (1998).

appeared, beginning in the 1990s. These calculations were performed using the most advanced quantum-chemical methods at the time. Overviews of their application to transition elements are given by Pyykkö (1988), to actinides by Pepper and Bursten (1991), and to transactinides by Pershina (1996, 2003), Pershina and Hoffman (2003), and Schwerdtfeger and Seth (1998). All-electron *ab initio* methods based on the Dirac–Coulomb–Breit (DCB) Hamiltonian with some possible corrections such as the radiative correction, the extension of the finite nuclei, and coupling with nuclear spin offer fully relativistic treatment of any atomic system. Since the Dirac equation is written for one electron, the real problem of *ab initio* methods is the treatment of the instantaneous electron–electron interaction, called electron correlation. Correlation effects are taken into account by the configuration interaction (CI) technique, the many-body perturbation theory (MBPT) and currently, most accurately by the Fock-space coupled cluster (CC) procedure, called single double CC excitations (CCSDs) (Ishikawa and Kaldor, 1996; Kaldor and Eliav, 1998, 2000). However, the CCSD method is presently limited to treating electronic configurations with no more than two electrons or holes beyond the closed shell. The DCB CCSD calculations have been performed for elements as heavy as 103, 104, 111–115, 118–122 (Kaldor and Eliav, 2000; Eliav *et al.*, 2002).

Atomic calculations using approximations of the DCB equations and some numerical techniques were very successful in the past. Calculations of the electronic structures of the heaviest elements up to very high Z were performed by Desclaux (1973), Mann and Waber (1970), Fricke and Waber (1971), and Fricke *et al.* (1971) using the one-configuration Dirac–Fock (DF) or the Dirac–Slater (DS) methods. (The DS method contains the Slater potential for the exchange-correlation term.) Later, a correlated method, the multi-configuration Dirac–Fock (MCDF) in some slightly different modifications (Desclaux, 1975; Grant, 1986; Parpia *et al.*, 1996), was applied in calculations of the electronic structures of many of the heaviest elements up to $Z = 118$ (Desclaux and Fricke, 1980; Pyper and Grant, 1981; Glebov *et al.*, 1989; Johnson *et al.*, 1990, 1999, 2002; Fricke *et al.*, 1993).

Molecular fully relativistic DF linear combination of atomic orbitals (DF-LCAO) codes including correlation effects are still under development (Grant, 1994; Grant and Quiney, 2000). Calculations are restricted to molecules with very few atoms, such as $(113)_2$ (Wood and Pyper, 1981), 111H, 117H, (113), (117), and $114H_4$ (Saue *et al.*, 1996; Seth *et al.*, 1996; Faegri and Saue, 2001). Algebraic solution of the molecular Dirac equation encounters difficulties due to the fact that the Dirac operator is unbound. Some special techniques like the projection operator technique are used to avoid the variational collapse connected with it. In contrast to nonrelativistic calculations, large basis sets are needed to describe accurately the inner-shell region where relativistic perturbation operators are dominant. The condition of kinetic balance relating the large and small components of the four-component wave function (Grant, 1986) must be observed. Kinetically balanced Gaussian type wave functions with a Gaussian distribution for the nuclear potential are presently the best suited for these purposes. These methods place heavy demands on computer memory and computational time.

Some pseudopotentials (PPs) (Schwerdtfeger *et al.*, 1989; Schwerdtfeger and Seth, 1998) or relativistic effective core potentials (RECPs) (Ermler *et al.*, 1988; Nash *et al.*, 1997; Han and Lee, 1999) are used to solve the many-electron problem in an efficient way. According to these approximations, frozen inner shells are omitted and replaced in the Hamiltonian by an additional PP term. As a result, the number of basis functions is drastically reduced, and, hence the number of two-electron integrals is reduced. Then, the one-electron integrals are solved for the valence basis functions and this additional term by applying *ab initio* schemes at the self-consistent-field (SCF) level or with electron correlation (CI, MBPT, or CCSD) included. The RECP and the PP have been generated for the transactinides (Nash *et al.*, 1997; Schwerdtfeger and Seth, 1998) and quite a number of calculations have been performed for gas-phase compounds of the heaviest elements.

The next group of methods that can successfully be applied to the calculations of the ground state properties of large, chemically interesting systems are methods based on the density functional theory (DFT). This is a theory of the electronic ground state structure couched in terms of the electronic density distribution $\rho(r)$ (Kohn *et al.*, 1996; Rosen, 1997). It has become increasingly useful in calculations of the ground state density and energy of molecules, clusters, and solids, as well as of solvation and adsorption processes. It is an alternative and complementary approach to the traditional methods of quantum chemistry expressed in terms of the many-electron wave function $\psi(r_1, \ldots, r_N)$. The modern DFT is exact and the methods are accurate upon the introduction of the non-local effects via accurate exchange-correlation potentials, like the relativistic general gradient approximation (RGGA). The electronic structures of a number of the heaviest element compounds have been calculated (Bastug *et al.*, 1993; Varga *et al.*, 1999; Pershina and Bastug, 2000; Pershina *et al.*, 2001, 2002a,b) using the fully relativistic four-component RGGA DFT method. A slightly different Beijing DFT code (Liu *et al.*, 1997; Liu and van Wüllen, 1999) was used for some calculations on the simple heaviest systems. The DS discrete-variational (DS-DV) method, a predecessor of the RGGA DFT method which is intrinsically approximate, was extensively used previously by Pershina *et al.* Reviews of the systems for the heaviest elements are given in Pershina (1996), Pershina and Fricke (1999), Pershina and Hoffman (2003), and Pershina (2003).

There are many other theoretical methods appropriate for calculations of the electronic structures of the heaviest element systems, with some limitations. Their descriptions can be found elsewhere (Pepper and Bursten, 1991; Pershina, 1996; Schwerdtfeger and Seth, 1998). Presently, the combination of the PP (RECP) and DFT methods is the best way to study the electronic structures of the heaviest systems.

14.5 PREDICTIONS OF CHEMICAL PROPERTIES FOR ELEMENTS 104 THROUGH 112

14.5.1 Atomic properties

(a) Electronic configurations

Table 14.4 shows the current best calculations of the electronic configurations of the 6d element atoms and ions in comparison with their 5d homologs. The filling of the 6d shell takes place in the first nine of the transactinide elements, $Z = 104$ through 112. Relativistic changes in the energies of the 7s and 6d electrons (Fig. 14.6) result in the stabilization of the $7s^2$ electronic pair in the ground and first ionized states over the entire 7th period of the periodic table, which is different from the ground states of Pt($5d^96s$) and Au($5d^{10}6s$) or from some of the 1+ and 2+ ionized states, as shown in Table 14.4. For example, the nonrelativistic configuration of element 111 is $6d^{10}7s$ according to Eliav *et al.* (1994). It was thought earlier that the relativistic stabilization of the $7p_{1/2}$ electrons of Rf (the $7s^27p6d$ ground state) indicated by MCDF calculations (Glebov *et al.*, 1989; Johnson *et al.*, 1990) would influence the properties of its compounds, but the $7s^27p6d$ electronic configuration was not confirmed by the more accurate CCSD calculations of Eliav *et al.* (1995a). Inclusion of dynamic correlation was required to obtain the correct $6d^27s^2$ ground state for Rf. However, the CCSD calculations of Eliav *et al.* (1995b) did confirm the $7s^27p_{1/2}$ ground state of Lr obtained earlier from the MCDF calculations of

Desclaux and Fricke (1980). The relativistic stabilization of the $7p_{1/2}$ electrons manifests itself in some excited states of the transactinides that are different from those of their lighter homologs. For example, the first excited state of Rf is $6d7s^27p(^3D_2)$, only 0.3 eV above its $6d^27s^2(^3F_2)$ ground state (Eliav *et al.*, 1995a), in contrast to Hf, whose first excited state is $5d^26s^2(^3F_3)$, although its ground state is $5d^26s^2(^3F_2)$. Ionized states of elements 104 through 112 show no 7p character, so properties of their compounds in the most typical oxidation states also should not be influenced by this orbital.

(b) Stabilities of oxidation states and ionization potentials

The most accurate IPs calculated for the 6d elements are given in Table 14.5. IPs for elements of the 7th period are shown in Fig. 14.8 in comparison with those of elements of the 6th period. Earlier predictions of stable oxidation states were made on the basis of atomic DF calculations as given in the review of Fricke (1975). They indicated the 4+, 5+, and 6+ states as the most stable for gaseous compounds of Rf, Db, and Sg, respectively, although in solutions the 4+ state was suggested as the most stable for Sg, though not confirmed by later calculations (Pershina *et al.*, 1999). The close proximity of the energy levels of the 7s and 6d electrons (Fig. 14.6) is the reason for the increased stability of the maximum oxidation states of the 6d elements. Indeed, recent MCDF calculations for elements 104 through 108 (Johnson *et al.*, 1990, 1999, 2002; Fricke *et al.*, 1993) have shown a decrease in the multiple IP ($0 \rightarrow Z^+_{\mathrm{max}}$) within the transition element groups 4 through 8, as illustrated in Fig. 14.7. This is also the reason that lower oxidation states are not stable at the beginning of the 6d series: the 7s and 6d levels are spatially so close to each other that the stepwise ionization process, for example, for Db or Sg, results in the $6d^2$ and not in the $7s^2$ configuration of Db^{3+} or Sg^{4+} (Pershina *et al.*, 1999). Since the 6d orbitals of the 6d elements are more destabilized than the 4d and 5d orbitals of the 4d and

[c] DF calculations, best expectation value (Fricke, 1975). Values in parentheses are estimates.

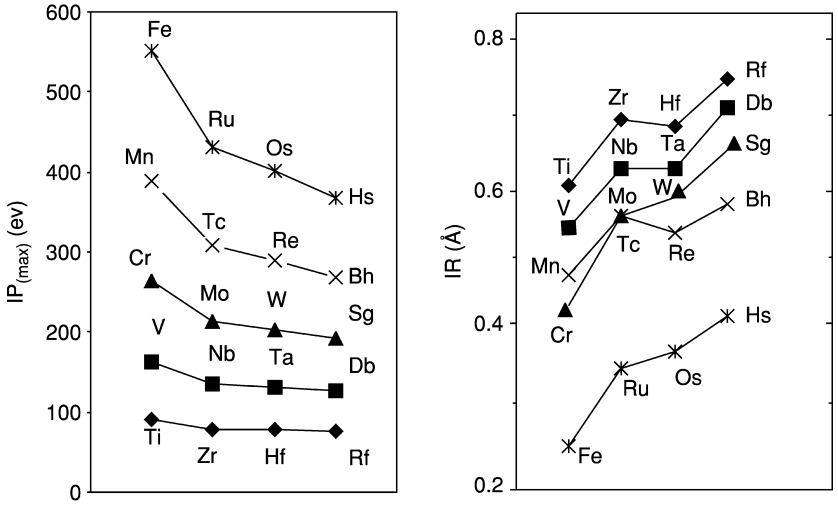

Fig. 14.7 *Ionization potentials (IP$_{max}$) and ionic radii (IR) for elements* 104 *through* 108 *in their maximum oxidation states obtained as a result of the MCDF calculations (Johnson* et al., 1990, 1999, 2002; *Fricke* et al., 1993).

5d elements, respectively, Db^{3+} and Sg^{4+} will be even less stable than Ta^{3+} and W^{4+}. Redox potentials estimated on the basis of these MCDF calculations, as discussed in Section 14.5.3a, indicate that the 6+ state of Sg will also be the most stable in solutions (Pershina *et al.*, 1999).

Predicted stable oxidation states of elements 107 through 110 vary widely. They were discussed in an early paper of Penneman and Mann (1976) that used relativistic Hartree–Fock calculations of the gaseous ion and the hydration parameters of Jorgensen to predict that the most stable oxidation states of elements 107 through 110 in aqueous solutions would be 3+, 2+, 1+, and 0. Earlier, Cunningham (1969) predicted 7+, 8+, 6+, 6+, respectively, for oxidation states of these elements, based on extrapolation by group in the periodic table. Since the Jorgensen hydration parameters did not consider the stabilizing effects of oxyanion formation as observed experimentally for W(vi) and for Re and Os, the higher oxidation states suggested by Cunningham are probably more realistic for solutions where oxyanions can be formed. No predictions based on modern relativistic calculations have been reported for elements 107 through 110.

A most stable oxidation state of 3+ was suggested for element 111, predicted to be a noble metal. It was considered to be as reactive as Au^{3+}, but with more extensive complex formation. Oxidation state 1− was also thought to be possible by analogy to Au^{-}, while 1+ was predicted to be less stable than for Au. The destabilization of the 6d orbitals at the end of the transactinide series is a reason for the 6d electrons to be chemically active. As a consequence, an enhanced stability of higher oxidation states can be expected, for example, of the 5+ states of element 111, and of the 4+ state of element 112 (Fricke, 1975; Schwerdtfeger and Seth, 1998).

It was suggested that the 2+ oxidation state of element 112 would be less stable than that of Hg as its IP_2 of 22.49 eV is larger than that for Hg of 18.75 eV (see Table 14.5). The 1+ state of element 112 also will be less stable than that of Hg (see Fig. 14.8) and probably will not be realized in element 112 at all, since compounds of Hg(I) exhibit the diatomic species $(Hg–Hg)^{2+}$. Higher oxidation states such as 4+ will surely be important in aqueous solutions and in compounds. The neutral state of element 112 is also likely to be very stable due to the inertness of the $7s^2$ electrons.

(c) Ionic radii and polarizability

The ionic radii (IR) of elements are defined by the maximum of the radial charge density, $r_{\max}$, or the expectation values $\langle r_{nj} \rangle$ of an outer valence orbital of an ion. The DF $\langle r_{nj} \rangle$ values for elements up to $Z = 120$ were tabulated by Desclaux (1973). The MCDF $r_{\max}$ for elements 104 through 108 in various oxidation states were calculated by Johnson *et al.* (1990, 1999, 2002) and by Fricke *et al.* (1993). Using these $r_{\max}$, IR of elements 104 through 108 were estimated by these workers using a linear correlation between $r_{\max}$ and the experimentally known IR for the lighter group 4 to 8 elements (Shannon, 1976). The predictions

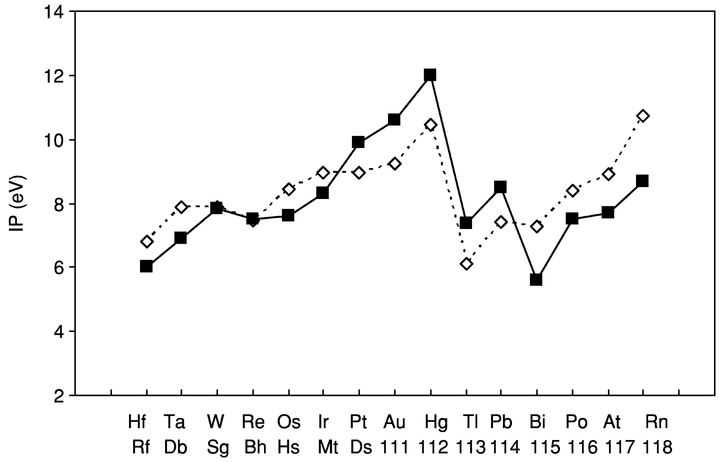

Fig. 14.8 *First ionization potentials for the* 7*th period* (*calculated, solid line*) *and the* 6*th period elements* (*experimental, dashed line*). *CCSD calculations for Rf and elements* 111 *through* 115 (*Eliav* et al., 1994, 1995*b*, 1996*a*, 1998*a*,*b*; *Landau* et al., 2001); *MCDF for elements* 105 *through* 108 (*Fricke* et al., 1993; *Johnson* et al., 1999, 2002; *Pyper and Grant*, 1981).

for the IR of Rf through Hs in their highest oxidation states are summarized in Table 14.6 and Fig. 14.7 together with experimental values for the lighter elements.

The indicated IR of the 4d and 5d elements are almost equal due to the lanthanide contraction, which is 86% a nonrelativistic effect, while the IR of the transactinides are about 0.05 Å larger than the IR of the 5d elements due to an orbital expansion of the $6p_{3/2}$ orbitals, the outer orbitals for the maximum oxidation state. Nevertheless, they are still smaller than the IR of the actinides due to actinide contraction (of 0.030 Å), which is mostly a relativistic effect. Relativistic effects on polarizability (α) change roughly as Z^2 and α should be the smallest in group 12 and in the 7th period for element 112. Its α is relativistically decreased from 74.66 to 25.82 a.u., as shown by PP CCSD(T) calculations (Seth *et al.*, 1997). As a consequence, element 112 is expected to have the weakest van der Waals bond and be extremely volatile.

14.5.2 Gas-phase compounds

(a) Electronic structures of Rf through element 112 and role of relativity

(*i*) *Rf through Hs*

A large series of calculations were performed for halides, oxides, and oxyhalides of Rf through Hs using the DFT and RECP methods: MCl_4 (M = Zr, Hf, and Rf), MCl_5 and MBr_5, $MOCl_3$, and $MOBr_3$ (M = V, Nb, Ta, and Db), MF_6 and MCl_6, $MOCl_4$, MO_2Cl_2, and MO_4^{2-} (M = Mo, W, and Sg) (Pershina, 1996, Pershina and Fricke, 1999), MO (M = Nb, Ta, and Db) (Dolg *et al.*, 1993), $M(CO)_6$ (M = Mo, W, and Sg) (Nash and Bursten, 1995; Nash and Bursten, 1999b), MO_3Cl (M = Tc, Re, and Bh) (Pershina and Bastug, 2000), and MO_4 (M = Ru, Os, and Hs) (Pershina *et al.*, 2001). Various electronic structure

[b] More realistic values obtained from the geometry optimization of molecular compounds are IR = 0.76 Å for Rf^{4+} (Varga *et al.*, 2000) and 0.69 Å for Db^{5+} (Han *et al.*, 1999a).

properties such as IP, electron affinity (EA), electron transition energies, charge density distribution and bonding, as well as their trends in the groups, have been predicted.

Bonding in the compounds of Rf through Hs was shown to be typical of d-element compounds. The bonding is dominated by the large participation of both $6d_{3/2}$ and $6d_{5/2}$ orbitals. The 7s orbital, as well as both $6p_{1/2}$ and $6p_{3/2}$ orbitals, each contribute about 15% to the bonding, and this contribution is increased relative to that of the lighter homologs. The contribution of the $7p_{1/2}$ orbital of 9.4% in $DbCl_5$ is, for example, 50% larger than the contribution of the $5p_{1/2}$ orbital of Nb in $NbCl_5$ (Pershina *et al.*, 1992a). The contribution of the 6d orbitals with respect to that of the 7s and $7p_{1/2}$ orbitals is thus decreased, although it does not change the d-character of the chemical properties.

Molecular orbital (MO) levels for the highest chlorides of Rf, Db, and Sg are shown in Fig. 14.9. They are similar to those of d-element compounds. The group of binding (occupied) levels (with the upper MOs of predominantly 3p character of Cl) is separated from the group of the unoccupied levels of d-character by the energy gap ΔE. A decrease in ΔE from $RfCl_4$ to $SgCl_6$ is indicative of a decrease in the metal–ligand overlap of the atomic wave functions.

The most common feature found in the calculations for all these compounds is an increase in covalence, i.e. a decrease in the effective charge, Q_M, and an increase in the overlap population (OP), as shown in Figs. 14.10 and 14.11. The OP is the amount of the electronic density localized on the bond between atoms in a molecule and is a direct counterpart of the covalent contribution to the

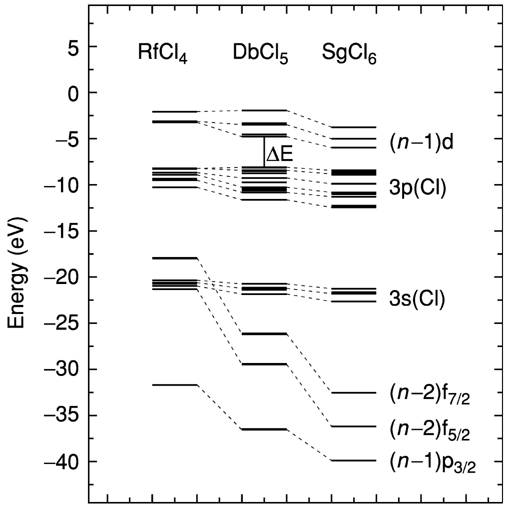

Fig. 14.9 *MO levels for $RfCl_4$, $DbCl_5$, and $SgCl_6$ (Pershina and Fricke,* 1994).

binding energy (Mulliken, 1955). Comparison of the relativistic with nonrelativistic calculations (Fig. 14.10) shows this increase to be a purely relativistic effect due to the increasing contribution of the relativistically stabilized and contracted 7s and $7p_{1/2}$ atomic orbitals (AOs), as well as of the expanded 6d AOs in bonding (Pershina and Fricke, 1993).

Calculated molecular properties of gas-phase chlorides, oxychlorides, and oxides of groups 4 through 8 elements and of their homologs studied experimentally are summarized in Table 14.7. Results of molecular calculations (Pershina and Fricke, 1993; Pershina, 1996) have shown that relativistic effects increase IP, decrease EA, and increase the stability of the maximum oxidation state in each compound of the *n*d transition elements, with these effects increasing with increasing Z within the chemical groups. As a consequence, IP, ΔE, and the stabilities of the maximum oxidation states increase from the 4d to the 6d compounds, while the EAs decrease. Nonrelativistically, trends in all these properties would just be reversed from the 5d to the 6d compounds, similarly to the Q_M and OP shown in Fig. 14.10.

Trends in binding energies, D_e, and equilibrium bond distances, R_e, for various types of compounds are depicted in Fig. 14.12. There is a decrease in D_e for almost all of the 6d relative to the 5d element compounds except for MO_4 (M = Ru, Os, and Hs) and MCl_6 (M = Mo, W, and Sg). Within all the groups, relativistic effects enhance bonding of the compounds with increasing Z, though increasing SO splitting of the d-orbitals partially diminishes the binding energy, reaching a decrease of about 1.5 eV for 6d element compounds like SgO_2Cl_2, as shown by RECP calculations (Han *et al.*, 1999a). This is one of the reasons that most of the transactinide compounds have atomization energies lower than those of the homologous 5d elements. The other reason is a decrease in the ionic contribution to bonding, which is also a relativistic effect. The calculated R_e (Fig. 14.12) reflect the experimentally known similarities of bond lengths for the 4d and 5d compounds (due to the lanthanide contraction) and they show an increase in R_e of about 0.05 Å in the transactinide compounds compared to the 5d compounds.

Another important trend is the decrease in the metal–ligand single bond strength in going from the group 4 to the group 6 halides, as well as a decrease in the relative stability of the maximum oxidation state. As a consequence, volatile species such as $SgCl_6$ and $SgOCl_4$ are expected to decompose (a weak Sg–Cl bond) into compounds of Sg(v) at high temperatures by analogy with $MoCl_6$ and $MoOCl_4$. SgO_2Cl_2 was found to be the most stable of all the halides or oxyhalides and was, therefore, recommended (Pershina, 1996) for gas-phase chromatography experiments (Schädel *et al.*, 1997a). An increase in dipole moment, μ, of the low-symmetry molecules within the transition element groups was predicted for all the group 4 to 7 compounds (Table 14.7). The μ and α, as well as the molecular sizes, are decreased by relativistic effects. The PP calculations performed for the gas-phase MO (M = Nb, Ta, and Db) (Dolg *et al.*, 1993) have shown that relativistic effects stabilize the $^2\Delta$ ground state by 2.74 eV

(the nonrelativistic configuration is $^4\Sigma^-$) in contrast to the $^4\Sigma^-$ state observed for NbO. The relativistic effects also stabilize the binding energy of DbO by 1.93 eV. (Σ and Δ denote molecular spectroscopic states.)

(*ii*) *Mt through element* 112

Elements 109 (Mt) and 110 (Ds) have received little attention in recent years. The position of these elements in the periodic table indicates that they should be noble metals. Volatile hexafluorides and octafluorides might be produced and used for chemical separations. The relativistic DS-DV molecular calculations of Rosen *et al.* (1979) and of Waber and Averill (1974) performed for DsF_6 have shown that its electronic structure is very similar to that of PtF_6, with similar values of IP.

Earlier detailed predictions of chemical properties of element 111 based on atomic calculations were made by Keller *et al.* (1973). Due to the fact that the maximum of relativistic effects in the *n*s shell in group 11 occurs at element 111, there has been widespread interest in the electronic structure of its compounds. The effect of the 7s orbital contraction was investigated for the simplest molecule, 111H, whose electronic structure was calculated by a variety of methods including the fully relativistic DCB *ab initio* method (Seth *et al.*, 1996; Liu and van Wüllen, 1999). The bonding was shown to be considerably increased by relativistic effects, which doubled the dissociation energy, though the SO splitting diminished it by 0.7 eV. Calculations (Liu and van Wüllen, 1999) were also performed for other dimers, AuX and 111X where X = F, Cl, Br, O, Au, and 111.

The stability of higher oxidation states of element 111 was examined in calculations of energies of the decomposition reactions $MF_6^- \rightarrow MF_4^- + F_2$ and $MF_4^- \rightarrow MF_2^- + F_2$ using the relativistic PP method (Seth *et al.*, 1998a,b). The results support the earlier predictions that the 3+ and 5+ oxidation states will be more stable for this element than they are for Au (due to a larger participation of the 6d orbitals in bonding) and that the 1+ oxidation state of element 111 may be difficult to prepare. The SO coupling was shown to stabilize the molecules in the following order: $MF_6^- > MF_4^- > MF_2$. This order is consistent with the relative involvement of the $(n-1)$d electrons in bonding for each type of molecule.

The most interesting among the heaviest elements from the chemical point of view is element 112, where the maximum of relativistic effects on the 7s shell in the entire 7th period and within group 12 occurs (see Fig. 14.5). Due to the strong relativistic contraction and stabilization of the 7s orbitals (and accordingly its highest IP in group 12) and its closed-shell configuration, it is expected to be rather inert and may be a distinctly noble metal. It was suggested that the interatomic interaction in the metallic state will be small, possibly even leading to high volatility as in the noble gases. Pitzer (1975a) estimated that the very high excitation energy of about 8.6 eV for the $6d^{10}7s^2 \rightarrow 6d^{10}7s7p$ transition into the configuration of the metallic state will not be compensated by the energy gain of the metal–metal bond formation. An extrapolation of the sublimation enthalpy from its homologs, Zn, Cd, and Hg, also suggests that element 112 should be quite volatile (Eichler, 1974). Recently, a similar conclusion was obtained by using a more sophisticated empirical model (Ionova *et al.*, 1996).

Estimates of adsorption enthalpies of element 112 on various metal surfaces using some adsorption models suggest, nevertheless, that element 112 can be deposited on some metals, like Ag, Au, Pd, or Pt (Eichler and Rossbach, 1983). The ability of element 112 to form a metal–metal bond was also predicted by recent relativistic MO calculations for 112M, where M = Cu, Pd, Pt, Ag, and Au (Pershina *et al.*, 2002a). Element 112 was calculated to form a rather strong bond with the above-mentioned transition elements, only about 15–20 kJ mol^{-1} weaker than that of HgM, with the D_e of 112Pd being the largest.

Molecular relativistic PP calculations (Seth *et al.*, 1997) have predicted that the 2+ oxidation state of element 112 will be less stable than that of Hg. They have calculated that $112F_2$ is, indeed, less stable than HgF_2 and that it will decompose readily into 112 and F_2. Seth *et al.* (1997) also came to the conclusion that element 112 should exhibit a typical transition element character in higher oxidation states, because its 6d orbitals are relativistically destabilized and, therefore, should participate more in coordination bonding. Thus, for example, the 4+ oxidation state of element 112 as in $112F_4$ may be accessible while the 2+ state may not. In combination with an appropriate polar solvent, the species $112F_5^-$ and/or $112F_3^-$ should be formed rather than $112F_4$ or $112F_2$, although these compounds will probably undergo strong hydrolysis in aqueous solutions, and perhaps bromides or even iodides will be more stable and would be better for experimental investigations.

(b) Predictions of volatilities

A more extensive series of the DFT calculations (Pershina, 1996; Pershina and Bastug, 2000; Pershina *et al.*, 2001) permitted establishment of some relationships between molecular properties such as covalence or dipole moment and volatility. Because covalent compounds are typically more volatile than ionic compounds, the higher covalence of high-symmetry halides or oxides of the transactinides is expected to result in their higher volatilities compared with those of their 4d and 5d homologs. For example, $RfCl_4$ is expected to be more volatile than $HfCl_4$ since it is more covalent and is expected to have the T_d symmetry shown by $HfCl_4$ in the vapor phase. Low-symmetry compounds, e.g. oxyhalides of C_n symmetry, have dipole moments and, therefore, are attracted more strongly to the surface of a chromatographic column due to an additional electrostatic (dipole moment–surface charge) interaction than are high-symmetry compounds of the same element such as pure halides. Therefore, one expects that $DbCl_5$ (D_{3h} symmetry) will be more volatile than $DbOCl_3$ (C_{3v} symmetry). For low-symmetry compounds, a trend in volatility in a chemical group will be opposite to the trend in μ, since larger dipole moments cause stronger electrostatic interactions with the surface of a chromatography column. Accordingly, the following decreasing trends in volatility were predicted: $MoO_2Cl_2 > WO_2Cl_2 > SgO_2Cl_2$ and $TcO_3Cl > ReO_3Cl > BhO_3Cl$. These trends are opposite to the increasing dipole moments. Indeed, these trends were confirmed experimentally by the observations (Kadkhodayan, 1993; Kadkhodayan *et al.*,1996; Türler *et al.*, 1998b; Sylwester *et al.*, 2000) that $RfCl_4$ is more volatile than $HfCl_4$, while $DbOCl_3$ (Türler *et al.*, 1996), SgO_2Cl_2 (Schädel *et al.*, 1997a; Türler *et al.*, 1999), and BhO_3Cl (Eichler *et al.*, 2000) are less volatile than the corresponding compounds of their lighter homologs in the respective chemical groups.

In addition, enthalpies of adsorption, $\Delta H_{ads}(BhO_3Cl) = -78.5$ kJ mol^{-1} compared to $\Delta H_{ads}(TcO_3Cl) = -48.2$ kJ mol^{-1} and ΔH_{ads} $(ReO_3Cl) = -61$ kJ mol^{-1}, on the quartz surface of the chromatography column were predicted by Pershina and Bastug (2000) using a model of physisorption and by performing calculations of the electronic structures of those molecules. The obtained adsorption enthalpies indicate that volatility decreases as $TcO_3Cl > ReO_3Cl > BhO_3Cl$, in excellent agreement with the experimental value $\Delta H_{ads}(BhO_3Cl) = -77.8$ kJ mol^{-1} (Eichler *et al.*, 2000). In a similar way, $\Delta H_{ads} = -(36.7 \pm 1.5)$ kJ mol^{-1} on a quartz surface was predicted by Pershina *et al.* (2001) for HsO_4

as compared to $\Delta H_{\mathrm{ads}}(\mathrm{RuO_4}) = -(40.4 \pm 1.5)$ kJ mol^{-1} and ΔH_{ads} $(\mathrm{OsO_4}) = -(38.0 \pm 1.5)$ kJ mol^{-1}. Thus, the volatility of group 8 tetroxides in the specific experiments is expected to change as $\mathrm{RuO_4} < \mathrm{OsO_4} \leq \mathrm{HsO_4}$. Such a sequence is also expected from an extrapolation of this property within the group (Düllmann *et al.*, 2002b). This trend is in accord with the idea of increasing volatility with increasing covalence of compounds.

14.5.3 Solution chemistry

(a) Redox potentials

Some earlier estimates of oxidation states of the transactinides made on the basis of empirical modifications of the Born–Haber cycle were reviewed by Fricke (1975). They were mostly related to simple M^{z+} ions, and the results were rather inconsistent. Recently, redox potentials ($E°$) for complex species of Rf, Db, and Sg in aqueous solutions were estimated (Ionova *et al.*, 1992; Pershina and Fricke, 1994; Pershina *et al.*, 1999) using correlations between the MCDF-calculated IPs (Johnson *et al.*, 1990; 1999; Fricke *et al.*, 1993) and the tabulated redox potentials for group 4, 5, and 6 elements (Bratsch, 1989). Two correlation plots for groups 5 and 6 are shown in Fig. 14.13.

These estimates indicate that the stability of the maximum oxidation state increases with Z within groups 5 and 6, while that of lower oxidation states decreases. Thus, the 5+ and 6+ states of Db and Sg will be more stable than their 3+ and 4+ states, respectively. The 3+ state of Db will be less stable than the 3+ states of Nb or Ta, and the 4+ state of Sg will be less stable than the 4+ states of Mo and W.

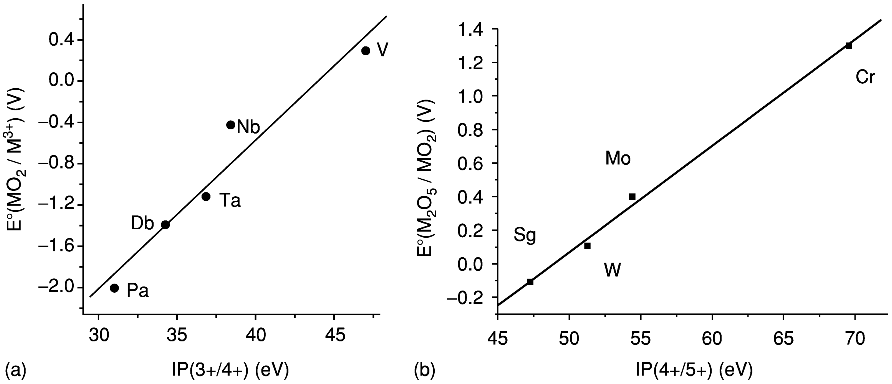

Fig. 14.13 (*a*) *Correlation between IP*(3+/4+) *and the standard potentials* $\mathrm{E}^o(MO_2/M^{3+})$ *where* $M = V$*, Nb, Ta, Db, Pa. The standard potential for Db is from Ionova* et al. (1992). *The standard potentials for Nb, Ta, and Pa are from Bratsch* (1989). (*b*) *Correlation between IP*(4+/5+) *and the standard potentials* $\mathrm{E}^o(M_2O_5/MO_2)$ *where M=Cr, Mo, W, and Sg* (*Pershina* et al., 1999).

The increasing stability of the maximum oxidation state and the decreasing stability of lower oxidation states at the beginning of the 6d series is a relativistic effect caused by destabilization of the 6d orbitals, as discussed earlier. Along the 6d series, the stability of the maximum oxidation state decreases in the order: $\mathrm{Lr}^{3+} > \mathrm{Rf}^{4+} > \mathrm{Db}^{5+} > \mathrm{Sg}^{6+}$. For comparison, the results are summarized in Table 14.8, together with those for Lr, the last of the actinides.

(b) Hydrolysis

Aqueous ions of transition elements undergo strong hydrolysis, as do their heaviest homologs. In acidic solutions, hydrolysis involves either the cation $\mathrm{M(H_2O)}_n^{Z+} \Leftrightarrow \mathrm{MOH(H_2O)}_{n-1}^{(Z-1)+} + \mathrm{H}^+$ or the anion, or both. The hydrolysis of cations of a given oxidation state is known to decrease within groups 4, 5, and 6 as one proceeds down the periodic table and it increases from group 4 to group 6 (Baes and Mesmer, 1976). Hydrolysis/protonation of group 4, 5, and 6 cations and of their compounds was considered theoretically on the basis of relativistic DFT calculations (Pershina, 1998a,b; Pershina and Kratz, 2001; Pershina *et al.*, 2002b).

For group 4 elements, about 50% of each type of the species indicated in the following equilibrium exists in aqueous solutions at pH = 0: $\mathrm{M(H_2O)}_8^{4+} \Leftrightarrow \mathrm{MOH(H_2O)}_7^{3+}$. For this reaction, the following trend in hydrolysis of the group 4 elements was predicted from the calculated Gibbs energy changes: Zr > Hf > Rf (Pershina *et al.*, 2002b). The first hydrolysis constant

log K_{11}(Rf) ≈ –4 was then calculated and compared to log K_{11}(Zr) = 0.3 and log K_{11}(Hf) = –0.25. This hydrolysis sequence is in agreement with the order of extraction of group 4 elements into thenoyltrifluoroacetone (TTA) obtained in the experiments described in Section 14.6.1c(iv).

For group 5 elements and Pa, hydrolysis proceeds very rapidly, with the ultimate formation of products such as M(OH)$_5$(aq). Hydrolysis of group 5 cations was studied theoretically for the following reaction: $M(H_2O)_6^{5+} \Leftrightarrow M(OH)_6^- + 6H^+$ where M = Nb, Ta, Db, and Pa. Calculations (Pershina, 1998a) of the Gibbs energy changes of this reaction showed that the trend toward decreasing hydrolysis is continued with Db, giving the sequence Nb > Ta > Db >> Pa.

Hydrolysis of group 6 elements proceeds even further than that of the group 5 elements, with the formation of MO_4^{2-} at higher pH according to the following scheme: $M(H_2O)_6^{6+}$ (this species is not observed) ⇔ … ⇔ $[M(OH)_4(H_2O)]^{2+}$ ⇔ $[MO(OH)_3(H_2O)_2]^+ \Leftrightarrow MO_2(OH)_2(H_2O)_2 \Leftrightarrow [MO_3(OH)]^- \Leftrightarrow MO_4^{2-}$. The protonation process, the reverse of the reaction shown above, was considered theoretically (Pershina and Kratz, 2001). The resulting relative values of Gibbs energy changes suggest that for the first two protonation steps (see Table 14.12) the trend in group 6 should be W > Sg ≥ Mo rather than Sg > W > Mo. For the third and subsequent protonation processes, the trend should be Sg > W > Mo. The values of log *K* were defined for Sg, as shown in Table 14.9. The predicted trends in log *K* are in agreement with experiments on Mo and W at various pH values (Baes and Mesmer, 1976) and with Sg for the protonation/hydrolysis of the positively charged complexes (Schädel *et al.*, 1998).

(c) Complexation

If one molecular complex ML_i, among many others, is extracted into an organic phase, the distribution coefficient, K_d (expressed in terms of the complex formation constant β_i), is a good measure of its stability and the sequence in the K_d values for a given series should reflect the sequence in the stability of the complexes (Ahrland *et al.*, 1973). Thus, by predicting $\log\beta_i = \Delta G^r/2.3RT$ one

Table 14.9 *Values of log* K *for the stepwise protonation of* MO_4^{2-} (*M = Mo, W, and Sg*) (*Pershina and Kratz*, 2001).

	log K$_n$		
Reaction	*Mo*	*W*	*Sg*
$MO_4^{2-} + H^+ \Leftrightarrow MO_3(OH)^-$	3.7	3.8	3.74
$MO_3(OH)^- + H^+ + 2H_2O \Leftrightarrow MO_2(OH)_2(H_2O)_2$	3.8	4.3	4.1 ± 0.2
$MO_4^{2-} + 2H^+ + 2H_2O \Leftrightarrow MO_2(OH)_2(H_2O)_2$	7.50	8.1	8.9 ± 0.1
$MO_2(OH)_2(H_2O)_2 + H^+ \Leftrightarrow MO(OH)_3(H_2O)_2^+$	0.93	0.98	1.02

can predict sequences in the extraction of complexes into an organic phase or their sorption by cation- or anion-exchange resins.

Complex formation is known to increase within the transition element groups with increasing Z. However, in aqueous solutions it competes with hydrolysis as described by the following equilibrium: $x\mathrm{M(H_2O)}_{w^{\circ}}^{z+} + y\mathrm{OH}^- + i\mathrm{L}^- \Leftrightarrow \mathrm{M}_x\mathrm{O}_u\mathrm{(OH)}_{z-2u}\mathrm{(H_2O)}_w\mathrm{L}_a^{(xz-y-i)} + (xw^{\mathrm{o}} + u - w)\mathrm{H_2O}$. This may change trends in the stabilities of the complexes and, consequently, their extraction into an organic phase.

(*i*) *Rf through Sg*

Complexation of group 4 elements in HF solutions is described by the following equilibria:

$$\mathrm{M(H_2O)}_8^{4+} \Leftrightarrow \mathrm{MF(H_2O)}_7^{3+} \Leftrightarrow \mathrm{MF_3(H_2O)}_5^{-} \Leftrightarrow \tag{14.1}$$

$$\mathrm{MF_4(H_2O)_4} \Leftrightarrow \mathrm{MF_5(H_2O)}^{-} \Leftrightarrow \mathrm{MF}_6^{2-}. \tag{14.2}$$

Results of DFT calculations of the relative Gibbs energy changes of these equilibria (Pershina *et al.*, 2002b) suggest that the trend in the formation of the positively charged complexes according to equation (14.1) should be Zr $\geq$ Hf $>$ Rf. This means that the K_d values for sorption by a cation resin of the positively charged complexes formed at HF concentrations below <0.01 M will have the following trend in group 4: Rf $>$ Hf $\geq$ Zr. (In the case of the formation of positively charged complexes of a lower charge from complexes with a higher charge (equation (14.1)), the sequence in the K_d values is opposite to the sequence in the complex formation, since complexes with a lower positive charge are more poorly sorbed on cation exchange resin than those with a higher charge.) For the formation of anionic complexes (equation (14.2)) sorbed by an anion-exchange resin, the trend becomes more complicated depending on the pH, i.e. depending on whether the fluorination process starts from the hydrated or the hydrolyzed species. Thus, for experiments conducted at HF concentrations above 0.001 M where some hydrolyzed or partially fluorinated species are present, the trend for the formation of MF_6^{2-} (equation (14.2)) and hence of K_d should be reversed in group 4: Rf $\geq$ Zr $>$ Hf.

The predicted sequences are in agreement with experiments on cation- and anion-exchange resin separations of Zr, Hf, and Rf from mixed HF/HCl solutions, where fluorinated complexes were sorbed on the resin and Cl^- ions served as counter-ions competing for its active centers (Trubert *et al.*, 1999). At high HCl concentrations, where no hydrolysis takes place, the complexation reaction is $\mathrm{M(H_2O)}_8^{4+} + 6\mathrm{HCl} \Leftrightarrow \mathrm{MCl}_6^{2-}$. Results of the DFT calculations of Gibbs energy changes for this reaction (Pershina *et al.*, 2002b) suggest that the trend in complex formation and in the K_d values should definitely be continued with Rf to give the sequence Zr $>$ Hf $>$ Rf.

Group 5 elements form a large variety of complexes, such as $M(OH)_2Cl_4^-$, $MOCl_4^-$, $MOCl_5^{2-}$, and MCl_6^- (M = Nb, Ta, Db, and Pa), in HCl solutions with different degrees of hydrolysis. Their formation is described in a general form by the following equilibrium reactions: $M(OH)_6^- + iL^- \Leftrightarrow MO_u(OH)_{z-2u}L_i^{(6-i)-}$. The DFT calculations of Gibbs energy changes for these reactions (Pershina, 1998b) showed the following trend in the complex formation and extraction of group 5 elements: Pa >> Nb ≥ Db > Ta. Thus, a reversal of the trend from Ta to Db was predicted for group 5 elements. The following sequence in the formation of various types of complexes as a function of increasing acid concentration was predicted (Pershina and Bastug, 1999): $M(OH)_2Cl_4^- > MOCl_4^- > MCl_6^-$. For the acids of interest, the sequence was predicted as: $MF_6^- > MCl_6^- > MBr_6^-$.

Complex formation of the group 6 elements, Mo, W, and Sg, in HF solutions is described as: MO_4^{2-} (or $MO_3(OH)^-$) + HF $\Leftrightarrow MO_3F^- \Leftrightarrow MO_2F_2(H_2O)_2 \Leftrightarrow MO_2F_3(H_2O)^- \Leftrightarrow MOF_5^-$. The calculated Gibbs energy changes of these reactions show a very complicated dependence of trends in the complex formation on HF concentration and pH. Thus, at low [HF] < ~0.1 M, a reversal of the trend from W to Sg should occur, while at high [HF] > 0.1 M, the trend is continued with Sg: Sg > W > Mo. It should be noted that such complicated trends could not be obtained by any extrapolation of properties within the group, but are the result of considering complex formation in equilibrium with hydrolysis and by calculating relativistically the electronic structure of the complexes.

(*ii*) *Bh through element* 112

The aqueous chemistry of these elements promises to be very interesting and should provide extensive information about complexing ability as well as information about the potential reduction reactions. Some general considerations on the basis of atomic calculations are presented by Fricke and Waber (1971); Fricke (1975). Some aspects of the complex formation of elements 107 through 112 in aqueous solution were discussed by Keller and Seaborg (1977) and Seaborg and Keller (1986). It is expected that element 112 will have extensive complex-ion chemistry, as do other elements of the second half of the 6d transition series. From early relativistic atomic calculations, Pitzer (1975a) postulated some very interesting properties for element 112 caused by relativistic effects on the $7s^2$ shell. He suggested that element 112, eka-Hg, would be more noble than Hg, and even though the oxide, the chloride, and the bromide would be unstable, $112Cl_4^{2-}$ and $112Br_4^{2-}$ would exist in solution, and $112F_2$ would be stable.

Recently, Seth *et al.* (1997) have considered the possibility of formation of $112F_5^-$ and $112F_3^-$, by analogy with Hg where the addition of F^- to HgF_2 or HgF_4 was found to be energetically favorable. However, in aqueous solutions these complexes probably undergo strong hydrolysis. Thus, experiments might only be possible with $112Br_5^-$ or $112I_5^-$.

14.6 MEASURED CHEMICAL PROPERTIES FOR ELEMENTS 104 THROUGH 112

The experimental results for Rf, Db, and Sg, the results of the first experimental investigations for Bh and Hs, and a preliminary report of experiments designed to study element 112 are briefly reviewed. Several more detailed reviews of the experimental techniques, measured chemical properties of Rf, Db (Ha), and Sg, and prospects for studies of still heavier elements are available and should be consulted for additional information (Schädel, 1995, 2002; Gregorich, 1997a; Hoffman and Lee, 1999; Kratz, 1999b).

A summary of some predicted chemical properties of elements 104 through 112 is given in Table 14.10. First experimental investigations of the chemical properties of the transactinides focused on the most fundamental and simplest properties. For example, the determination that the most stable oxidation states of elements 104 and 105 in aqueous solutions were 4+ and 5+, respectively, allowed their placement at the bottom of groups 4 and 5 in the periodic table as members of the 6d transition series. In later experiments, attempts were made to perform more complex studies of transactinide properties for comparison with their lighter homologs in the periodic table. Such studies present even greater challenges because of the need to investigate the transactinides and their lighter homologs under exactly the same chemical conditions – the ideal situation being to measure them all in the same on-line experiments conducted at the accelerators where they are produced.

14.6.1 Chemistry of rutherfordium (104)

(a) Historical

In early gas-phase studies at Dubna, Zvara *et al.* (1969, 1970) reported that the chloride of a 0.3-s SF activity produced in the ^{242}Pu(^{22}Ne,4n) reaction and initially assigned to ^{260}Rf formed a chloride, presumably $RfCl_4$, that was less volatile than $HfCl_4$. However, the existence of such an isotope has never been confirmed (see Fig. 14.2) and these claims were apparently incorrect as discussed in detail by Kratz (1999b). Zvara *et al.* (1972) later proposed that they were actually measuring the SF branch of the known alpha-emitting 3-s ^{259}104, which was produced in the same experiments via the ^{242}Pu(^{22}Ne,5n) reaction. They then reported that the volatility of the Rf tetrachloride was similar to that of $HfCl_4$ and much more volatile than the chlorides of the actinides and Sc. They concluded from their results that Rf properly belonged to group 4 of the periodic table. However, only SF events were measured and there is still some doubt about the magnitude of the SF branch of ^{259}104, which decays predominantly by alpha emission. The results could not be considered definitive because positive identification of the element being studied was not possible since only SF decay was detected.

Studies of the solution chemistry of element 104 were conducted in 1970 by Silva *et al.* (1970b) using 75-s ^{261}Rf (see Table 14.3). Positive identification of ^{261}Rf was made by measuring its known half-life and characteristic alpha-decay sequence. Elutions with α-hydroxyisobutyrate solutions from cation-exchange resin columns were used to compare the behavior of ^{261}Rf with No^{2+}, trivalent actinides, Hf^{4+}, and Zr^{4+}. In several hundred repetitive experiments in which 100 atoms were produced for study, the behavior of element 104 was shown to be similar to that of the group 4 elements Zr and Hf, which did not sorb on the column. Its behavior was entirely different from that of No^{2+} and the trivalent actinides that did sorb on the column at pH 4.0.

Some time later, Hulet *et al.* (1980) used ^{261}Rf to perform further experiments to compare the anionic chloride complexes of Rf with those of Hf, Cm, and Fm. Extraction chromatography with a column containing trioctylmethylammonium chloride on an inert fluorocarbon powder was used rather than an ion-exchange resin column because of the faster kinetics. The products recoiling from the nuclear reaction were transported to a fast computer-controlled apparatus that performed the many repetitive experiments necessary to get statistically significant information. The results showed that in 12 M HCl solutions the anionic chloride complexes of Rf and the Hf tracer were strongly extracted by the quaternary amine while the trivalent actinides were not and ran through the column. The chloride complexation of Rf was clearly similar to Hf and much stronger than that of the trivalent actinides, again confirming its position in group 4 of the periodic table. This experiment is especially noteworthy in that it was the first sophisticated, computer-controlled automated system to be used to perform very rapid solution chemistry experiments on an atom-at-a-time basis.

Following these pioneering studies of Rf, a rather long period of time elapsed before additional experiments were conducted in the late 1980s. MCDF calculations (Desclaux and Fricke, 1980; Glebov *et al.*, 1989) indicated that relativistic effects might cause replacement of the expected 6d orbital in Lr by $7p_{1/2}$ orbitals. Spurred by Keller's (1984) extrapolation that Rf might have the configuration $7s^27p^2$ rather than $6d^27s^2$ as expected by analogy to the $5d^26s^2$ configuration of Hf, experimental investigations of relativistic effects in Rf were undertaken. In 1989, Zhuikov *et al.* (1989) examined the volatility of 3-s ^{259}Rf relative to Au, Tl, and Pb tracers in on-line measurements in a quartz column at 1170°C. Under reducing conditions using Ar/H_2 carrier gas, they found that Hf and Rf did not pass through the column while the other elements did. They deduced a lower limit of 370 kJ mol^{-1} for the sublimation enthalpy of metallic 104, much higher than for Pb and other heavy 'p-elements'. Later MCDF relativistic calculations (Glebov *et al.*, 1989; Johnson *et al.*, 1990) indicated that the ground state of Rf is 80% [$6d7s^27p$] while the $7s^27p^2$ state is 2.9 eV above the ground state. Zhuikov *et al.* (1990) and Ryzhkov *et al.* (1992) further concluded that there was no basis for expecting any distinct 'p-character' in the chemical properties of Rf and evaluated various experimental approaches for investigating relativistic effects, including volatilities in the elemental state, thermochromatography of tetrahalides, and the stability of lower oxidation states. Zhuikov *et al.* warned that gas chromatography experiments that depend on Rf or Hf in the atomic state are not useful for investigating relativistic effects because of the difficulty in stabilizing the atomic states at the temperatures above 1500°C that are needed for chromatography columns. However, they suggested that thermochromatography of the tetrahalides appeared promising.

(b) Gas-phase chemistry

In the late 1980s an international team of scientists from Switzerland, Germany, and the USA studied the gas-phase properties of the tetrahalides of Rf using the automated isothermal systems OLGA (Türler *et al.*, 1996) and HEVI (Kadkhodayan *et al.*, 1992). The alpha-emitting isotope 75-s ^{261}Rf (see Table 14.3), produced at the LBNL 88-Inch Cyclotron, was used in the experiments and was positively identified by using surface barrier detectors to measure α–α correlations from its known decay scheme. The Zr and Hf activities were identified via gamma spectroscopy. A schematic diagram of HEVI and the arrangement used in some of the gas-phase studies of element 104 tetrachlorides and tetrabromides at LBNL is shown in Fig. 14.14.

The adsorption enthalpies on the SiO_2 surface of the column were calculated from Monte Carlo fits to the measurements of the relative yields as a function of the isothermal temperature between about 100 and 600°C. The Monte Carlo model was introduced by Zvara (1985) and adapted for use with isothermal gas chromatography by Türler (1996). The calculation takes account of the flow rate, half-life of the isotope, temperature, and other variables to generate yield curves as a function of temperature. A rather complete description of this model has been given by Gäggeler (1997). The adsorption enthalpies resulting from the most recent experiments on the tetrabromides (Sylwester *et al.*, 2000) are shown, together with those for the tetrachlorides (Kadkhodayan *et al.*, 1996), in Fig. 14.15.

Under these conditions, Rf produced volatile $RfCl_4$ at about the same temperature as $ZrCl_4$, indicating their similar volatilities. $HfCl_4$ was unexpectedly less volatile. The analysis of the data using the Monte Carlo model gave the following ΔH_{ads} for group 4 chlorides on SiO_2: $-(74 \pm 5)$ kJ mol^{-1} for Zr, $-(96 \pm 5)$ kJ mol^{-1} for Hf, and $-(77 \pm 6)$ kJ mol^{-1} for Rf (Fig. 14.14). $RfCl_4$ showed about the same volatility as $ZrCl_4$ within the error bars as expected from relativistic calculations (Pershina and Fricke, 1994). 'Nonrelativistic' extrapolations gave lower volatility for $RfCl_4$ (Türler *et al.*, 1996). The observation of the relatively high volatily of $RfCl_4$ was a confirmation of the influence of relativistic effects. Experiments with the bromides showed that they are generally less volatile than the chlorides and that $RfBr_4$ is more volatile than $HfBr_4$ (Fig. 14.14), in agreement with theoretical predictions (Pershina and Fricke, 1999). No attempts to measure the volatilities of the fluorides have yet been reported.

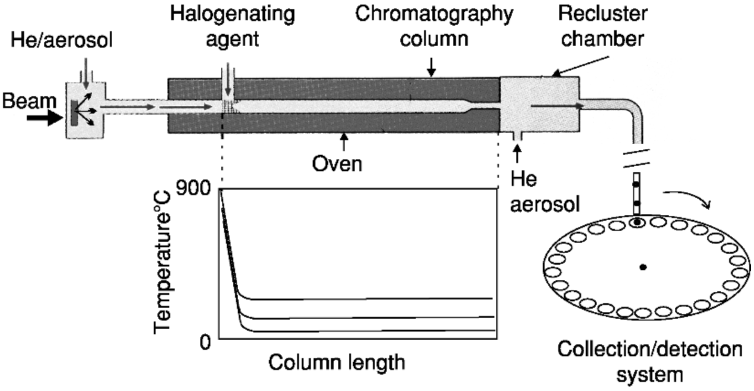

Fig. 14.14 *Schematic diagram of a system used for gas-phase studies is shown. The recoiling products from the reaction are attached to either KCl, KBr, or MoO_3 aerosols and transported in He gas to the entrance to HEVI where they were deposited on a quartz wool plug and halogenated at* 900°C. *Volatile products are transported through the quartz column in flowing He gas and are again attached to aerosols and transported in a gas-jet system and deposited on thin polypropylene films placed on the periphery of a horizontal wheel that is rotated so as to position the foils successively between pairs of surface barrier detectors for* alpha *and SF spectroscopy.*

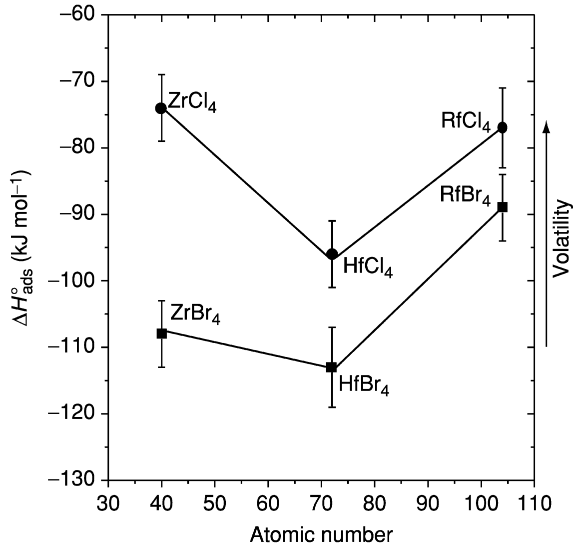

Fig. 14.15 *Adsorption enthalpy values on SiO_2 for Zr, Hf, and Rf chlorides and bromides* (*Kadkhodayan,* 1993*; Kadkhodayan* et al., 1996*; Sylwester* et al., 2000).

(c) Solution chemistry

Additional experimental investigations of the solution chemistry of Rf were initiated in the late 1980s. Manual studies to compare the extraction from aqueous solutions into triisooctylamine (TIOA), tri-*n*-butylphosphate (TBP), and TTA of 75-s ^{261}Rf, its lighter homologs Zr and Hf, and the pseudohomologs Th(IV) and Pu(IV) were reported by the Berkeley group (Czerwinski, 1992b; Czerwinski *et al.*, 1994a,b; Bilewicz *et al.*, 1996; Kacher *et al.*, 1996a,b; Hoffman and Lee, 1999). A comprehensive review and summary, as of 1997, of the results from experiments on the extraction behavior of Rf was given by Gregorich (1997a). Later studies used ARCA for repeated chromatographic studies and SISAK for very rapid automated liquid–liquid extractions (Alstad *et al.*, 1995; Omtvedt *et al.*, 2002).

(*i*) *Extraction of anionic species*

Batch extractions

In repeated manual extractions taking about a min each and using only microliters of each phase, the effect of chloride concentration and pH on extractions into TIOA were investigated. In general, these extractions (Czerwinski *et al.*, 1994a,b; Kacher *et al.*, 1996a,b) confirmed the earlier results (Hulet *et al.*, 1980), showing that Rf generally behaves as a group 4 element, and unlike the trivalent actinides, forms negatively charged complexes in concentrated HCl that are extracted efficiently. Rf is nearly 100% extracted into TIOA from 12 M HCl, as are Zr and Nb, while Th and trivalent actinides and lanthanides are poorly extracted.

Extractions into TIOA/xylene from HF solutions were also performed (Kacher *et al.*, 1996b). Although there were some experimental difficulties with the experiments, they clearly showed that Rf was extracted from 0.5 M HF but not from 4 M HF. This was attributed to the extraction of F^- at the higher fluoride concentrations, which complexes all of the TIOA, thus limiting the extraction of the anionic metal fluoride complexes. The extractability of the group 4 elements was found to decrease in the order: Ti $>$ Zr $\sim$ Hf $>$ Rf. This behavior was cited as evidence that the equilibria for the group 4 elements are the same and that Rf is extracted in the chemical form RfF_6^{2-} similarly to Ti, Zr, and Hf, which are extracted as MF_6^{2-} complexes.

Column separations

Pfrepper *et al.* (1998) produced ^{261}Rf and $^{165-169}$Hf isotopes (few-minute half-lives) simultaneously at the Dubna U-400 cyclotron and devised a multi-column technique for continuous on-line processing and detection of ^{253}Es, the long-lived descendant of ^{261}Rf. Using an anion-exchange column with 0.27 M HF/ 0.1–0.2 M HNO_3 as the eluant, Es was eluted and measured to obtain the K_d values for Rf, which were nearly the same as those for Hf. The ionic charge of the Rf complex was obtained from measurements of K_d vs. [HNO_3]. The ionic charge was calculated to be –(1.9 ± 0.2), similar to that of Hf, indicating formation of RfF_6^{2-}. This again indicates that Rf is similar to Hf and to other members of group 4. The technique, though extremely complex, ensures that equilibrium has been attained and has the virtue of measuring both Rf and Hf in the same experiment. However, it does not give any additional information about specific differences in the chemical behavior of Rf and of its lighter homologs and pseudohomologs.

Other researchers (Haba *et al.*, 2002) used batch extractions with an anion-exchange resin (CA08Y) to determine K_d values for the Rf homologs Zr and Hf, and the pseudohomologs Th(IV) and Pu(IV) as a function of HCl and HNO_3 concentrations in order to determine appropriate conditions for on-line studies with ^{261}Rf and ^{169}Hf at the same time. They then performed on-line measurements of ^{261}Rf and ^{169}Hf produced in ^{18}O-induced reactions with a ^{248}Cm target containing natural Gd, to study their sorption behavior on this anion-exchange resin in solutions of 1.0–11.5 M HCl and in 8 M HNO_3 using an automated ion-exchange separation apparatus coupled to an alpha-spectroscopy detection system. They found that the adsorption of Rf increased steeply with increasing HCl concentration between 7.0 and 11.5 M, as did the adsorption of Zr and Hf, indicating that like Zr and Hf, anionic complexes such as $Rf(OH)Cl_5^{2-}$ or $RfCl_6^{2-}$ are formed. Their results are consistent with previous experiments with Aliquat 336 (Hulet *et al.*, 1980) and TIOA (Czerwinski *et al.*, 1994a). The adsorption order in the region of 9 M HCl was Rf > Zr > Hf. This behavior is quite different from that of Th(IV), whose distribution coefficients are less than 1 and further decrease in this region. In 8 M HNO_3, more than 80% of Rf, Hf, and Zr were eluted while 99% of the pseudohomolog Th(IV) was retained, indicating that Rf, like Hf and Zr, formed cationic or neutral species, unlike Th(IV) or Pu(IV).

(*ii*) *Extraction of neutral complexes with TBP*

It is well known that TBP extracts neutral complexes by forming adducts with neutral metal salts that are extractable into the TBP organic phase. The adduct is presumed to have the form $ML_4 \cdot x\mathrm{TBP}_{(org)}$ where x can be determined by measuring the slope of log K_d as a function of log [TBP]. If the TBP concentration is too high, aggregation of the TBP molecules may give erroneous results. Furthermore, there are very large statistical uncertainties in determination of K_d values when the small number of atoms produced is measured only in the organic phase. The calculation of K_d = (extraction yield)/(1−extraction yield) is probably only accurate for relatively small K_d values because if the K_d values are high the denominator becomes a very small difference between two very similar numbers with large errors. Extractions from HCl into TBP are also unusually dependent on both [H^+] and [A^-], indicating that hydrolysis plays an important role.

Batch extractions

Extractions of ^{261}Rf, Hf, Zr, Th, and Pu into TBP were first studied by Czerwinski *et al.* (1994b) using manual extractions from aqueous solutions of 8, 10, and 12 M HCl, with $[H^+]$ held constant at 8, 10, and 12 M and $[Cl^-]$ adjusted with LiCl to 8, 10, and 12 M. The Zr, Th, and Pu(IV) results were obtained from off-line tracer experiments. In pure HCl solutions, the extraction of Pu, Th, and Zr was nearly 100% at all three molarities, consistent with previously reported (Peppard *et al.*, 1956) data for Zr and Th, while extraction of Rf and Hf was low at 8 M and increased to higher values at 10 and 12 M HCl. Extraction of Hf remained lower than that of Rf at all molarities. With $[H^+]$ held at 8 M, an increase in $[Cl^-]$ to 10 and 12 M resulted in significant decreases of both Rf and Pu extraction into TBP/benzene while extraction of Zr, Hf, and Th remained high. This was interpreted as indicating that chloride complexation is stronger for Rf than for Zr, Hf, and Th, and that Rf, similarly to Pu(IV), forms anionic species of the type MCl_6^{2-}, which does not extract into TBP. The trends in extraction yields vs. $[H^+] = 8$, 10, and 12 M for $[Cl^-]$, which are constant at 12 M, show that the Hf yields are independent of $[H^+]$ and remain nearly constant between 75 and 80% while the extraction yields for Rf sharply increase, indicating different extraction mechanisms for Rf and Hf. At the highest $[Cl^-]$ concentrations, the extraction yield for Hf follows that of Th, which does not form anionic chloride complexes, while the trend for Rf follows Pu(IV), which does. Problems with losses of Rf and Hf on Teflon collector foils used in some of the on-line studies resulted in absolute values that were probably too low for the higher K_d values. Nevertheless, much useful information can be obtained from an examination of relative extraction yields.

The extractability decreases in the order Zr > Pu > Rf > Hf > Th for 8 M HCl, in the order Zr > Pu > Rf ~ Th > Hf for 10 M HCl, and in the order Zr ~ Rf ~ Pu > Th > Hf for 12 M HCl. A striking observation that needs to be investigated further is that with $[H^+]$ held constant at 8 M the extraction of Rf increases to ~80% when $[Cl^-]$ is increased to 10 M and then decreases sharply to ~25% when $[Cl^-]$ is increased to 12 M, similar to the extraction of Pu(IV), which decreases to less than 20% while that of Zr remains at ~100% and Hf and Th increase to 80–90%. This would indicate formation of an anionic species of Rf similar to $PuCl_6^{2-}$ and unlike all the other group 4 elements and Th. Extraction as a function of $[H^+]$ between 8 and 12 M with $[Cl^-]$ constant at 12 M indicated little effect on the extraction of Zr and Hf, but the extraction of Rf increased from 25 to ~100%. The extracted complex might be of the type $RfCl_4 \cdot x HCl \cdot y TBP$, where x is 1 or 2, values that have been observed in extraction of other elements into TBP.

Kacher *et al.* (1996a) conducted studies to compare extractions of these elements from HBr solutions into TBP with the results of the previous HCl/TBP experiments. They expected the stability of the bromide complexes to differ from that of the HCl complexes because bromide is a larger and more polarizable anion than chloride. They found that the most likely extracted form of Zr was $ZrBr_4 \cdot {\sim}1TBP$ for the HBr/TBP system and ~2TBP for the HCl/TBP system. In general, the extraction of these elements from HBr is much lower than from HCl, and 0.35 M TBP was used to obtain increased extraction. At 9 M HBr, essentially no Rf was extracted but increasing $[Br^-]$ with LiBr to 10, 12, and 13 M resulted in more than 88% extraction of Zr and Rf and ~80% extraction of Th throughout this range while extraction of Pu(IV) increased from about 25 to 70%. In these experiments, Pt collection foils were used to avoid losses of the on-line cyclotron-measured isotopes Rf and Hf. (The Pu tracer was fumed with $NaNO_2$ to make sure it was in the tetravalent state.) Extraction as a function of [HBr] from 7.75 to 9 M HBr solutions was investigated, but without addition of LiBr neither Th nor Rf was extracted. Zr begins to extract at a somewhat lower concentration than Hf, indicating a somewhat stronger tendency to form neutral complexes; Ti extracted only above 9 M HBr. Thus the order of extractability is $Zr > Hf >> Ti \sim Rf$, a reversal in the trend $Zr > Rf > Hf$ seen in the HCl/TBP extractions. Experiments to examine the extraction at concentrations up to 12 M HBr are necessary to confirm this trend.

Column experiments

In order to check and resolve some of the differences in the previously reported results for the TBP/HCl system, Brüchle *et al.* (1998) and Günther *et al.* (1998) measured K_d values for the TBP/HCl system for the carrier-free radionuclides ^{98}Zr (from fission), and ^{169}Hf and ^{261}Rf produced on-line at the Paul Scherrer Institute (PSI) cyclotron. The recoiling products were transferred via He(KCl) jet to ARCA II whose 40 microchromatographic columns (1.6-mm diameter × 8-mm long) were filled with the inert support Voltalef™ (Lehmann & Voss, Hamburg, Germany) coated with undiluted TBP. The use of undiluted TBP is expected to shift the complete extraction of both Zr and Hf to higher HCl concentrations, as shown earlier (Czerwinski *et al.*, 1994b), and prior batch experiments from >10 M HCl confirmed this. From 8 M HCl, 80% Zr and only 20% Hf extraction was found. Chromatographic separations of Zr and Hf were then conducted with ARCA. The radioactive ions were sorbed from 12 M HCl. Most (75%) of the Hf and no Zr were eluted with 8 M HCl and then the remaining Hf and Zr were stripped with 2 M HCl. The K_d for Hf was calculated to be 53 from the relationship, $K_d = [(100)(\%aq)^{-1}{-}1][vol_{aq}/vol_{org}]$, consistent with batch measurements. Subsequent experiments to determine the K_d for Rf in 8 M HCl were conducted at the PSI cyclotron in the same way. After 90 s collection times, the reaction products were sorbed on the columns in 12 M HCl. Hf and Zr fractions were eluted with 8 and 2 M HCl, respectively, and analyzed for alpha decays from ^{261}Rf and its daughter ^{257}No. Two α–α mother–daughter correlations were observed in the Hf fraction and three in the Zr fraction, indicating that Rf extraction is somewhere between that of Hf and Zr in 8 M HCl. After lengthy and complex considerations of contributions from random and background effects, they (Günther *et al.*, 1998) concluded that the K_d for Rf is 150 compared to the K_d of 1180 for Zr and of 60 for Hf obtained from the batch experiments with 8 M HCl, giving the order of decreasing extraction Zr > Rf > Hf. The percentage extraction in their work, 52% for Rf and 25% for Hf from 8 M HCl, appears to be consistent with that of ~60% for Rf and ~25% for Hf obtained by Czerwinski *et al.* (1994b). In a detailed discussion of corrections for the differences in volumes used in the two studies and the dependence of the equilibrium constant on the differences in the TBP concentrations in the organic phase, they finally concluded that Czerwinski's K_d values for Hf and probably for Rf are significantly too low (probably due to sorption on the Teflon collection foils), but that their K_d values were also lower than expected for undiluted TBP because of aggregation effects.

Thus it appears that measurements of relative extractability can be obtained for experiments carried out under exactly the same conditions, but that determination of absolute K_d values is subject to numerous difficulties. The inconsistencies in the K_d results reported by various researchers are probably due in large part to differences in the exact details of the experimental conditions and can greatly affect the measurements, as pointed out above. In addition, results of on-line experiments for the transactinides often are compared with results of off-line tracer studies of their homologs. Furthermore, in the very rapid separations with ion-exchange resin columns required in the study of short-lived isotopes it is necessary to make sure that equilibrium is attained in order to obtain valid results. Some evidence of non-equilibrium effects was reported by Paulus *et al.* (1999) for most amines other than Aliquat 336 and will require further study. Care must be taken in batch experiments to remove any fluoride ion that may have been present in stored tracer solutions. Kacher *et al.* (1996b) found that fluoride ion concentrations as low as 0.02 M reduced the K_d values for extraction into TBP from HBr by about 2 for Hf and 10 for Zr.

(*iii*) *Extraction of fluoride complexes*

Cationic complexes

The fluoride complexation of Zr, Hf, ^{261}Rf, and Th in mixed HNO_3/HF solutions was investigated (Strub *et al.*, 2000) by studying K_d values for both anion- and cation-exchange resins using ARCA. A detailed study of the complexation as a function of fluoride- and nitrate-ion concentrations was performed. They found all four elements to be strongly sorbed on the cation-exchange resin Aminex A6 at HF concentrations below 0.001 M. The K_d values for Zr and Hf decreased between 0.001 and 0.01 M HF, presumably due to the formation of fluoride complexes. Those for Rf and Th decreased at an order of magnitude higher HF concentrations, and the K_d for Rf remained very high even in 0.01 M HF. The K_d for Rf was found to be >148 in 0.1 M HNO_3/ 5×10^{-4} M HF while under these conditions ^{265}Sg had been found to elute (Türler *et al.*, 1998a). As discussed in Section 14.5.3c (Eqs. 14.1 and 14.2) at [HF] < 0.01 M, positively charged complexes of higher charge will be formed, which will sorb on the cation resin. The observed order of sorption Rf > Hf $\geq$ Zr corresponds to the opposite trend in the complex formation, as discussed in Section 14.5.3c, in agreement with theoretical predictions.

Anionic complexes

Trubert *et al.* (1999) determined distribution coefficients for Zr, Hf, and Rf on the macroporous anion exchanger Bio-Rad (Bio-Rad Laboratory, Hercules, CA, USA) AG® MP-1 from HF/HCl media with concentrations between 0.02 M and concentrated HF and [HCl] $\leq$ 0.8 M. They used batch experiments with Zr and Hf tracers and examined the K_d values as a function of free H^+, Cl^-, and F^- species in solution. They performed on-line column experiments using their automated system at the tandem accelerator at Orsay where ^{261}Rf and ^{167}Hf were produced.

A rather complicated two-column technique (Pfrepper *et al.*, 1998) was used in which the Rf or Hf parents were partially sorbed on a first anion-exchange resin column and the remainder plus the trivalent decay products Fm and Lu are sorbed on a subsequent cation-exchange resin column. One-hour irradiation times were used and the longer-lived ^{253}Fm–^{253}Es granddaughters of ^{261}Rf were finally measured to deduce the K_d for Rf. The one K_d value for Rf obtained for 0.02 M HF/0.4 M HCl was slightly higher than those for Zr and Hf, respectively, in agreement with the theoretically predicted trend Rf $>$ Hf $\geq$ Zr (Section 14.5.3c), but more data are needed before any conclusions can be drawn.

An increase in K_d values for Zr and Hf was observed by Strub *et al.* (2000) with the anion-exchange resin (similar to Bio-Rad AG®1-X8) and solutions between 0.001 and 0.01 M HF, consistent with the observation of decreasing values in the HF range for the cation-exchange resin. Surprisingly, the results of the experiments showed that again Rf and Th behaved differently from Zr and Hf and did not show the high K_d values expected for anionic fluoride complexes even at HF concentrations as high as 1 M. Rf seemed to resemble Th rather than Zr and Hf, which was different from the theoretical predictions (Pershina *et al.*, 2002b). There were indications that the action of the counter-ion was responsible for the unexpected behavior, and by varying the NO_3^- concentration Strub *et al.* (2000) were able to show that Rf did form anionic species, but apparently NO_3^- competed more effectively than F^- for the binding sites on the anion resin. Additional experiments are needed to investigate the effect of varying [NO_3^-] at constant [F^-] and varying [F^-] at much lower [NO_3^-].

(*iv*) *Extraction of cationic complexes*

TTA batch extractions

The chelating agent TTA extracts cationic species from aqueous solutions. Its electron donor groups are oxygen atoms and the tendency for different metals to be extracted is a measure of their affinity for oxygen atoms. This affinity should have a strong correlation with the log of the first hydrolysis constants of the metal ions. Thus TTA can be used to obtain information about hydrolysis of the group 4 ions.

The Berkeley group (Czerwinski, 1992b) performed some preliminary measurements of the extraction of the group 4 elements, Th, and Pu from 0.1 and 0.4 M HCl into 0.5 M TTA/benzene. The initial measurements gave K_d values, decreasing in the order Zr > Hf ~ Pu > Rf > Th, similar to the decreasing values of the logs of the first hydrolysis constants that have been measured for Zr, Hf, Th, and Pu (Baes and Mesmer, 1976). These extraction results are discussed by Gregorich (1997b), who states that on this basis the tendency for Rf to hydrolyze should be between that for Th and Pu and less than that for Zr and Hf. This prediction is in agreement with the theoretical calculation for the hydrolysis of group 4 elements (Pershina *et al.*, 2002b). However, more tracer measurements of the effect on extraction as a function of [HCl] and [TTA] are needed to determine if the equilibria involved in the extraction of Pu and Th are the same as for the group 4 elements. The kinetics of TTA extractions are relatively slow so they may not be the best choice for rapid separations of short-lived species.

HDBP extractions with SISAK

The SISAK microcentrifuge liquid–liquid extraction system described in Section 14.3.3b was used to study extraction of 4.7-s ^{257}Rf [1] from 6 M HNO_3 and 0.25 M dibutylphosphoric acid (HDBP) in toluene. ^{257}Rf was produced at the LBNL 88-Inch Cyclotron in the ^{208}Pb(^{50}Ti,n) reaction, with a cross section of ~10 nb.[1] In preliminary test experiments, ^{257}Rf was pre-separated in the BGS, which reduced unwanted background activities by more than three orders of magnitude, and then transferred to the specially designed Recoil Transfer Chamber (RTC) attached at the BGS focal plane (Kirbach *et al.*, 2002). The Rf ions passed from the BGS detector chamber (held at a pressure of only 1.3 mbar) through a thin Mylar window into the RTC containing He gas whose pressure could be varied from 480 to 2000 mbar, as appropriate, to stop the separated ions. The positive identification of Rf atoms entering the RTC was accomplished by measuring their α decay with an array of Si-strip detectors and six to seven ^{257}Rf–^{253}No α–α correlations per hour were found in these experiments. They were then sorbed on aerosols in a He/KCl gas-jet system and transported without chemical separation directly to the SISAK liquid scintillation detection cells. The transport time was measured with $^{170-x}$Hf isotopes (half-lives > 1 min) produced at the same time in ^{120}Sn(^{50}Ti,xn) reactions. An alpha event in the appropriate preset energy range caused the cell to close and to switch to daughter mode. The cell remained closed for more than five ^{253}No ($t_{1/2}$ = 1.6 min) daughter half-lives. In this way an α–α correlation matrix was successfully obtained and clearly showed that the SISAK liquid scintillation system could detect nuclides at a rate of less than one atom per hour. A number

---

[1] ^{257}Rf has been reported (Hessberger *et al.*, 1997) to have a metastable state with a half-life of ~4.0 s from which ~60% of the α-decay is estimated to originate and a ground state that α-decays with a half-life of ~3.5 s, but this has not yet been confirmed. Both decay primarily by α-emission so for the purposes of this experiment it makes very little difference.

of other important improvements including pulse-shape discrimination to reduce the beta-background, real-time scintillation yield monitoring by continuous measurement of the Compton edge of ^{137}Cs γ-rays, and improvements in the detection cell efficiencies were also made. Experimental details of the system have been published (Omtvedt *et al.*, 2002). The pre-separation thus permits designing studies of the chemical properties of Rf without the necessity for adding time-consuming and yield-loss steps to remove radioactive isotopes that would interfere with its detection and measurement.

After this successful demonstration, liquid–liquid extraction experiments were performed to compare the extraction behavior of Rf from 6 M HNO_3 into 0.25 M HDBP/toluene with that of its lighter homologs Zr and Hf. A schematic diagram of the setup is shown in Fig. 14.16. The activity-containing aerosols in the He jet are dissolved in the 'de-gasser' centrifuge containing 6 M HNO_3 and the He gas is removed. The main extraction is performed in the next centrifuge. An important step is to wash any dissolved HNO_3 from the organic phase before adding the scintillator ingredients because the acid will cause degradation of the energy resolution, as will any O_2. It is removed by sparging with He, which is removed in the last centrifuge. Flow rates of the order of 0.4–0.8 ml s^{-1} were used and the centrifuges typically operate at 25000–40000 rpm. This was the first time a transactinide, Rf, was extracted and unequivocally identified by the SISAK liquid scintillation system and demonstrates that this method can be used to investigate the chemical properties of the transactinides. The results indicate that Rf behaves similarly to Zr and Hf, as expected. In this demonstration, the conditions were chosen to maximize extraction of Rf and the other group 4 elements rather than to investigate possible differences among them. The next step will be to use the pre-separation technique to conduct experiments with chemical systems designed to distinguish differences in the behavior of individual elements within a periodic table group.

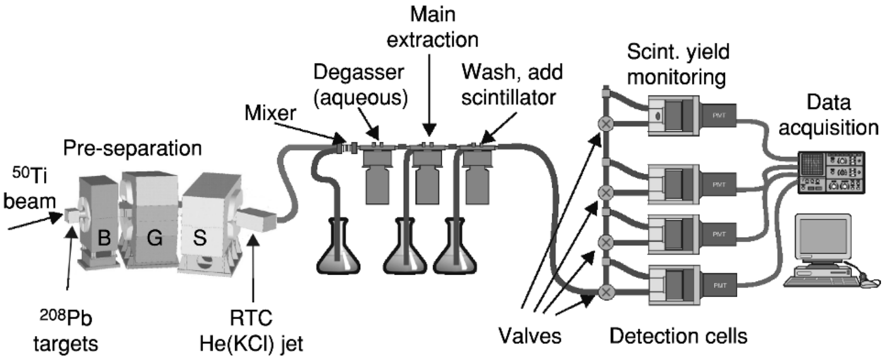

Fig. 14.16 *Schematic diagram of a typical SISAK liquid–liquid extraction configuration with BGS as a pre-separator.*

14.6.2 Chemistry of dubnium/(hahnium) (105)

As discussed in Section 14.5 and shown in Tables 14.4–14.6, the ground state configuration for element 105 is predicted to be $6d^37s^2$ although the relativistic destabilization of the 6d electrons and the close proximity of the 7s and 6d levels should stabilize the higher oxidation states of the 6d elements relative to their 5d homologs. Thus, the most stable oxidation state of Db is expected to be 5+ and the 3+ and 4+ states are even less stable than in its lighter homolog Ta.

(a) Historical

In the only published studies of the early chemistry of element 105, Zvara *et al.* (1974, 1976) reported investigations of the volatilities of the chlorides and bromides of element 105 with 1.8-s ^{261}Db compared to those of Nb and Hf. They used a thermochromatographic system similar to that used in the studies of Rf. Again, they detected SF events from the SF branch in mica track detectors placed along the chromatography column. After corrections for the much shorter half-life of ^{261}Db, the distribution of the fission tracks was compared with the adsorption zones of the tracers (3.3-min ^{169}Hf and 14.6-h ^{90}Nb). From these experiments, Zvara *et al.* concluded that the volatility of Db bromide was less than that of Nb bromide and about the same as that of Hf bromide. Again, only SF events were detected and because the SF branch ($\leq$18%?) is still not well known, it is not certain that the detected fissions belonged to element 105. A complete discussion of these early results was given by Hyde *et al.* (1987), who interpreted these results as indicating that Db behaved more like the group 4 element Hf than like Nb and Ta.

(b) Solution chemistry

No further studies of element 105 chemistry were reported until 1988 when Gregorich *et al.* (1988) reported the very first study of its behavior in aqueous solutions. These experiments were undertaken simply to show whether its most stable oxidation state in aqueous solution was 5+. At that time it had been postulated (Keller, 1984) that Ha might have a $7s^26d7p^2$ rather than a $6d^37s^2$ valence configuration expected by analogy with Ta, whose most stable state in aqueous solution is 5+. The α-emitting, 35-s ^{262}Db (then called Ha), produced in the reaction of ^{18}O with the radioactive target, 320-d ^{249}Bk (see Table 14.3) at the LBL 88-Inch Cyclotron, was used. The recoiling reaction products attached to KCl aerosols were transferred from the target system and outside the cyclotron shielding via a He gas-jet system to a 4-position collection site in a fume hood located outside the radiation area. Here very simple 'manual' chemistry was performed using only a few microliters of solution. The sorption of Ha on glass cover slips after fuming twice with concentrated nitric acid and washing with 1.5 M HNO_3 was compared with that of tracers of the group 5 elements Nb and Ta and with the group 4 elements Zr and Hf produced on-line under similar conditions. These group 5 elements are known to sorb on glass surfaces while the group 4 elements do not. Measurements of the energy and time distribution of the alpha decay and of time-correlated pairs of alphas from ^{262}Db and its 4-s daughter ^{258}Lr were recorded and analyzed to provide positive identification that element 105 was detected. Some 800 manual extractions taking about 50-s each were performed and a total of 26 alpha and 26 SF events were recorded. Element 105, like its group 5 homologs Nb(v) and Ta(v), was found to sorb on the glass surfaces while Zr and Hf and the trivalent actinides did not. This confirmed the group 5 character of Ha and demonstrated that it properly belonged in the periodic table as the heaviest member of group 5. Its extraction behavior into methylisobuytlketone from mixed HNO_3/HF solutions under conditions in which Ta was extracted but Nb was not was also investigated (Gregorich *et al.*, 1988). Surprisingly, it was found that element 105 did not extract and that its behavior was more like Nb than Ta, indicating that details of complexing behavior cannot be predicted based only on simple extrapolations of trends within a group in the periodic table. This behavior was explained much later (Pershina, 1998b), as discussed in detail in Sections 14.5.3b and 14.5.3c.

This surprising result provided the impetus for further exploration of the complex behavior of element 105. Chromatographic experiments using ARCA II to carry out the thousands of required repetitive experiments were performed jointly by the GSI/Mainz, PSI/Bern, and LBL/Berkeley groups in 1988, 1990, and 1993 at LBL, and in 1992 at GSI. In the first extraction chromatography column separations with the anion exchanger TIOA on inert supports, all the group 5 elements and Pa(v) were extracted from concentrations of HCl > 10 M. At lower concentrations of HCl, small amounts of added HF gave selective back extraction, showing different chemical behavior for these elements (Kratz *et al.*, 1989; Zimmermann *et al.*, 1993). Element 105 showed a marked non-Ta-like behavior at concentrations below 12 M HCl and follows the behavior of Nb and the pseudohomolog Pa(v). Because of this similarity to Nb and Pa, it was concluded that the complex was $DbOX_4^-$ or $[Db(OH)_2X_4]^-$. ARCA was also used to investigate the extraction of Db from HBr into diisobutyl carbinol (DIBC), a specific extractant for Pa, with subsequent elutions with mixed HCl/HF and HCl. The extraction sequence Pa $>$ Nb $>$ Db was obtained and attributed to the increasing tendency to form non-extractable polynegative complexes (Gober *et al.*, 1992). Due to the difficulties encountered in the theoretical interpretation of the results of these experiments because of the small amounts of HF added to the various halide solutions (long recommended for reducing hydrolysis of group 5 elements to prevent them from unwanted sorption on containers, etc.), it was recommended that future experiments be carried out in pure rather than mixed halide solutions (Pershina, 1998b).

Experiments conducted with ARCA also showed that Ha was eluted promptly from cation-exchange columns with α-hydroxyisobutyrate (Kratz *et al.*, 1992;

Schädel *et al.*, 1992) together with Nb, Ta, and Pa, whereas trivalent and tetravalent ions were retained, again confirming that Ha is most stable in aqueous solution as a pentavalent species. The new isotope 27-s ^{263}105 was also identified in these experiments.

Subsequently, Pershina (1998b) and Pershina and Bastug (1999) predicted the sequence Pa >> Nb $\geq$ Db > Ta for extraction into the anion exchanger TIOA from halide solutions. Paulus *et al.* (1999) remeasured K_d values for Nb, Ta, and Pa in new batch extraction experiments with the quaternary ammonium salt Aliquat-336 and pure HCl, HBr, and HF solutions. New chromatographic column separations with ARCA II were then conducted to study chloride and fluoride complexation separately. The Aliquat-336/HCl experiments confirmed the extraction sequence Pa >> Nb $\geq$ Db > Ta, as theoretically predicted. In the Aliquat 336/HF system the K_d value for element 105 in 4 M HF was >570, close to those for Nb and Ta of >1000 and different from that of ~10 for Pa.

In his review of transactinide chemistry, Kratz (1999b) discussed all the results for the ARCA experiments on element 105 in detail and concluded that the amine extraction behavior of dubnium halide complexes is always close to Nb, consistent with the predicted inversion of the trend in properties between the 5d and the 6d elements. In pure HF solution, Db differs most from Pa, and in pure HCl solution, it differs from both Pa and Ta. In mixed HCl/HF solutions, it differs markedly from Ta. The experimental results are in agreement with the calculated Gibbs energy changes (see Section 14.5.3c) of 12, 20, and 22 eV for the reactions for complex formation (Pershina *et al.*, 2002b) of the fluorides, chlorides, and bromides, respectively. For example, the equilibrium between hydrolysis and halogenation always favors formation of an extractable fluoride complex rather than the hydrolyzed species even at very low HF concentrations, whereas [HCl] > 3 M is required for formation of extractable chloride complexes, and [HBr] > 6 M is required for the formation of extractable bromide complexes.

(c) Gas-phase chemistry

The first on-line isothermal gas chromatography experiments were performed by an international group (Gäggeler *et al.*, 1992; Türler *et al.*, 1992) using OLGA II with 35-s ^{262}Db. The volatile species were deposited on a moving tape that was subsequently stepped in front of six large-area-passivated implanted planar Si detectors to measure alpha particles and SF events to identify element 105. From the yields as a function of isothermal temperature measured for the bromides of Nb, Ta, and Db, adsorption enthalpies of –88, –94, and –155 kJ mol^{-1}, respectively, were obtained from least-squares fits of Monte Carlo simulations to the isothermal yield curves. Within the error limits, the adsorption enthalpies (volatilities) are nearly the same for Nb and Ta, but Db appears to be significantly less volatile. It was postulated that traces of oxygen in the system might have led to formation of the oxytribromide of Db, which was predicted to be less volatile than the pentabromide (Pershina *et al.*, 1992b), and Db was also predicted to have a much stronger tendency to form oxyhalides than Nb or Ta, as discussed in Section 14.5.2b.

Investigations (Kadkhodayan *et al.*, 1996; Türler, 1996) of the volatility of the chlorides of the group 5 elements showed that they were more volatile than their respective bromides, with element 105 being similar to Nb, but for Ta, only a species with much lower volatility, presumably $TaOCl_3$, was observed. In more recent experiments conducted by Türler *et al.* (1996) the volatilities of Db and Nb chlorides were studied as a function of controlled partial pressures of O_2. It was shown that the concentrations of O_2 and oxygen-containing compounds were extremely important in determining whether or not the oxychlorides were formed and in determining the resultant volatilities of the Nb and Db compounds. The results showed that for pO_2 between 1 ppm (vol.) and 80 ppm (vol.) both a volatile species and a less volatile species, presumably MCl_5 and $MOCl_3$, were formed in about equal amounts. The more volatile species, $NbCl_5$, was shown to be the major component at $pO_2 \leq 1$ ppm (vol.). Subsequent experiments with Db were conducted under similar conditions and a two-step yield curve was obtained indicating that both $DbCl_5$ and $DbOCl_3$ were present. Adsorption enthalpies of –80 and –99 kJ mol^{-1} for the Nb species and –98 and –117 kJ mol^{-1} for the Db species were deduced, indicating that the Db species are less volatile than those of Nb. As predicted, the oxychlorides are less volatile than the chlorides, but the experiments need to be extended to lower temperatures for Db with pO_2 kept as low as possible to see if $DbCl_5$ can be measured as a single component, and the measurements need to be extended to Ta.

14.6.3 Chemistry of seaborgium (106)

(a) Historical

Early attempts were made to study the chemistry of Sg using 0.9-s ^{263}Sg produced in the ^{249}Cf(^{18}O,4n) reaction at the U-400 cyclotron at Dubna (Timokhin *et al.*, 1996; Yakushev *et al.*, 1996). Recoiling reaction products were thermalized and carried in Ar gas from the target chamber into a fast on-line TC consisting of a 3.5 mm i.d. by 120 cm long tube of fused SiO_2 where air saturated with $SOCl_2$ was used as a chlorinating agent. The inner surface of the silica column served as a solid-state detector for SF events. In two experiments, Timokhin *et al.* (1996) found a total of 29 fission tracks in zones in the temperature region of 150–250°C, close to the deposition temperature of 16-s ^{166}W. No tracks were found in the start zone or outside the indicated region while alpha activities from actinide products were seen mostly in the start zone. They claimed that this was the first chemical identification of element 106 as SgO_2Cl_2 and that it formed an oxychloride similar to that of W. However, the assignment of the fissions to element 106 based on detection of a small fission branch of ^{263}Sg is uncertain because it was not shown that the observed fissions did not belong to elements 104 or 105. Kratz (1999b) gave a detailed critique of the Timokhin reports and concluded that their conclusions were not justified.

The discovery by a Dubna–Lawrence Livermore National Laboratory (LLNL) collaboration (Lazarev *et al.*, 1994; Lougheed *et al.*, 1994) of the longer-lived isotopes ^{266}Sg and ^{265}Sg in ^{248}Cm(^{22}Ne,4n,5n) reactions with cross sections of ~80 and 260 pb for 116 and 121 MeV ^{22}Ne projectiles, respectively, made chemical studies of element 106 much more feasible. These new isotopes were separated and identified using the gas-filled recoil separator at the Dubna U-400 cyclotron. The partial alpha half-lives of 2–30 s for ^{265}Sg and 10–30 s for ^{266}Sg had to be estimated from the measured alpha-decay energies because the time intervals between the Sg isotopes and their Rf daughters were not measured as the signals from the implanted Sg isotopes were below the threshold of their detector system. On-line procedures for studying the chemistry of element 106 with both OLGA and ARCA were developed using W and Mo, the presumed lighter group 6 homologs of element 106.

(b) Gas-phase chemistry

Theoretical predictions (Pershina and Fricke, 1996) based on relativistic MO calculations indicated that SgO_2Cl_2 was the most stable of the Sg oxychlorides. Based on this prediction, the gas-phase chromatography experiments discussed in Section 14.5.2b were conducted under conditions designed to study and identify SgO_2Cl_2. The trend in volatilities of these oxychlorides within group 6, which was predicted using relationships between molecular properties such as covalence or dipole moment and volatility, was $MoO_2Cl_2 > WO_2Cl_2 > SgO_2Cl_2$. Eichler *et al.* (1999) estimated the thermochemical quantities for chlorides, oxychlorides, and oxides of Sg by extrapolation. By the use of empirical correlations, they also found SgO_2Cl_2 to be the most suitable compound for the gas-phase chemistry experiments and expected its standard sublimation enthalpy to be between 125 and 144 kJ mol^{-1}, resulting in an adsorption enthalpy between –97 and –108 kJ mol^{-1} and less volatile than its W homolog.

OLGA III was used in experiments to study the behavior of fission-product Mo isotopes and short-lived W isotopes produced at the PSI Philips cyclotron in preparation for studies of element 106 (Gärtner *et al.*, 1997). The reactive gas mixture O_2, Cl_2, and $SOCl_2$ at 900°C was used; adsorption enthalpies of −90 and −100 kJ mol^{-1} were measured for MoO_2Cl_2 and WO_2Cl_2, respectively, in agreement with predictions. The isothermal yield curve was measured for 58-min ^{229}U produced in the ^{232}Th(α,7n) reaction and the resulting adsorption enthalpy of −91 kJ mol^{-1} was interpreted as indicating formation of UCl_6.

The first chemical experiments on Sg were conducted in 1995 and in 1996 at the Universal Linear Accelerator (UNILAC) at GSI using the ^{248}Cm

(^{22}Ne,4n,5n) reactions to produce ^{266,265}Sg. The reaction products recoiling out of the target were thermalized in helium gas containing carbon aerosols (~0.1 – 1 μm diameter, generated using a spark discharge generator). In about 3 s, the flowing helium gas continuously transported the reaction products attached to the carbon aerosols through a capillary to a quartz wool plug in the reaction chamber (900–1000°C) at the inlet of OLGA III. There the reactive chlorinating gas consisting of O_2, Cl_2, and $SOCl_2$ was added to form volatile compounds, which were transported through the 1.5-mm i.d. × 1.8 m long isothermal quartz chromatography column to a recluster chamber where the chemically separated volatile Sg compounds were again attached to aerosol particles. They were transported within about 6 s to a rotating wheel system and collected on thin polypropylene foils placed in the 64-collection positions located around the periphery of a wheel that was stepped every 10 s to move the collected activity consecutively between pairs of Passivated Ion-implanted Planar Silicon (PIPS) detectors for measurement of alpha and SF activities. The times, energies, and positions of all events were recorded in list mode by a computer. A mother–daughter stepping mode was used to avoid interference from 45-s ^{212}Po^{m} contamination in the alpha energy region of interest (8.8 MeV). In this mode every other position on the 64-position wheel was left empty. When an alpha particle with the decay energy of ^{265,266}Sg was detected in a bottom detector, the daughter Rf nucleus was assumed to have recoiled out of this aerosol deposit onto the top detector. This initiated the daughter mode, causing a single step that positioned the empty collection sites between the detector pairs. The system waited for 2 min to permit the Rf daughter on the detector to decay in an environment clean of contamination. In the first experiment, two decays of ^{265}Sg were identified in daughter mode, one triple correlation was observed in parent mode, and one α–α correlation from ^{266}Sg–^{262}Rf was recorded (Schädel *et al.*, 1997a).

The isothermal temperature was varied in the second experiment conducted in 1996 (Türler *et al.*, 1999) to obtain the adsorption enthalpy for Sg. The experimental conditions were similar except that a 200 s wait in the daughter mode was used. The yield of short-lived W isotopes produced from ^{22}Ne reactions with ^{152}Gd incorporated in the ^{248}Cm target was measured with a high-purity Ge detector and used to monitor the yield of the chemical separation. An adsorption enthalpy of –(96 ± 1) kJ mol^{-1} was obtained for $^{168}WO_2Cl_2$, in agreement with the previous measurement. The isothermal yield curves obtained for SgO_2Cl_2 along with those for the Mo and W compounds are shown in Fig. 14.17. Based on detection of 11 events attributable to Sg, an adsorption enthalpy of –(100 ± 4) kJ mol^{-1} was derived. Adsorption enthalpies of –(90 ± 3) kJ mol^{-1} and –(96 ± 1) kJ mol^{-1} were obtained for Mo and W oxychlorides, respectively. Thus the volatility sequence is $MoO_2Cl_2 > WO_2Cl_2 > SgO_2Cl_2$, as theoretically predicted. Türler *et al.* (1998a) analyzed the decay properties of the 13 correlated chains of ^{265}Sg and ^{266}Sg observed in these experiments and recommended the following half-lives and cross sections for

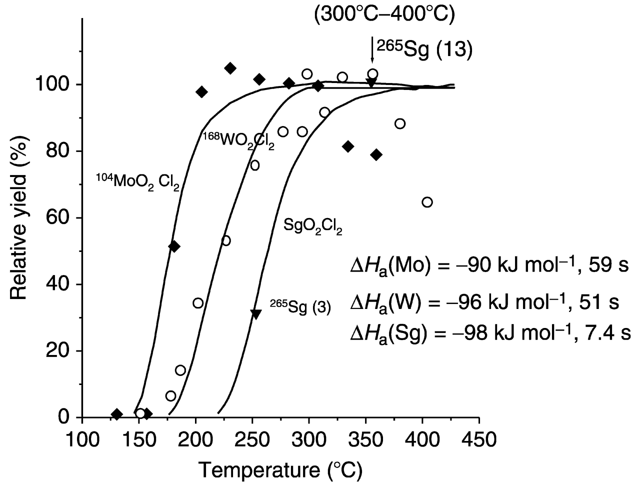

Fig. 14.17 *Relative yields vs. isothermal temperatures for* MoO_2Cl_2 *(solid diamonds),* WO_2Cl_2 *(open circles), and* SgO_2Cl_2 *(solid triangles). (Data from Türler* et al., 1999).

^{22}Ne energies between 120 and 124 MeV: ^{265}Sg, $t_{1/2} = 7.4^{+3.3}_{-2.7}$ s, cross section ~240 pb; ^{266}Sg, $t_{1/2} = 21^{+20}_{-12}$ s, cross section ~25 pb.

Hübener *et al.* (2001) reported that Sg forms volatile oxide-hydroxides similar to those of U and the group 6 elements Mo and W. They used high-temperature on-line isothermal gas chromatography with quartz columns to study Sg and W in the O_2–$H_2O(g)/SiO_2$ system. ^{266}Sg, produced as above, was transported in a He/MoO_3 gas-jet system into the chromatography system. Group 6 elements formed oxide-hydroxides that were volatile at a temperature of 1325 K upon addition of O_2. ^{266}Sg was unambiguously identified by measuring its decay chain. They postulated a dissociative adsorption and associative desorption process to explain their results.

(c) Solution chemistry

The first successful studies of the chemical properties of Sg in aqueous solution were reported by Schädel *et al.* (1997a,b) using ^{265,266}Sg produced in the reaction of 121 MeV ^{22}Ne projectiles with ^{248}Cm targets of 0.15 mg cm^{-2} in the first experiment and 0.95 mg cm^{-2} in the second experiment at the UNILAC at GSI. The emphasis in these experiments was on rapid preparation of samples for alpha spectroscopy with decontamination from the high-energy Bi and Po alpha activities and of trivalent actinides, and efficient separation of the Rf and No daughter activities from Sg. If these conditions are met, Rf and No isotopes observed later in the chemically separated Sg fraction can be presumed to be daughters of Sg precursor nuclei. A system with anionic or possibly neutral oxy- and oxyfluoride compounds was chosen because the formation of neutral and anionic complexes with F^- ions is a characteristic property of group 4, 5, and 6 elements, with distinct differences between the behaviors of the three groups. Based on previous on-line tracer experiments, a solution of 0.1 M HNO_3/5 × 10^{-4} M HF was used to elute the activity from the columns of the cation-exchange resin Bio-Rad AG Aminex A6. The recoiling activities attached to KCl aerosols were swept from the recoil chamber with He gas into a capillary and transported in flowing He some 18 m to ARCA II where they were collected, dissolved, and fed into the 1.8-mm i.d. × 8-mm chromatographic columns filled with the cation-exchange resin Aminex A6. The transport and collection efficiency of about 45% was monitored frequently by checking the production rate of $^{252-255}$Fm isotopes of known cross section. Although the mean separation time of Sg from Rf and No took only 5 s, the evaporation of the eluted samples took about 20 s and on the average, α-particle and SF measurements using a system of eight PIPS detectors were not begun until 38 s after the end of the collection. The energies, times, and detector positions were recorded in list mode on a magnetic disk and tape for later data analysis and identification of the Sg isotopes. Collections times of 45 s were used for most of the 3900 collection and elution cycles. Observation of three correlated α–α events identified as the ^{261}Rf(78 s)$\rightarrow$^{257}No(26 s)$\rightarrow$decay sequence indicated the decay of ^{265}Sg in the chemically separated Sg fractions. From this observation, it was concluded that Sg behaved as a typical hexavalent group-6 element as did W studied previously in similar on-line experiments. This indicated the formation of SgO_2F_2 by analogy to its Mo and W homologs and showed behavior different from the pseudohomolog U(VI), which remained on the column, presumably as UO_2^{2+}.

An investigation of the fluoride complexation of Zr, Hf, Rf, and Th in mixed HNO_3/HF solutions was undertaken (Strub *et al.*, 2000) to verify experimentally that under the conditions of the first experiments on the solution chemistry of Sg using ARCA, ^{261}Rf would not be eluted from the cation-exchange resin. These detailed studies of sorption on both cation- and anion-exchange resins using ARCA confirmed the validity of the assumption in the Sg experiments that Rf would remain on the Aminex A6 cation-exchange resin column. Therefore, it was concluded that Rf could only have been in the Sg fraction as a result of the alpha decay of 7-s ^{265}Sg.

A new series of 4575 experiments was conducted (Schädel *et al.*, 1998) with ARCA using the same Aminex A6 cation-exchange resin to determine if Sg would form SgO_4^{2-} under the same conditions as before if fluoride ions were not present. The activity was dissolved in 0.1 M HNO_3 without any HF; subsequent analysis of the effluent showed that Sg still remained on the column while W was eluted with 0.1 M HNO_3. This non-tungsten-like behavior of Sg was tentatively attributed to its weaker tendency to hydrolyze in dilute HNO_3 so that its hydrolysis stopped at $M(OH)_4(H_2O)_2^{2+}$ or $MO(OH)_3(H_2O)_2^{+}$ while hydrolysis of Mo and W proceeded to the neutral species $MO_2(OH)_2$. Thus, in the previous experiments in the presence of fluoride ions, Sg might have been eluted from the cation-exchange column as neutral or anionic fluoride complexes of the type SgO_2F_2 or $SgO_2F_3^-$ rather than as SgO_4^{2-}.

This hypothesis has been examined theoretically by considering hydrolysis of group 6 elements, as described in Sections 14.5.3b and 14.5.3c. The calculations (Pershina and Kratz, 2001) show that between a pH of 0 and 1, Sg forms complexes with charges of 1+ or 2+ while W forms neutral complexes. Hydrolysis of group-6 elements proceeds even faster at higher pH and a reversal of the trend in group-6 should be observed at pH > 4 (see Section 14.5.3b). Theoretical considerations of complex formation in HF solutions (Pershina *et al.*, 2002b) indicate that it competes with hydrolysis in aqueous solutions, that the dependence on pH and HF concentrations is very complicated, and that reversals of the trends occur. Further experiments can be planned based on the theoretical predictions that cover a wide range of pH values. These reversals of trends among the group 6 elements and U(IV) should be investigated experimentally.

14.6.4 Chemistry of bohrium (107) and hassium (108)

(a) Bohrium

The isotope, 17-s ^{267}Bh (Wilk *et al.*, 2000), produced in the ^{249}Bk(^{22}Ne,4n) reaction, was used in studies to compare the volatility of the oxychloride of Bh with those of its group 7 homologs Re and Tc in on-line isothermal gas chromatographic experiments using the OLGA system (Eichler *et al.*, 2000) conducted at the PSI cyclotron. The recoiling reaction products were sorbed on carbon particles suspended in He gas and continuously transported over a distance of a few meters to the OLGA where they were treated with HCl and oxygen to produce the volatile oxychlorides. These were conducted into the quartz chromatographic column, where their retention time is primarily dependent on the sorption interaction with the chlorinated column surface at a given isothermal temperature and the carrier gas velocity. The molecules passing through the column were attached to aerosols and then deposited stepwise on foils placed in positions on the circumference of a rotating wheel where their decay by alpha emission and SF was measured to identify them positively as ^{267}Bh based on their decay sequences to known daughter activities as reported in Wilk *et al.* (2000). Six such decay chains were observed over nearly 1 month of irradiation time. The relative yields for the trioxychlorides of ^{267}Bh as well as for those for Re and Tc obtained in similar experiments as a function of the isothermal temperatures are shown in Fig. 14.18.

A Monte Carlo program based on a microscopic model of the adsorption process was used to deduce ΔH_{ads} of –75 kJ mol^{-1} with a 68% confidence interval of –66 to –81 kJ mol^{-1} for BhO_3Cl, the most probable oxychloride under these conditions. The ΔH_{ads} values for the Tc and Re oxychlorides studied under the same conditions are –51 and –61 kJ mol^{-1}, respectively. Thus Bh oxychloride shows a stronger adsorption interaction with the chlorinated quartz

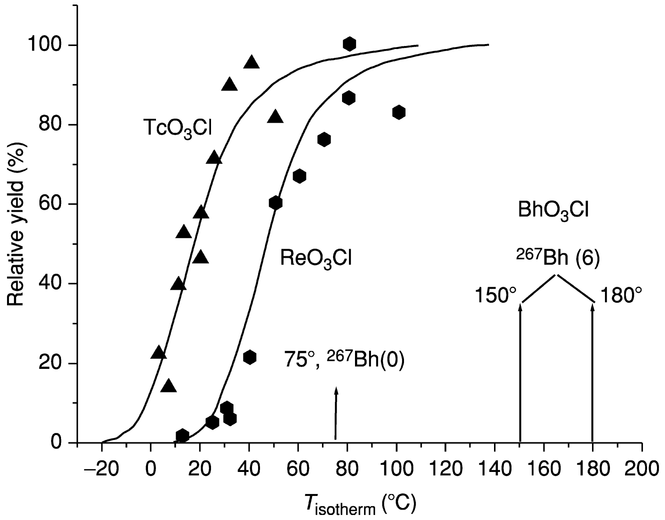

Fig. 14.18 *Relative yields vs. isothermal temperatures for* TcO_3Cl *(solid triangles) and* ReO_3Cl *(solid hexagons). A total of six events attributed to* ^{267}Bh *were detected at the isothermal temperatures of* 150 *and* 180°*C* (*Eichler* et al., 2000). *No events were detected at* 75°*C.*

surface than either Tc or Re compounds and it is less volatile than Re and Tc. This is in very good agreement with the calculations (Pershina and Bastug, 2000) where ΔH_{ads} of –48.2 kJ mol^{-1} for Tc and –78.5 kJ mol^{-1} for Bh were predicted, giving a volatility sequence of $TcO_3Cl > ReO_3Cl > BhO_3Cl$ (see discussion in Section 14.5.2).

(b) Hassium

Systems were developed for separating and detecting Hs as a volatile oxide based on the expectation that it would form a highly volatile tetroxide, as do its group 8-homologs osmium and ruthenium. Fully relativistic density functional calculations have been performed for MO_4 (M = Ru, Os, and Hs), as discussed in Section 14.5.2b. The volatility sequence for the tetroxides was predicted to be $HsO_4 \geq OsO_4 > RuO_4$ based on the calculated adsorption enthalpies of –(36.7 ± 1.5), –(38.0 ± 1.5), and –(40.4 ± 1.5) kJ mol^{-1}, respectively (Pershina *et al.*, 2001).

In preparation for experiments with Hs, Kirbach *et al.* (2002) developed the Cryo-Thermochromatographic Separator (CTS) to perform on-line investigations of the oxides of the α-emitters ^{171,172}Os (8 s,19 s) produced in ^{118,120}Sn (^{56}Fe,3–5*n*) reactions at the LBNL 88-Inch Cyclotron. The CTS consists of a channel formed by two facing rows of 32 PIN (Positive Implanted N-type silicon) diode α-particle detectors upon which a negative temperature gradient from 247 K at the entrance to 176 K at the exit was maintained. The volatile species deposit on the detector surfaces at a characteristic temperature and are identified from their measured α-decay energies.

After pre-separation with the BGS to remove unwanted transfer reaction products and scattered beam particles, the separated Os ions were stopped in the RTC (described earlier) in a mixture of He gas containing 10 vol% O_2 at 100 kPa. The Os activities were transferred in a continuously flowing He/O_2 mixture through a Teflon capillary to a quartz tube heated to 1200 K where OsO_4 was formed and then transported through another capillary to the CTS. The detector pair in which the activity was deposited and the alpha spectra at each position were recorded to identify these activities. The temperature was determined from thermocouple measurements and also from the measured resistances of the PIN diodes. Monte Carlo fits to the adsorption distributions were obtained by adjusting the model to more closely approximate the slit-like CTS cross section and resulted in an adsorption enthalpy of –(40.2 ± 1.5) kJ mol^{-1} for quartz surfaces.

Düllmann *et al.* (2002a) devised the *In-situ* Volatilization and On-line detection apparatus (IVO) in which products recoiling from a nuclear reaction are thermalized and stopped in a recoil chamber containing He gas while the high-energy beam particles travel directly through the chamber to a beam stop, thus removing them from the system. The thermalized recoil products are then converted *in situ* to the volatile species to be studied and are swept by the carrier gas to a chromatography column. Volatile species pass through the column to a recluster chamber where they are sorbed on aerosols and transported via gas jet either to an additional quartz column to measure the retention times of the volatile species or directly to an on-line detection system. Short-lived Os isotopes were used to test IVO for future chemical studies with Hs. From the Monte Carlo simulations an adsorption enthalpy of –(38.0 ± 1.5) kJ mol^{-1} was obtained for $^{173}OsO_4$ on quartz surfaces, in agreement within the uncertainty limits with the value of –(40.2 ± 1.5) kJ mol^{-1} obtained by Kirbach *et al.* (2002). Subsequent to these prototype experiments, an international team of scientists (Düllmann *et al.*, 2002b) conducted the first studies of the chemistry of hassium, the heaviest element to date whose chemistry has been successfully investigated. The ^{248}Cm(^{26}Mg,5n,4n) reactions with estimated production cross sections of only a few picobarns were used to produce ~10 s ^{269}Hs reported previously (Hofmann *et al.*, 1996, 2002) and possibly ^{270}Hs (~4 s) (Türler *et al.*, 2003) at the UNILAC at GSI. Three ^{248}Cm targets were positioned on a rotating wheel to increase the production rate. The IVO device was used to transport recoiling products to a quartz wool plug where Os and Hs were oxidized to the tetroxides by treatment with oxygen at 600°C. They were transported in helium through a Teflon capillary to the entrance to the Cryo On-Line Detector (COLD) TC formed by 12 pairs of opposing Si PIN-photodiode detectors with an outermost layer of Si_3N_4 positioned so that the gas flow was confined to the active detector surfaces. A schematic diagram of the system is shown in Fig. 14.19.

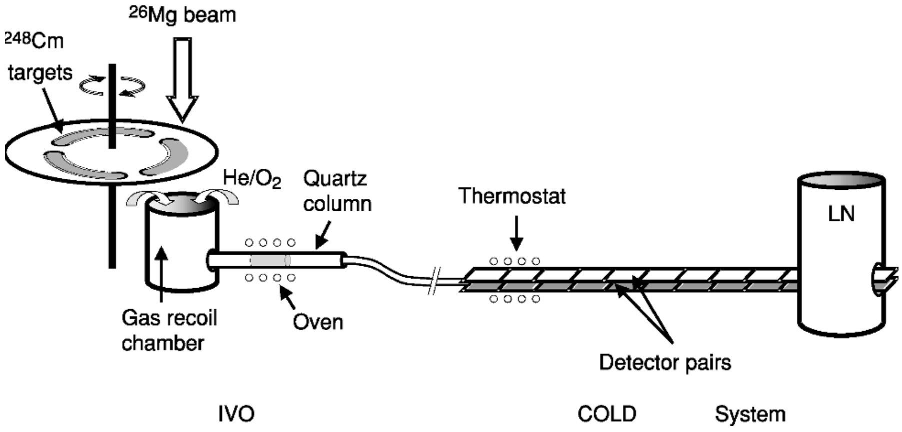

Fig. 14.19 *Schematic of IVO-COLD system for study of gas-phase properties of* HsO_4 *and lighter homologs* (*adapted from Düllmann* et al., 2002*b*).

Spectra of the alpha particles and SFs of the species deposited within each of the detectors of the array were measured and recorded to provide identification of the ^{269,270}Hs isotopes. The detection efficiency was about 77% for detection of a single alpha particle. A negative temperature gradient from –20 to –170°C was established along the TC formed by the detector array and measured at five positions. The system was checked at the beginning and at the end of the experiment by on-line measurements of the short-lived Os isotopes. In the 64 h experiment performed to produce Hs, three α–α-correlated decay chains were detected and assigned to the decay of ^{269}Hs. Two others, possibly due to the new nuclide ^{270}Hs or an isomer of ^{269}Hs, were detected, but a definite assignment could not be made. Based on detection of the three decay chains attributable to ^{269}Hs and two to a new nuclide ^{270}Hs (Türler *et al.*, 2003), HsO_4 was found to condense at a higher temperature than OsO_4 under similar conditions, indicating that the Hs oxide is less volatile than that of Os. The data for Hs and Os are shown in Fig. 14.20.

The Monte Carlo simulations that best fit these data give an adsorption enthalpy of –(39 ± 1) kJ mol^{-1} for OsO_4 on the silicon nitride surface, in good agreement with the previously measured values for SiO_2. An adsorption enthalpy of –(46 ± 2) kJ mol^{-1} was deduced for HsO_4 using only the three events assigned to ^{269}Hs and a $t_{1/2}$ value of 11 s in the analysis. This value is considerably more negative than the predicted value of –(36.7 ± 1.5) kJ mol^{-1} and suggests that HsO_4 is less volatile than OsO_4, in disagreement with calculations (Pershina, 1998a) that indicated that they should be nearly the same. More data and a better half-life measurement for ^{269}Hs are needed to investigate this discrepancy further. The possibility of different behaviors of HsO_4 on the Si_3N_4 detector surface compared to the SiO_2-coated detector surfaces should

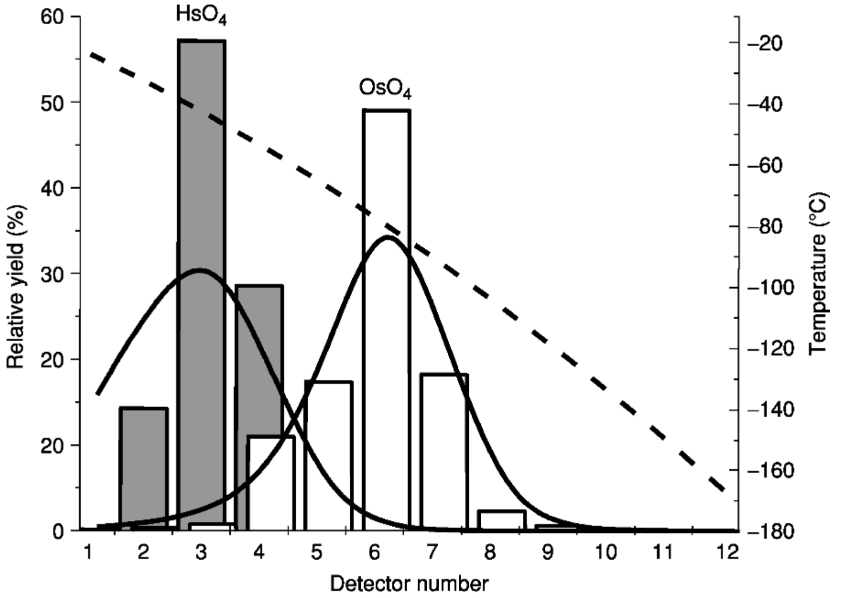

Fig. 14.20 *Combined thermochromatograms for Hs and Os oxides based on deposition positions (temperatures) for each of the* 12 *detector pairs. Dashed line indicates the temperature profile. The bars represent measured values and the curves result from Monte Carlo simulations of the migration process along the column.*

be considered and experiments with the tetroxide of Ru, predicted to be more volatile than those of either Os or Hs, should be conducted on both surfaces to investigate possible differences and the possibility that other oxides may be formed.

14.6.5 Summary of measured compared to predicted chemical properties

(a) Gas-phase studies

Observed trends in the volatility of the compounds of groups 4 through 8 compared to the theoretical predictions are summarized in Table 14.11. It can be seen that the measured and predicted trends in volatilities of the halide and oxyhalide compounds are in excellent agreement. However, in the case of the presumed tetroxides of Os and Hs there appears to be a discrepancy. This discrepancy emphasizes the need for additional investigations because few Hs disintegrations events were measured and their nuclear characteristics have not been unequivocally established.

Table 14.11 *Comparison of measured and predicted trends in volatilities of the compounds of Rf, Db, Sg, Bh, and Hs and their lighter homologs in periodic table groups* 4 *through* 8.

(b) Aqueous-phase studies

The measured trends in hydrolysis, complex formation, and extraction of complexes of Rf, Db, and Sg and their lighter homologs in groups 4 through 6 of the periodic table under a variety of experimental conditions compared to theoretical predictions for the same systems are summarized in Table 14.12. Care must be taken to ensure that the conditions for the experimental studies are the same as for the theoretical predictions since small differences in pH, purity of halide solutions, etc. can affect the equilibria that determine whether hydrolysis or complex formation dominates and whether the resultant complexes are neutral or charged. The order of extraction into organic solvents and sorption in cation- and anion-exchange chromatography differs greatly, depending on the charge on the complex. In general, agreement of the experimental results with the predictions is excellent when these factors are carefully controlled, as discussed in Section 14.5.3c.

There are some prospects for studies of the aqueous chemistry of elements heavier than 106 as well as for more detailed studies of elements 104, 105, and 106 using shorter-lived isotopes that may have higher production rates. The RTC (Kirbach *et al.*, 2002) coupled with the BGS could be used so that the separated isotopes can be transported to different rapid chemical separation systems such as SISAK-III described earlier (Omtvedt *et al.*, 2002) for few-second liquid–liquid extractions or other automated systems such as ARCA. This might permit detailed studies of complex formation of elements Bh and Hs that would be of special interest in acid solutions.

14.6.6 Prospects for experimental studies of chemistry of Mt through element 112

(a) Predictions of half-lives and production modes

Prospects for chemical studies of Mt depend on the confirmation of longer-lived isotopes than ^{268}Mt, currently the longest-lived known isotope of Mt. This isotope decays primarily by alpha emission, with a half-life reported to be about 40 ms; it was detected as the alpha-decay product of ^{272}111 produced with a cross section of 2.5 pb in the ^{209}Bi(^{64}Ni,n) reaction (Hofmann *et al.*, 2002). The half-lives of the ^{264}Bh daughter and the ^{260}Db granddaughter of ^{268}Mt are only about 1 s, so even techniques involving chemical separation of the daughters to infer the parent chemical properties do not appear feasible. Longer-lived isotopes of Mt are expected around the deformed nuclear shell at 162 neutrons and might be produced using the ^{238}U(^{37}Cl,4n) or the ^{249}Bk (^{26}Mg,4n) reaction to make ^{271}Mt. The half-life of this odd-proton, odd-neutron isotope was estimated from interpolation of Smolańczuk's (1997) calculations

for even proton–even neutron nuclides to be a few seconds and decay primarily by alpha emission. The cross section for the first reaction is expected to be similar to that of 2.5 pb, measured for the ^{238}U(^{34}S, 5n)→^{267}Hs reaction (Lazarev *et al.*, 1995) as the enhancement of the cross section due to the extra two neutrons in ^{37}Cl compared to ^{34}S is expected to balance the decrease due to the higher Z of Mt. Based on this cross section, detection of two or three chains a week might be expected using multiple ^{238}U targets in the BGS. The BGS is capable of positively separating and identifying such a new nuclide based on measurement of the known alpha-decay chain of its daughters even if the ^{271}Mt half-life is as short as a few tenths of a second. The overall yield for the reaction with the highly radioactive target ^{249}Bk will be much lower because the cross section is expected to be only a few tenths of 1 pb and it is much more difficult to use multiple targets.

The production of longer-lived isotopes of elements 110, 111, and 112 with half-lives in the range of seconds to minutes have now been reported using 'warm/hot' fusion reactions or as decay products of elements 114 and 115. (See Table 14.2 and Fig. 14.2(b) and discussion in Section 14.1.) It may be possible to produce ^{277}110 directly in the 'warm' fusion reaction ^{232}Th(^{48}Ca,3n), but the cross section may be low and the systematics of these reactions need to be investigated further. The isotope ^{280}110 with a half-life of 7.6 s has been reported as the granddaughter of ^{288}114 produced in a four neutron out reaction in the bombardment of ^{244}Pu targets with ^{48}Ca (Oganessian *et al.*, 2000a; Oganessian, 2001), but this indirect production method is not favorable for chemical studies. Currently, there appear to be no suitable reactions for direct production of the very neutron-rich isotopes of Ds.

Some isotopes of the odd-proton element 111 should have half-lives of seconds or more and hindrances toward fission and alpha decay should exist. An isotope with mass number 280 and with a half-life of 3.6 s has been reported in the alpha-decay chain of ^{288}115 produced in the bombardment of ^{243}Am with ^{48}Ca projectiles (Oganessian *et al.*, 2004a).

SF activity attributed to ^{283}112 produced in the ^{238}U(^{48}Ca,3n) reaction and from the alpha decay of ^{287}112 produced via the ^{242}Pu(^{48}Ca,3n) reaction has been reported by Oganessian *et al.* (1999a,c, 2004b) who obtained a half-life of $\sim$5 min by averaging these results. However, as discussed in Section 14.1, it is difficult to positively identify a new nuclide that decays only by SF and even if this assignment is verified, its positive identification in chemical studies would be equally difficult and likely to be inconclusive. The production of 112 isotopes in ^{238}U(^{48}Ca,xn) reactions should be investigated further to determine the cross sections and if there is an alpha branch in ^{283}112 or ^{284}112. Then more definitive chemical studies could be undertaken. Such experiments would also help to assess the usefulness of 'warm' fusion reactions for production of a broad range of heavy element reactions for chemical studies.

(b) Chemical methods

Even though it appears that isotopes of the elements from Mt through element 112 can exist with half-lives long enough for chemical studies, the most difficult problem will be to increase the production rates and to perform on-line experiments with continuous separation and detection capabilities that can be operated for times long enough to obtain statistically significant results. These times will be of the order of weeks or months and will certainly require computer-controlled automated systems to carry out both gas-phase and solution chemistry. As the production cross sections for the elements of interest become ever smaller, the use of some pre-separation technique – either physical such as BGS or chemical such as IVO – will become mandatory in order to separate out the multitude of unwanted products before use of the more selective systems mentioned below.

The stable oxidation states of these elements both in the gas phase and in solution are predicted to vary widely, as shown in Table 14.10. From element 107 on, the maximum oxidation state is expected to be relatively unstable in aqueous solutions. Experimental studies designed simply to try to determine the most stable oxidation states in aqueous solution should be devised. Thus, for example, the stability of Bh(IV) relative to Bh(VII), or Hs(IV) relative to Hs(VIII) could be investigated by performing anion-exchange separations from HCl solutions in which the 4+ states might form negatively charged complexes that would be retained on the anion column. The relative positions of the peaks of the elution curves associated with reduction would give information about relative stabilities of lower oxidation states. Complex formation can also be studied for elements 109 and heavier. The imaginative gas-separation techniques developed for study of Bh and Hs can be applied to Mt and Ds, which are predicted to form volatile hexafluorides and octafluorides, as discussed in Section 14.5.2b.

Some preliminary chemical experiments on element 112 have been reported by Yakushev *et al.* (2001) and by Yakushev (2002) using the spontaneously fissioning nuclide $^{283}112$ (~5 min) reported by Oganessian *et al.* (1999a, 2004b) to be formed in the $^{238}U(^{48}Ca,3n)$ reaction with a cross section of 5 pb. The experiment was designed to determine whether element 112 behaved similarly to its periodic table homolog Hg, which had been shown to deposit on Au- or Pd-coated silicon surface barrier detectors (Yakushev *et al.*, 2001), or whether it behaved as a noble gas like Rn and remained in the gas phase. An unambiguous answer about the physical or chemical properties of element 112 was not obtained. The system was improved by introducing a special ionization chamber after the silicon detectors to measure alpha decays and SF events of nuclei remaining in the gas. More than 95% of the simultaneously produced Hg isotopes were deposited on the first Au-coated detector. Again, no events attributable to element 112 were detected on either the Au- or the Pd-coated silicon detectors, but eight SF events were registered in the ionization chamber (Yakushev, 2002). These SF events were attributed to element 112, which indicates that it is more chemically inert than Hg and remained in the gas phase. The ΔH_{ads} of element 112 was deduced to be more positive than -55 kJ mol^{-1}. Further experiments with a temperature gradient in the chromatography column are now planned to better define ΔH_{ads}. It is also important to confirm that the observed SF events actually belong to element 112. If an alpha-decaying isotope of element 112 with a suitable half-life and production rate can be identified it would be much more suitable for chemical studies because it could be positively identified from its half-life and characteristic alpha-decay chain.

Experiments on element 112, similar to those conducted in Dubna, are planned by researchers at PSI (Soverna *et al.*, 2001) using a chromatographic column with a negative temperature gradient from 35 to –190°C. Silicon detectors coated with Au and Pd will be placed along the chromatographic column to detect element 112 and its deposition temperature will be determined relative to those of Hg at 115°C and Rn at –115°C in order to deduce ΔH_{ads}.

Eichler and Schädel (2002) investigated the adsorption of Rn on polycrystalline surfaces of transition metals and found the strength of adsorption to decrease in the order: $\mathrm{Ni} > \mathrm{Pd} \approx \mathrm{Cu} > \mathrm{Au} > \mathrm{Ag}$. They suggest that low-temperature vacuum thermochromatographic techniques could be used to rapidly separate element 112 from 114 and Rn and to determine whether its behavior is more like its lighter homolog Hg or an inert noble gas.

Isotopes of Hg have been studied by carrying them on Pd aerosols to serve as a model system for possible studies of elements 112 or 114 (Düllmann *et al.*, 2002a). Recoiling Hg isotopes produced in $^{168}\mathrm{Yb}(^{22}\mathrm{Ne},xn)^{190-x}\mathrm{Hg}$ reactions in the IVO setup at the PSI Philips cyclotron were thermalized in He, swept through an isothermal quartz column at 800°C to the re-cluster chamber, and transported on Pd aerosols to a suitable detection device for measurement of alpha spectra. The short-lived nuclides $^{183-185}\mathrm{Hg}$ were identified, indicating that volatile metals such as Hg can be transported in gas-flow systems without the presence of aerosol particles and then quickly adsorbed on metal aerosols if the enthalpy of adsorption is sufficiently large. The aerosols can then be transported to a detection system for measurements at low pressure and room temperature. Such a technique may also be applicable to measurements of transactinides with $Z = 112$ to 117.

Plans to separate elements with $Z > 108$ as noble metals by electrochemical deposition from aqueous solutions have been described (Kratz, 1999a). The choice of an appropriate electrode material is very important and estimates of suitable electrodes have been made for lighter homologs of the heaviest elements (Eichler and Kratz, 2000). Pd and Pt were found to be suitable electrode metals for the deposition of Hg, Tl, Pb, Bi, and Po, the homologs of elements 112 through 116.

14.7 FUTURE: ELEMENTS BEYOND 112 (INCLUDING SHEs)

14.7.1 Predictions of electronic structures and chemical properties

(a) Introduction

The ground state configurations of the free neutral atoms of elements 113 through 184 obtained from relativistic DF calculations are summarized in Table 14.13.

[a] Fricke (1975).

Chemical properties for elements 113 through 121, as predicted by various researchers, are summarized in Table 14.14. A rather complete discussion and summary of the chemical properties predicted for these elements as of 1986 was given by Seaborg and Keller (1986).

(b) Elements 113 through 115

In elements 113 through 118, the filling of the 7p shell is expected to takes place. Chemistry of these elements will be strongly influenced by relativistic effects: the large relativistic stabilization of the $7s^2$ electron pair (a large 7s–7p gap hindering the hybridization) and a very large SO splitting of the 7p levels into $7p_{1/2}$ and $7p_{3/2}$, reaching 11.8 eV for element 118 (Fig. 14.21). Since the electrons occupying the $7p_{1/2}$ orbital will then form a closed subshell, an enhanced stability of lower oxidation states of these elements is expected. However, destabilization of the 6d levels would contribute to a more transition element character for the earlier 7p elements (Han *et al.*, 1999b; Seth *et al.*, 1999).

(*i*) *Element* 113

Element 113 has one electron in the $7p_{1/2}$ valence shell. Due to relativistic stabilization of the $7p_{1/2}$ electrons, its first IP of 7.306 eV, as shown in Table 14.15, is the largest in group 13 (Eliav *et al.*, 1996a). The 1+ state is thus predicted to be the most stable.

The CCSD calculations (Eliav *et al.*, 1996a) revealed a dramatic reduction in the excitation energy of an electron from the d^{10} shell: the $d^{10}s \rightarrow d^9s^2$ energy of 113^{2+} is 0.1 eV as compared to 8 eV for Tl^{2+}. It is, therefore, predicted that divalent or trivalent compounds of element 113 with an open $6d^9$ shell could exist. The calculated EA of Tl and element 113 are 0.4 and 0.68 eV, respectively.

The very large SO splitting of the 7p orbital will influence the chemistry of element 113 compounds by destabilizing the binding energy by almost 1 eV in the monohydride 113H. In this molecule, the 6d and 7s orbitals were shown to participate little in bonding (Han *et al.*, 1999a,b, 2000; Seth *et al.*, 1999) and all the effects are defined by the large participation of the $7p_{1/2}$ shell. Element 113 was calculated to be more electronegative than Ga, In, Tl, and even Al among all the monohydrides. Involvement of the 6d electrons in bonding in element 113 was confirmed by PP calculations (Han *et al.*, 1999b; Seth *et al.*, 1999) for $113H_3$, $113F_3$, and $113Cl_3$. As a consequence, a T-shape geometric configuration rather than a trigonal planar was predicted for these molecules. The stability of a high-coordination compound MF_6^- with the metal in the 5+ oxidation state is foreseen. $113F_5$ will probably be unstable since the energy of the reaction $113F_5 \rightarrow 113F_3 + F_2$ is only –53.4 kJ mol^{-1} (Seth *et al.*, 1999). The calculated energies of the decomposition reaction $MX_3 \rightarrow MX + X_2$ (M = B, Al, Ga, In, Tl and element 113) confirmed a decrease in the stability of the 3+ oxidation state in group 13.

The standard electrode potential $E°(113^+/113)$ was predicted to be +0.6 eV and 113^+ is expected to be more easily complexed than Tl^+ and to be similar to Ag^+ (Keller *et al.*, 1970). For example, the solubility of TlCl in water is not increased much by adding excess HCl (Alekseeva *et al.*, 1972) or NH_3, whereas AgCl dissolves when NH_3 is added. Element 113 is expected to be more like silver in this respect. The smallest sublimation enthalpy in the group was predicted for element 113 by extrapolation (Keller *et al.*, 1970) and can be explained by the relativistic stabilization of the $7p_{1/2}$ orbital.

(*ii*) *Element* 114

The most interesting among the 7p elements is element 114 where a very large SO splitting of the 7p orbital and the relativistically stabilized 7s and $7p_{1/2}$ electrons result in a closed-shell ground state $7s^27p_{1/2}{}^2$, suggesting that the element should be rather inert. This is also reflected by the largest IP in group 14 (Table 14.15). One of the most striking features seen in Table 14.14 is the great decrease in boiling point in going from element 113 to element 114. This decrease was predicted by Keller *et al.* (1970) on the basis of extrapolations of the heats of sublimation of the group 13 and 14 elements versus periods of the periodic system. The boiling points were then calculated using Trouton's rule. This effect is a result of adding a second $7p_{1/2}$ electron in element 114 to form a

closed-shell $7p_{1/2}{}^2$ configuration, similar to the s^2 one, making this configuration responsible for much weaker bonding in a metallic state.

The group 14 elements show increasing stability of the 2+ oxidation state relative to the 4+ state as one goes to higher atomic numbers. Lead is known to be most stable of the group 14 elements in the 2+ oxidation state. Due to the very large 7s orbital stabilization, the sp^3 hybridization energy needed for the 4+ valence is very large in element 114, so that the 4+ oxidation state of element 114 is expected to be unstable, while the 2+ state should be the most stable in the group. Recent calculations (Liu *et al.*, 2001) have, indeed, shown $114O_2$ to be thermodynamically unstable in contrast to PbO_2. Energies of the decomposition reactions $MX_4 \rightarrow MX_2 + X_2$ and $MX_2 \rightarrow M + X_2$ (M=Ge, Sn, and Pb; X = H, F, and Cl) were calculated at the PP level (Seth *et al.*, 1998b; Nash and Bursten, 1999a). The results confirm a trend of decreasing stability of the 4+ oxidation state in the group. The neutral (monatomic) state was calculated to be more stable for element 114 than for Pb. Element 114 should also have a greater tendency to form complexes in solutions than Pb. Because the stability of the 2+ state increases within group 14, element 114 would probably form MX^+, MX_2, MX_3^-, or MX_4^{2-} (X = Cl, Br, and I) by analogy with Pb. $114F_6^{2-}$, suggested by Seth *et al.* (1998b), will probably be unstable in the aqueous phase due to strong hydrolysis of the fluorides in aqueous solutions. Thus, aqueous complexes of element 114 such as $114Br_3^-$ or $114I_3^-$ should be preferentially formed. Pitzer (1975a) predicted stable $(114)X_2$ (X = F, Cl, and Br). The standard electrode potential $E°(114^{2+}/114)$ was estimated as +0.9 V by Keller *et al.* (1970). We thus see that relativistic effects on the $7p_{1/2}$ electrons cause a diagonal relationship to be introduced into the periodic table near element 114, causing 114^{2+} to be somewhere between Hg^{2+} or Cd^{2+} and Pb^{2+} in its chemistry and causing 113^+ to act more like Ag^+ than Tl^+.

(*iii*) *Element* 115

In element 115, one electron is located in the relativistically destabilized $7p_{3/2}$ orbital and, therefore, is loosely bound,while $7p_{1/2}{}^2$ serves as an inert pair. Thus, the 1+ oxidation state of element 115, like that of Tl^+, should be preferred. This is also supported by a drastic decrease in the first IP between 114 and 115 (Fig. 14.8). Furthermore, calculations show that element 115 has the smallest IP in group 15 and in the 7th period, as shown in Table 14.15 and Fig. 14.8. Keller *et al.* (1974) made some detailed predictions of the chemical properties of element 115 based on extrapolations of the properties of group 15 elements and relativistic atomic DS and DF calculations. Their results indicate that the chemical properties of element 115 should be analogous through a diagonal relationship to those of Tl (group 13) as well as to those of Bi. They predicted a standard electrode potential $E°(115^+/115) = –1.5$ V, indicating that element 115 metal should be quite reactive. They also suggested that 115(III) should be relatively stable and have some chemical properties somewhat similar to Tl(III), but that its chemical properties will be closer to those of Bi(III). The 5+ state seems unlikely. Melting and boiling points of the metal should be close to those of element 113.

(c) Elements 116 through 118

The chemistry of elements 116 through 118 will be defined mostly by the participation of the $7p_{3/2}$ orbital in bonding. Certain predicted volatility characteristics of elements 116, 117, and 118 or their compounds may offer advantages for chemical identification. This will be especially true for element 118. The chemical properties of element 116 can be deduced by extrapolations from Po, though the 2+ state should be more stable than the 4+ state because the $7p_{1/2}^2$ electrons are expected to be rather inert. Estimates of formation enthalpies of MX_2 and MX_4 ($X = F$, Cl, Br, I, SO_4^{2-}, CO_3^{2-}, NO_3^-, and PO_4^{3-}) for Po and element 116 (Grant and Pyper, 1977) on the basis of the MCDF atomic calculations are consistent with the expected instability of 116^{4+}. The chemistry of element 116 is expected to be mainly cationic, i.e. the relative ease of formation of the divalent compounds should approach that of Be or Mg, and tetravalent compounds such as $116F_4$ should be formed only with the most electronegative atoms.

In element 117, the 1– oxidation state becomes less important than that of the lighter group 17 halide ions due to the destabilization of the $7p_{3/2}$ orbital. The EA of element 117 is the smallest in the group (2.6 eV as predicted by Cunningham, 1969 and 1.8 eV as given by Waber *et al.*, 1969). Therefore, the 3+ state should be at least as important as the 1– state, so that element 117 might resemble Au^{3+} in its ion-exchange behavior in halide media. The trend to decreasing participation of the $np_{1/2}$ orbital bonding in group 17 was found to be continued further with element 117 (Hoffman, 1996; Saue *et al.*, 1996; Nash and Bursten, 1999c; Han *et al.*, 2000). In the group HI, HAt, and H117, an increasing trend in R_e and a decreasing trend in D_e are continued with H117. Analogous to its lighter homologs, Element 117 should form dimers X_2. The DCB CCSD(T) calculations for X_2 ($X = F$ through At) (Visscher *et al.*, 1996) found a considerable antibonding σ-character in the HOMO of At_2 due to the SO coupling while without the SO coupling it is an antibonding π-orbital. The bonding in $(117)_2$ is predicted to continue this trend and have a strong π-character.

The elements in the noble gas group become less inert with increasing Z. Earlier predictions of properties of element 118 were made by extrapolation from lighter homologs within the group (Grosse, 1965; Pitzer, 1975a,b). Early calculations of Penneman and Mann (1976) indicated that ionization energies of element 118 should be less than the experimental values for xenon, and that chemical compounds should be expected for 118. The first IP of element 118 is 8.7 eV (see Table 14.15), about the same as the $IP(114) = 8.54$ eV and smaller than $IP(Rn) = 10.74$ eV and $IP(112) = 11.97$ eV. The outer 8s orbital of element 118 is relativistically stabilized to give the atom a positive EA of 0.056 eV, as shown by recent CCSD calculations (Eliav *et al.*, 1996b). The polarizability of 118 is expected to be the largest in group 18. Its largest polarizability, together with its smallest IP, implies that it will have the highest reactivity in the group. It should be stable in the 4+ oxidation state, and should form stable tetrafluorides and tetrachlorides as well. Recent RECP calculations (Han and Lee, 1999) of free energies of the reactions $M + F_2 \rightarrow MF_2$ and $MF_2 + F_2 \rightarrow MF_4$, where M = Xe, Rn, and element 118, confirmed an increase in the stabilities of the 2+ and 4+ oxidation states in group 18. The SO effects were shown to stabilize $118F_4$ by a significant amount, about 2 eV, though they elongate R_e by 0.05 Å. The influence of the SO interaction on the geometry of MF_4 was investigated by RECP calculations (Han and Lee, 1999; Nash and Bursten, 1999a,b). It was found that the D_{4h} geometrical configuration for XeF_4 and RnF_4 becomes slightly unstable for $118F_4$. A T_d configuration was shown to be more stable than D_{4h} by about 0.20 eV. The reason was the availability of only stereochemically active $7p_{3/2}$ electrons for bonding. An important observation was made that the fluorides of element 118 will most probably be ionic rather than covalent as is the case of Xe. Therefore, they are predicted to be non-volatile.

(d) Elements 119 through 121

In elements 119 and 120, the filling of the 8s shell will take place, so that these elements should be homologs of the alkali and alkaline earth elements in groups 1 and 2 and will be stable in the 1+ and 2+ oxidation states, respectively. Their first IPs (Fricke, 1975) should be about 0.5 eV higher than those of Fr and Ra, respectively, due to the relativistic stabilization of the 8s electrons, and closer to the values of Rb and Sr. Thus, an upturn in the IPs from Cs to element 119 and from Ba to element 120 (see Fig. 14.22) was predicted (Penneman and Mann, 1976). Recent DK CCSD calculations (Lim *et al.*, 1999) showed the first IP of element 119 to be relativistically increased from 3.31 to 4.53 eV, while polarizability is decreased from 693.94 to 184.83 a.u. Due to the relativistic stabilization of the 8s orbital, the EA for element 119, of 662 meV, is 20 meV higher (being the highest in the group) than that for Fr, according to recent DCB CCSD calculations (Landau *et al.*, 2001).

The atomic radii of elements 119 and 120 are expected to be 2.4 and 2.0 Å, respectively, very similar to the values of Rb and Sr, as shown in Fig. 14.23. They show the same reversal of the trend (a downturn from Cs/Ba to 119/120) as do the IPs in groups 1 and 2 (Fricke, 1975). Thus, the chemical properties of elements 119 and 120 should be close to those of Rb and Sr, respectively, rather than to Fr and Ra in the 1+ and 2+ oxidation states. On the other hand, the ions will have larger radii than Rb^+ and Sr^{2+} because of the larger extension of the filled 7p shell compared to the lower p-shells. Another important point is that due to the relatively small ionization energy of the outer $7p_{3/2}$ electrons and their spatial extension, higher oxidation states like 3+ or 4+, respectively, could be reached in elements 119 and 120.

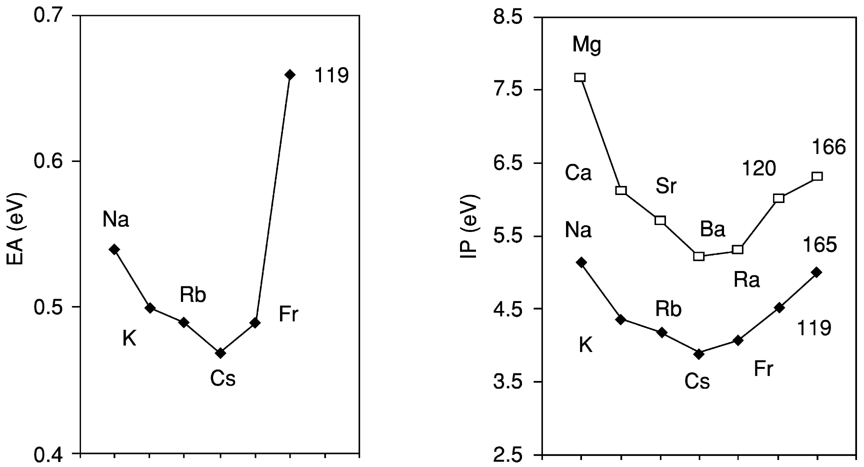

Fig. 14.22 *Electron affinities (EAs) and ionization potentials (IPs) for alkali and alkaline-earth elements. The data for Na through Fr and Mg through Ra are experimental. The value for Element* 119 *is from DF CCSD calculations (Landau* et al., 2001). *The values for elements* 120, 165 *and* 166 *are from DF calculations (Fricke,* 1975).

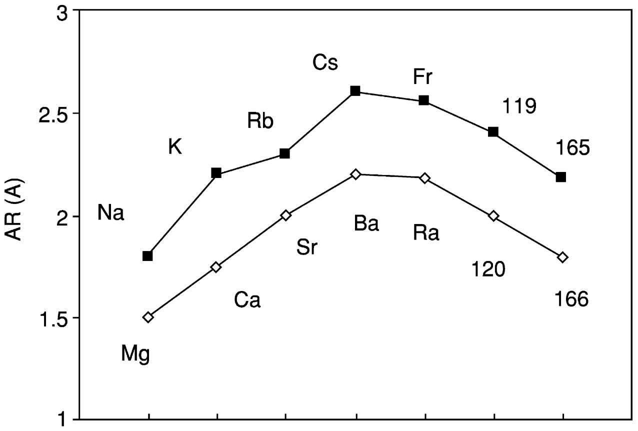

Fig. 14.23 *Atomic radii (AR) of alkali and alkaline earth elements. The data for Na through Cs and Mg through Ra are experimental. The other data are from DS calculations. (Redrawn from Fricke,* 1975).

The next element, 121, will have a relativistically stabilized 8p electron in its ground state electronic configuration $8s^28p_{1/2}$ (see Table 14.13) in contrast to that of $8s^27d$ predicted by a simple extrapolation within the group. As early as 1969, Griffin *et al.* (1969) showed that the large SO splitting brings an 8p electron into the stable atomic ground state. Recent CCSD calculations for element 121 (Eliav *et al.*, 1998a) gave $IP_1 = 4.45$ eV and EA = 0.75 eV, the highest EA in group 3. Griffin *et al.* also showed that large changes occur in the spatial distribution of the valence orbitals in going from element 120 to 121. For example, the effective radius of the 5g electrons changes from 25 Bohr units for element 120 in the excited configuration $8s^15g^1$ to 0.8 Bohr units for element 121 in the configuration $8s^17d^15g^1$. This phenomenon, called 'radial collapse', occurs as late as element 125 as a consequence of indirect relativistic effects. Due to the proximity of the valence levels, higher oxidation states are possible.

(e) Superactinide elements and beyond

Element 122 belongs to a very long, unprecedented transition series that is characterized by the filling of not only 6f but also 5g orbitals with partially filled $8p_{1/2}$ orbitals, which is a direct relativistic effect. These elements were dubbed 'superactinides' by Seaborg (1968) as early as 1968. Quite a number of theoretical calculations of the ground state electronic configurations (Griffin *et al.*, 1969; Mann, 1969; Mann and Waber, 1970; Fricke *et al.*, 1971) were performed for this region and the results have been summarized by Fricke (1975). The calculated ground state configurations of the free neutral atoms of elements 113 through 184 are listed in Table 14.13. Here, at the beginning of the superactinides, not only two but four electron shells, namely $8p_{1/2}$, $7d_{3/2}$, $6f_{5/2}$, and $5g_{7/2}$, are expected to compete simultaneously. These open shells, together with the 8s electrons, determine the chemistry.

As shown in Table 14.13, a 7d electron is added to the ground state in element 122 and the 8p electron is relativistically stabilized so that the configuration is $8s^27d8p$, in contrast to the $7s^26d^2$ state of Th. This is the last element where accurate CCSD calculations (Eliav *et al.*, 2002) exist. The first four calculated IPs of element are 5.6, 11.3, 20.4, and 27.14 eV as compared to the first and the fourth IPs, 6.54 and 28.75 eV, of Th. A decrease in the first IP from Th to element 122 is due to the ionized $8p_{1/2}$ electron.

Elements 122 through 152 might have chemical properties somewhat similar to those of the actinides but there will be some differences. The very small binding energies of all the valence electrons will cause the higher oxidation states to be reached in these elements. This will be a continuation of the trend from the lanthanides (where 3+ states are highest) to the superactinides.

For ionic compounds it is important to establish which external orbitals are left after all outer s-, p-, and d-electrons are removed. Will there be some g- and f-electrons left or will they be easily excited to an outer electron shell, so that they can be removed as well? Some investigations showed that for element 126 in the divalent state, one g-electron will move to an f-electronic state, and the 8s electrons will not be the first to be removed. Thus, the divalent ions are expected to act as soft Lewis acids and possibly form covalent complex ions readily. From some calculations of excited states, it is assumed that very high oxidation states may be possible around element 128 in complex compounds, but that normally these elements will have 4+ as their main oxidation state in ionic compounds. The maximum valence will be reduced to 6+ at element 132 and in the region of 140, it will be 3+ to 4+. At the end of the superactinide series, the normal oxidation states are expected to be only 2+ because the 6f shell will be buried deep inside the electron core and the 8s and $8p_{1/2}$ orbitals will be strongly bound. At element 156, only two 7d relativistically destabilized electrons will be available for bonding. This behavior should be similar to that of the low oxidation states of elements at the end of the actinides. Thus, at the end of the superactinide series, the elements will be more noble.

A contraction of bond lengths, analogous to the actinide contraction, is expected for the superactinide series. The total effect will be very large because of the 32 electrons, with the expected contraction of 0.02 Å per element. The predictions of chemical properties by extrapolation will be very difficult und unreliable in this area, since most of the elements have no homologs. From atomic calculations, one can already say that the behavior will be very different due to the stronger relativistic effects.

The fifth series of transition elements is expected to begin beyond the superactinides. Several early DF calculations in this region were performed. In elements 155 to 164, the filling of the 7d shell will take place so that they will be the d transition elements of the 8th period. The 8s and $8p_{1/2}$ electrons will be bound so strongly in these elements that they will not participate in the chemical bonding in contrast to the 7s electrons of the 7th period. Nevertheless, the 9s and $9p_{1/2}$ states will be easily available in 164 for hybridization so that the chemical behavior is expected to be similar to that of other d-elements. From DF calculations of excited states of element 164, Penneman and Mann (1976) suggested that the 7d orbitals will be chemically very active. Thus, in aqueous solutions, strong ligands can form tetra- and hexavalent bonds in addition to the predominant bivalent bonds. Consequently, tetrahedral $164(CO)_4$, $164(PF_3)_4$, and linear $164(CN)_2^{2-}$ might be prepared, which would be a striking contrast to lead (Fricke, 1975). The softness of element 164 should be similar to that of Hg, so that its location in the same group in the periodic table is justified. The metallic state of element 164 should have a larger cohesive energy than almost any other element because of covalent bonding, so that the melting point should be high (Fricke and Waber, 1971). The same authors indicated that the properties of elements 118 and 164 might also be analogous.

In elements 165 and 166, the 9s shell will be filled, suggesting that they should be homologs of group 1 and 2 elements and that their IPs and IR (Fricke, 1975) will be similar to those of the group 1 and 2 elements, respectively. Nevertheless, because of the underlying 7d shell, elements 165 and 166 might exhibit properties similar to those of the group 13 and 14 elements. Therefore, higher oxidation states than 1+ and 2+, respectively, might occur.

In elements 167 through 172 the $9p_{1/2}$ shell will fill before the $8p_{3/2}$ shell. The energies of these orbitals are so close to each other that this situation is analogous to the nonrelativistic p-shell in the 3d period. Thus, the common oxidation states of elements 167 to 179 will be 3+ to 6+. Element 171 is expected to have many states from 1– to 7+, as do halogens. H(171) would form due to its high electron affinity of 3.0 eV (Fricke *et al.*, 1971). Compounds with F and O are also expected. Element 172 might be a noble gas similar to Xe due to the similar values of their IPs. The major difference is that element 172 is predicted to be a liquid or a solid at normal temperatures because of its large atomic weight.

Mann reported that his program was unable to go beyond $Z = 176$. Model calculations of Fricke and Waber (1972) took into account a phenomenological formulation of quantum electrodynamic effects and made it possible to extend the DF calculations to even higher elements. They calculated the DF ground state for element 184, as shown in Table 14.13. The 10s and $10p_{1/2}$ electrons do not appear in the ground state configuration and only $8d^3$ and $7f^4$ electrons might be available for chemical bonding. The chemical behavior will be then even simpler than that of the early superactinides. With increasing ionization of the 184 ion, a redistribution of electrons occurs between the 6g and 7f shells so that the number of electrons in the 6g shell increases. Since the 6g electrons are very deep inside the ion, only 7f electrons will be available for bonding. By analogy to U, the 5+ and 6+ states may be easily reached, but in aqueous solution the 4+ oxidation state will be the most stable. Higher oxidation states are not likely because the binding energy of the electrons in the deeply buried 6g shell will increase rapidly with higher ionization. Thus, in the very long SHE transition series, where many outer electron shells are being filled simultaneously in the neutral atom, a large increase in ionization energies will occur so that extremely high or unusual oxidation states are not expected.

In summary, in the area of the SHEs, the relativistic effects are so strong that any classification based on the knowledge of their electronic configurations or extrapolations of properties from the known elements is inappropriate. It is interesting to note that even without relativistic effects, the chemistry of the heaviest SHEs would be different from that of their lighter homologs due to very large shell-structure effects. The nonrelativistic expansion and destabilization of the *n*s valence orbitals and contraction and stabilization of the *n*d, *n*f, and orbitals of higher angular quantum number *l* with very large *n* also would have drastically changed the properties of the SHEs. However, due to the opposite actions of relativistic and shell-structure effects, the relativistic and nonrelativistic changes are predicted to go in opposite directions. A more detailed periodic table up to element 172 was given by Fricke (1975). Some discussions of the chemistry of SHEs can be found in Penneman *et al.* (1971), Fricke (1975), and Jorgensen (1968), and more recently in a review of the evolution of the periodic table by Seaborg (1996).

14.7.2 Prospects for experimental studies of chemistry of elements beyond element 112, including SHEs

The prerequisites for successful studies of the chemistry of elements beyond 112 will be similar to those discussed previously for Mt through 112. These include the existence of isotopes with long enough half-lives for chemical studies, knowledge of their nuclear decay properties so that they can be positively identified as belonging to the element being studied, synthesis reactions with the highest possible cross sections, techniques for increasing the production rates such as cooled, multiple targets, the highest possible beam currents at accelerators with facilities for conducting these studies, and, ideally, dedicated beamlines for optimal utilization of facilities by international groups of scientists. After the chemistry of a given element is known, the atomic number of new isotopes can be positively assigned based on their established chemical properties and detailed studies of nuclear properties such as SF can be conducted on chemically separated samples.

(a) Chemical methods

A useful technique that should prove invaluable in the study of very low-yield, short-lived elements is pre-separation of the nuclides of interest from the host of unwanted activities using a dedicated on-line separator such as the BGS at the appropriate accelerator. At the focal plane the separated isotopes can be stopped in an RTC containing an appropriate gas and can even be treated chemically to adjust oxidation states and volatility. The resultant volatile species can then be rapidly and continuously transported to a cryo-thermochromatographic separator or any other desired chemical separation/detection system.

The ingenious isothermal gas-phase techniques that have already been applied in the studies of volatile Hs oxides can be used to study other volatile species that can be similarly swept in carrier gas directly to an on-line detection system or to a cryogenic TC composed of the particle detectors. In this way, simultaneous on-line measurements can be performed of the decay properties of the radioactive nuclides in the volatile species and their deposition temperature on the surface of the detectors that form the chromatography column. Vacuum cryo-thermochromatographic techniques in which the relative reactivity of elements 114 through 118 are determined based on their sorption on a variety of transition metal surfaces might be used to assess whether their behavior is more like their lighter homologs or the inert noble gases.

The continuous, computer-controlled automated procedures discussed in the previous sections can be used and other procedures designed specifically to exploit the chemistry predicted for each of these elements. Continuously operating, rapid systems for liquid–liquid extractions followed by detection in flowing liquid-scintillation detectors such as the SISAK-III/liquid scintillation system (Omtvedt *et al.*, 1998, 2002) can be used for on-line studies of isotopes with half-lives as short as a few seconds provided chemical systems that rapidly come to equilibrium can be devised. Alternatively, they could be used to continuously purify longer-lived SHEs. A variety of computer-controlled, continuous multi-ion-exchange column techniques that include automated transport of samples to the detection equipment have been developed (Haba *et al.*, 2002; Nagame *et al.*, 2002) for performing rapid separations of isotopes with half-lives as short as a few seconds and then inferring their presence based on detection of their longer-lived daughters in subsequent chemical separations. Such continuous systems might also be adapted for processing longer-lived SHEs for subsequent off-line detection.

New methods for studying gas-phase ion chemistry in a Penning trap have been reported by Rieth *et al.* (2002) and it has been shown by the ISOLTRAP group at the Centre Européen pour la Recherche Nucléaire (CERN) (Kugler *et al.*, 1992; Bollen *et al.*, 1996) that nuclides as short as a few tenths of a second can be used with Penning trap mass spectrometers. These techniques have potential application to gas-phase studies of elements beyond 112. Kinetic data on ion–molecule interactions can be obtained with single-ion detection, and mass spectrometry can be used to unambiguously determine the stoichiometry of the reaction products. However, the reaction rates must be increased in order to make the technique viable for the low production rates of less than one atom per week expected for the heaviest elements.

(b) Predicted and reported half-lives and nuclear properties of SHEs

One of the most significant nuclear properties of elements 107 through 112 is that they decay predominantly by alpha emission rather than SF, contrary to earlier predictions. This experimental discovery sparked a renewal of interest in searching for elements beyond 112 and revived hope that the long-predicted island of SHEs might finally be reached. Armbruster and Münzenberg (1989) proposed that even though the neutron-deficient isotopes of elements 107 through 112 are probably not spherical, they should qualify as SHEs because without the stabilization of nuclear shells they would not exist. These elements have not been generally recognized as SHEs.

The discovery of longer-lived isotopes in this region, ^{265,266}Sg, ^{267}Bh, and ^{269,270}Hs, substantiated the theoretical model and calculations (Sobiczewski *et al.*, 1994; Smolańczuk *et al.*, 1995) predicting a doubly magic deformed region of extra stability in the vicinity of proton number 108 and neutron number 162 in addition to the island of spherical stability originally predicted to be around $Z = 114$ and $N = 184$, as shown in Fig. 14.24.

Evidence for three isotopes of element 114, ^{287,288,289}114, has been reported (Oganessian *et al.*, 1999a) although only one event of 21-s ^{289}114 was detected

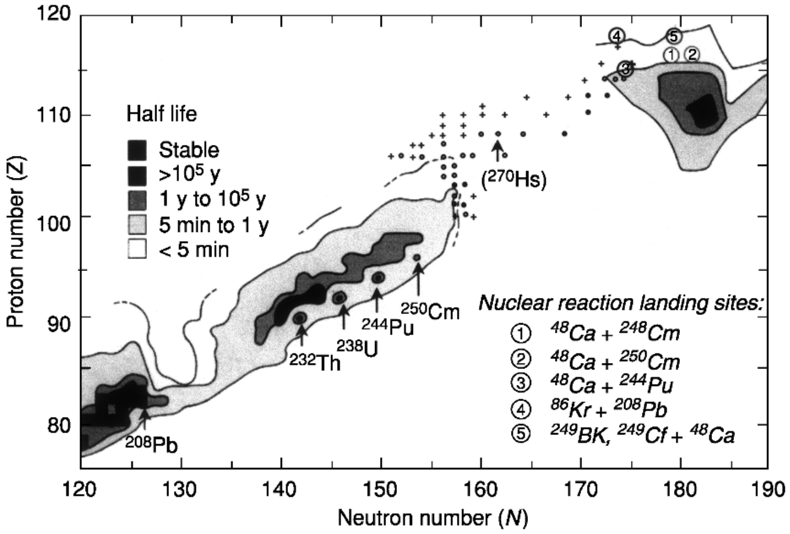

Fig. 14.24 *Updated plot of heavy element topology from* 1978 *showing some landing points for proposed reactions. Heavy element isotopes reported since* 1978 *up to mid-*2002 *are indicated with symbols denoting the following half-life ranges:* 0.1 ms to 0.1 s (+); 0.1 s to 5 min (○); > 5 min (●).

and it was not confirmed in subsequent experiments (Lougheed *et al.*, 2000). The discovery of isotopes of element 116, $^{292}116$, has been discussed by Oganessian (2002) and Oganessian *et al.* (2002, 2004c). Calculations (Smolańczuk, 1997) indicate that these isotopes are nearly spherical with deformation energies ranging from only about 0.1 MeV for $^{292}116$ to 0.3–0.2 MeV for the 114 isotopes, compared to zero deformation energy for the spherical doubly magic $^{298}114$ and 7.8 MeV for the doubly deformed magic nucleus, $^{270}108$. Thus, element 114 and 116 isotopes qualify as spherical SHEs even though they do not have the full complement of 184 neutrons. However, their existence still awaits confirmation by other groups.

Recent theoretical predictions (Chasman and Ahmad, 1997; Smolańczuk, 2001a,b) indicate that isotopes with half-lives of microseconds or longer will exist all along the way to the predicted islands of stability. However, the half-lives predicted for nuclei in the region of the spherical island of stability have decreased dramatically since the 1970s when half-lives of billions of years were predicted. For example, Smolańczuk (2001a,b) predicted that the spherical doubly magic superheavy nucleus $^{298}114$ will decay predominantly by alpha emission with a half-life of only 12 min, but that ^{292}Ds may alpha decay with a half-life of about 50 years.

Some other recent calculations (Kruppa *et al.*, 2000) predict that the strongest spherical shell effects might be at $Z = 124$ or 126 and $N = 184$ while still others propose the maximum effect might be at $Z = 120$ and $N = 172$. Doughnut-like, toroidal nuclear shapes with lower densities or a hole in the middle to alleviate the effects of Coulomb repulsion have even been postulated. How many more elements can exist is still unclear and it is even more unclear how many of these we can actually produce.

(c) Production reactions

So-called 'cold' fusion reactions in which the compound nucleus is produced with small excitation energy and emits only a single neutron were used to discover the elements from Bh through 112 (Hofmann, 1998). After the discovery of element 112 in 1996 (Hofmann *et al.*, 1996), researchers at GSI unsuccessfully attempted to produce element 113 using the cold fusion reaction ^{209}Bi (^{70}Zn,n) ^{278}113 (Hofmann and Münzenberg, 2000). From two experiments lasting about 3 weeks each, they set a limit of 0.6 pb on the cross section at a mean excitation energy of 10.5 MeV. They concluded that the cross section for production of element 116 would be only 1 femtobarn and that their experimental setup would have to be greatly improved in order to investigate this region further. Contrary to these expectations that the production cross sections for the 1n evaporation channel in cold fusion reactions to produce elements above 112 would continue to decrease exponentially with the proton number of the projectile, Smolańczuk (1999a) suggested that the cold fusion reaction ^{208}Pb(^{86}Kr,n) reaction to produce the hypothetical spherical SHE nuclide ^{293}118 with an excitation energy of only 13 MeV would have an unusually large cross section of a few hundred picobarns. The predicted increase in formation cross section was attributed to the fact that ^{86}Kr contains the magic number of 50 neutrons, which leads to a larger Q value with a subsequent increase in the transmission probability through the Coulomb barrier. He also predicted that ^{293}118 would decay by a unique decay sequence of six high-energy alpha particles. However, the results of Gregorich *et al.* (2002) setting upper limits of less than 1 pb for the formation cross section for this reaction based on detection of the predicted high-energy alpha-decay chain make the use of cold fusion reactions appear less attractive for production of SHEs. Estimates of the predicted cross section were later lowered to about 6 pb (Smolańczuk, 2001b), and it was pointed out that the excitation functions are quite narrow and have a rather sharp threshold (Smolańczuk, 1999c) so use of too low a bombarding energy might result in a negative result and the idea should not be totally abandoned.

Similar cold fusion reactions with ^{208}Pb or ^{209}Bi targets with ^{87}Rb or ^{86}Kr projectiles could be used to produce ^{294}119 (Smolańczuk, 1999a,b), whose half-life is estimated to be only microseconds. However, ^{294}119 is predicted to decay to isotopes of the new longer-lived, odd-Z elements 117, 115, and 113 via a succession of alpha emissions, ending with the known isotope 3.6-h ^{262}Lr. Production of ^{295}120 ($\sim$2 μs) via the ^{208}Pb(^{88}Sr,1n) reaction and detection of its high-energy alpha-decay chain have also been proposed (Smolańczuk, 2001a).

The reported elements 114 and 116 were synthesized using reactions of ^{244}Pu and ^{248}Cm with ^{48}Ca projectiles to form the compound nuclei ^{292}114 and ^{296}116, which then emitted four neutrons to produce 2.6-s ^{288}114 and 53-ms ^{292}116 (Oganessian *et al.*, 2000a,b; Oganessian, 2001, 2002). They were calculated to have excitation energies of only 33 and 31 MeV, respectively, due to the stability of the doubly magic projectile, compared to >45 MeV for 'hot' fusion reactions. The detection limit of these experiments was about 0.5 pb, several orders of magnitude more sensitive than in the unsuccessful attempt reported in 1984 by an international group of nuclear scientists, both chemists and physicists (Armbruster *et al.*, 1985), who conducted an exhaustive 'final' investigation of the reaction of ^{248}Cm with ^{48}Ca projectiles to produce SHEs. Oganessian also proposed that the reaction of ^{48}Ca with ^{249}Cf targets be used to produce element ^{294}118 via the '3n out' reaction. However, the viability of the '3n out' reactions in this region has yet to be confirmed. Loveland *et al.* (2002) set a limit of <2 pb for SF and alpha events for the ^{238}U(^{48}Ca,3n)^{283}Ds reaction. Hot fusion reactions between ^{48}Ca projectiles and ^{249}Bk and ^{249}Cf targets to produce elements ^{293,294}117 and ^{293,294}118, respectively, are under investigation by the Dubna/LLNL group.

The ^{237}Np and ^{249}Bk targets with ^{48}Ca projectiles can probably be used to make the odd-proton element 113 and more neutron-rich isotopes of element 117, respectively. Other highly radioactive targets such as ^{249}Cf or even ^{254}Es with appropriate projectiles might be used to make more neutron-rich isotopes of elements as heavy as 118, but considerable development work will be required.

Reactions that can produce a higher ratio of neutrons to protons will certainly be most advantageous and need to be investigated. Myers and Swiatecki (2000) have suggested that so-called 'unshielded' reactions in which the Coulomb barrier has sunk below the bombarding energy may result in enhanced production yields for some of the higher Z elements. Their hypothesis that the cross section for ^{277}112 produced in the symmetric reaction ^{142}Ce(^{136}Xe,n) might be much larger than that for the 112 discovery reaction ^{208}Pb(^{70}Zn, n)^{277}112 should be tested experimentally. If so, the unshielded reaction ^{170}Er (^{136}Xe,n) reaction to make ^{305}122, which has 183 neutrons, might be a method for getting closer to these regions. It should decay by successive alpha emission to the isotope ^{289}114, reported by the Dubna/LLNL group. Whether additional SHEs can be produced depends very much upon whether the cross sections for the 'cold' fusion reactions in which only a single neutron is emitted and the 'warm'/'hot' fusion reactions with three or four neutrons emitted are large enough to permit detection.

It now appears likely that many more relatively long-lived nuclides can exist than are presently known, but a major research effort to explore new types of production reactions, imaginative techniques for optimizing overall yields by using multiple targets and higher beam currents, innovative chemical separations, and a dedicated on-line installation for chemical studies at an appropriate accelerator with access to a pre-separator will be required in order to fully explore their chemical properties. If, on the other hand, relatively long-lived new elements are discovered, then methods for 'stockpiling' them for off-line studies or producing them as by-products of other experiments must be devised to facilitate studies of their chemistry. The prospect lies ahead of a whole new landscape for the exploration of the chemical properties of the heaviest elements and their compounds, determining the influence of relativistic effects, assigning their positions in the periodic table, and extending and further defining the architecture of the periodic table.
