THE CHEMISTRY OF THE
ACTINIDE AND TRANSACTINIDE ELEMENTS

Joseph J. Katz

Glenn T. Seaborg

This work is dedicated to
Joseph J. Katz and Glenn T. Seaborg,
authors of the first and second editions of
The Chemistry of the Actinide Elements
and leaders in the field of actinide chemistry.

PREFACE

The first edition of this work (*The Chemistry of the Actinide Elements* by J. J. Katz and G. T. Seaborg) was published in 1957, nearly a half century ago. Although the chemical properties of thorium and uranium had been studied for over a century, and those of actinium and protactinium for over fifty years, all of the chemical properties of neptunium and heavier elements as well as a great deal of uranium chemistry had been discovered since 1940. In fact, the concept that these elements were members of an "actinide" series was first enunciated in 1944. In this book of 500 pages the chemical properties of the first transuranium elements (neptunium, plutonium, and americium) were described in great detail but the last two actinide elements (nobelium and lawrencium) remained to be discovered. It is not an exaggeration to say that *The Chemistry of the Actinide Elements* expounded a relatively new branch of chemistry.

The second edition was published in 1986, by which time all of the actinide elements had been synthesized and chemically characterized, at least to some extent. At this time the chemistry of the actinide elements had reached maturity. The second edition filled two volumes, with a chapter for each of the elements (the elements beyond einsteinium were combined in one chapter) and systematic treatment of various aspects of the chemical and electronic properties of the actinide elements, ions, and compounds due to the filling of the 5f subshell. Six transactinide elements had been synthesized by 1986 but their experimentally determined chemical properties occupied only 1.5 pages of text in the second edition.

This edition was initiated by the editors of the second edition (J. J. Katz, G. T. Seaborg, and L. R. Morss) in 1997. They realized that the study of the chemical properties of the actinide elements had advanced to produce distinct subdisciplines of actinide chemistry, for example actinide coordination chemistry, actinide X-ray absorption spectroscopy, itinerancy in actinide intermetallics, organoactinide chemistry, and actinide environmental chemistry. These fields had sufficiently matured so that scientists could make more substantial contributions to predicting and controlling the fate of actinides in the laboratory, in technology, and in the environment. We now understand and are able to predict with some degree of confidence the chemical bonding and reactivity of actinides in actinide materials, in actual environmental matrices and in proposed nuclear waste repositories. Most of the unique properties of the actinides are caused by their accessible and partly filled 5f orbitals. In addition to advances with the actinides, there have been research groups at nuclear research centers in several countries that have dedicated themselves to carry out significant and systematic experimental studies on the transactinide elements for several decades. For these reasons the editors initiated the writing of a third edition, with the enlarged title *The Chemistry of the Actinide and Transactinide Elements* that is both broader and deeper than the second edition.

The third edition follows the plan enunciated by the authors of the first edition: "This book is intended to provide a comprehensive and uniform treatment of the chemistry of the actinide [and transactinide] elements for both the nuclear technologist and the inorganic and physical chemist." To fulfill this plan consistent with the maturity of the field, the third edition is organized in three parts.

The first group of chapters follows the format of the first and second editions by beginning with chapters on individual elements or groups of elements that describe and interpret their chemical properties. A chapter on the chemical properties of the transactinide elements is included.

The second group, chapters 15-26, summarizes and correlates physical and chemical properties that are in general unique to the actinide elements, because most of these elements contain partially-filled shells of 5f electrons whether present as isolated atoms or ions, as metals, as compounds, or as ions in solution.

The third group of chapters (chapters 27-31) focuses on specialized topics that encompass contemporary fields related to actinide species in the environment, in the human body, and in storage or wastes. There are also two appendices that tabulate important nuclear properties of all actinide and transactinide isotopes.

Each chapter has been written to provide sufficient background for the substantial parts of the readership that are not specialists in actinide science, nuclear-science-related areas (nuclear physics, health physics, nuclear engineering), spectroscopy, or solid-state science (metallurgy, solid state physics). The editors hope that this work educates and informs those readers who are scientists and engineers that are unfamiliar with the field and wish to learn how to deal with actinides in their research or technology.

The editors are deeply indebted to the contributors of each chapter, all of whom agreed enthusiastically to write their chapters and all of whom did so as a labor of love as well as a long-term professional responsibility. We take special pleasure in thanking Dr. Emma Roberts, Senior Publishing Editor of Springer, who provided the resources to turn more than thirty manuscripts into this attractive and useful professional series of volumes. We also thank Roger Wayman and Aaliya Jetha of Springer and all the other professional staff at Springer and SPI Publisher Services who brought this work to completion.

The editors dedicate this work to Joseph J. Katz and Glenn T. Seaborg, the first authors of the first edition and second editions of *The Chemistry of the Actinide Elements.* They provided inspiration for the generations of scientists who followed them and they set high standards in their research. Dr. Katz guided and motivated the editors and authors of the third edition to produce a work that followed the model of the first and second editions and provided leadership as this edition was unfolding. Because of his insights and leadership as an inorganic, physical, and actinide chemist, we have asked Dr. Katz to be listed on the title page as honorary editor, and he has agreed to accept this role. The editors also dedicate this work to the memory of Professor Seaborg, the co-discover of plutonium and many other actinide and transactinide elements, and pioneer in actinide chemistry. We note with sadness that he participated in planning this edition but passed away before any of the chapters had been written. We believe that he would have been pleased to see how productive has been the research of the authors and many other actinide and transactinide scientists who follow his leadership.

All of us who have participated in the writing, editing, and publishing *The Chemistry of the Actinide and Transactinide Elements* express our hope that this new edition will make a substantive contribution to research in actinide and transactinide science, and that it will be an appropriate source of factual information on these elements for teachers, researchers, and students and for those who have the responsibility for utilizing the actinide elements to serve humankind and to control and mitigate their environmental hazards.

CHAPTER ONE

INTRODUCTION

Joseph J. Katz, Lester R. Morss, Norman M. Edelstein, and Jean Fuger

The actinide elements are the 15 chemical elements with atomic numbers 89 through 103, the first member of which is actinium and the last member is lawrencium (Fig. 1.1). The transactinide elements (those beyond the actinides) are the heaviest known chemical elements. Both the actinide and the transactinide elements have chemical properties that are governed by their outermost electronic subshells. Each of these groups of elements is a unique transition series (a group of elements in which d or f electronic subshells are being filled).

The actinides are the transition elements that fill the 5f subshell. The actinide series is unique in several respects:

- Most of the elements (those heavier than uranium) were first discovered by synthetic methods: bombardment of heavy atoms with neutrons in nuclear reactors, bombardment with other particles in accelerators, or as the result of nuclear detonations.
- All actinide isotopes are radioactive, with a wide range of nuclear properties, especially that of spontaneous and induced nuclear fission.
- They are all metals with very large radii, and exist in chemical compounds and in solution as cations with very large ionic radii.
- The metals exhibit an unusual range of physical properties. Plutonium, with six allotropes, is the most unusual of all metals.
- Many of the actinide elements have a large number of oxidation states. In this respect plutonium is unique, being able to exist in aqueous solution simultaneously in four oxidation states.
- In metallic materials and in some other compounds with elements lighter than plutonium, the 5f orbitals are sufficiently diffuse that the electrons in these orbitals are “itinerant” (delocalized, chemically bonding, often with unique magnetic moments and electrical conductivity). In metallic materials and in most compounds with elements heavier than plutonium the 5f electrons are “localized” (not contributing significantly to electrical conductivity or to chemical bonds). Materials with plutonium and adjacent

elements can exhibit both itinerant and localized behavior, depending on conditions such as temperature and applied pressure.

- Actinium (which has no 5f electrons in the metal, free atom, or in any of its ions) and the elements americium through lawrencium are similar in many respects to the lanthanide elements (the elements that fill the 4f electron subshell). The elements thorium through neptunium have some properties similar to those of the d transition elements.
- Relativistic contributions to electronic properties and spin–orbit effects are important in the chemical properties of actinides.

The transactinide elements are at the frontier of both the periodic table (Fig. 1.1) and the chart of the nuclides. Transactinide chemistry has been in existence since 1970. Although these elements have unique properties, they are very difficult to study because their synthesis and identification require unique nuclear reactions and rapid separations. The heaviest transactinide element for which chemical properties have been identified (at the time of writing of this work) is hassium (atomic number 108). Experimental evidence and theoretical studies to date indicate that the elements through 112 are part of a 6d transition series of elements.

The transactinides are also unique in several respects:

- One-atom-at-a-time chemistry is required to compensate for low nuclear yields and short isotopic half-lives. Ingenious techniques have been developed to study their chemical properties in both gas phase and solution.
- Relativistic effects cause substantial contraction of the 7s (occupied), 7p (empty), and 6d (partially filled) orbitals. (Many electronic configurations have been calculated; see Chapter 14.) The contraction of the 7s orbitals stabilizes the $7s^2$ electron pair. The contraction of the 7p orbitals makes 7p terms accessible, e.g., the first excited multiplet of rutherfordium (element 104) outside the [Xe $5f^{14}$] core is calculated to be $6d7s^27p$.
- The first part of the transactinides constitutes a 6d transition series, with the calculated ionic radii intermediate between those of the 5d ions and actinide ions of the same charge. Relativistic effects decrease the polarizability of transactinide ions.
- Fundamental properties – electronic configurations, ionization energies of atoms and ions, oxidation–reduction potentials in solution – remain to be calculated theoretically and measured experimentally.

In the six decades that have elapsed since the "actinide concept" was enunciated by G. T. Seaborg, great advances have taken place in actinide and transactinide chemistry. As in many other important areas of science, new information and new concepts have accumulated to an extraordinary extent. This, in itself, would be ample justification for a comprehensive examination of the scientific aspects of the actinide elements. Of equal, or perhaps even greater, importance in the preparation of this third edition are the contributions that its many authors have made to provide the foundations for the solution of some of the most urgent technological and environmental problems that face humanity worldwide. We refer, of course, to the problems created by nuclear reactors used for electricity production; nuclear weapons production and dismantlement; the treatment and storage of nuclear wastes; and the cleanup of Cold War nuclear material sites. These are sources of acute global concern, in all of which the actinide elements are intimately involved.

In 1957, when the first edition of this work was published, the chemistry of the actinide elements was remarkably well developed, considering that the actinide concept itself had first been publicly described in 1945. (See Chapter 15, section 1.2, of this book) The elements thorium and uranium had already been studied by chemists for more than 100 years. Uranium enjoyed some small distinction as the heaviest element in nature, and as the terminus of the classical periodic table. In 1895 Becquerel had discovered that uranium undergoes radioactive decay, a discovery that permanently divested uranium of its obscurity, and that inaugurated the era of the Curies, Rutherford, Soddy, Hahn and Meitner, Fajans, and others who mapped the very complex radioactive transformations of the naturally occurring elements. The crucial importance of uranium, however, became fully apparent only after Fermi and his colleagues irradiated many of the elements, including uranium, with neutrons in the 1930s. They produced new radioactive species with chemical properties that were not identical with any of the known heavy elements. The Fermi group believed that they had created new elements heavier than uranium. In 1938 Hahn, Meitner, and Strassmann conducted definitive chemical experiments showing that the radioactive species produced by neutron irradiation of uranium were in fact fission fragments resulting from the cleavage of the uranium nucleus into smaller nuclei. Their experiments constituted the discovery of nuclear fission. The earlier formation of transuranium elements had been disproved, but the way to their synthesis was now open.

The first transuranium element, neptunium, was nevertheless the by-product of an investigation by McMillan and Abelson into the details of the fission process. While fission fragments recoil with enormous energy from a uranium nucleus undergoing fission, a radioactive species with a half-life of 2.3 days was observed to be formed with insufficient energy to escape from a thin film of irradiated uranium. Chemical investigation confirmed that a new element, neptunium, unknown in nature, with atomic number 93 and mass number 239, had been formed by neutron capture in ^{238}U.

$$^{238}_{92}\mathrm{U}+^{1}_{0}\mathrm{n} \rightarrow {}^{239}_{92}\mathrm{U} \xrightarrow[23.5\,\mathrm{min}]{\beta^-} {}^{239}_{93}\mathrm{Np} \quad (t_{1/2} = 2.36 \text{ days}) \tag{1.1}$$

The new prospects opened up by the discovery of the first transuranium element were rapidly explored, and soon the trickle became a flood. Table 1.1 lists the transuranium elements, the discoverers and the date of discovery, and the date of first isolation in weighable amount. The first of the transuranium elements to be synthesized on purpose, so to speak, was element 94 as the isotope of mass number 238. In 1940, Seaborg, McMillan, Kennedy, and Wahl at the University of California in Berkeley bombarded uranium oxide with 16 MeV deuterons produced in the 60 in. cyclotron and succeeded in isolating a long-lived alpha-particle emitter, chemically separable from both uranium and neptunium, which was identified as an isotope of element 94 and later given the name plutonium:

$$^{238}_{92}\mathrm{U} + {}^{2}_{1}\mathrm{H} \rightarrow {}^{238}_{93}\mathrm{Np} + 2^{1}_{0}\mathrm{n} \tag{1.2}$$

$$^{238}_{93}\mathrm{Np} \xrightarrow[2.1\mathrm{d}]{\beta^-} {}^{238}_{94}\mathrm{Pu} \quad (t_{1/2} = 87.7 \text{ years}) \tag{1.3}$$

Twenty isotopes of plutonium are now known. The plutonium isotope of major importance has always been the isotope of mass number 239. Research with ^{239}Pu has been strongly motivated by the fact that it was shown to be fissile by slow neutrons in the same way as ^{235}U, and would thus be able to sustain a neutron chain reaction. The isotope ^{239}Pu can thus be used for both military and nuclear energy purposes. To separate ^{235}U from ^{238}U requires an isotope separation of

---

[a] Discovery claimed and published but not confirmed by IUPAC/IUPAP.

formidable proportions, but separating ^{239}Pu in pure form requires only a chemical separation from other elements, likewise an intimidating problem, but one that is in principle a considerably simpler undertaking.

In 1941, Kennedy, Seaborg, Segré, and Wahl successfully obtained ^{239}Pu by radioactive decay from ^{239}Np, which was first produced by irradiating natural ^{238}U with cyclotron-generated neutrons:

$$^{238}_{92}\mathrm{U} + ^{1}_{0}\mathrm{n} \rightarrow ^{239}_{92}\mathrm{U} + \gamma \tag{1.4}$$

$$^{239}_{92}\mathrm{U} \underset{23.5\ \mathrm{min}}{\xrightarrow{\beta^-}} ^{239}_{93}\mathrm{Np} \underset{2.36\ \mathrm{days}}{\xrightarrow{\beta^-}} ^{239}_{94}\mathrm{Pu} \quad (t_{1/2} = 24\ 110\ \text{years}) \tag{1.5}$$

The isotope plutonium-239 indeed turned out to be fissionable, with a slow neutron cross section 1.7 times that of uranium-235. Later work at the wartime Los Alamos Laboratory established conclusively that sufficient neutrons were emitted in the act of fission to sustain a nuclear chain reaction. The exigencies of World War II soon made available the massive resources necessary to convert the scientific possibilities of the transuranium elements into actuality, and the nuclear age was truly upon us. Seaborg (1982, 1992) has given a vivid eyewitness account of the discovery and early experiments with plutonium. This chronicle describes in unusual detail the problems that confronted the investigators in this strange and intimidating new field of research, and how they were solved.

Twelve transplutonium elements were added to the periodic table in the 30 years between 1944 and 1974. The syntheses of the elements with atomic number 95 through 106 required the development of new and ingenious experimental techniques as well as new conceptual frameworks, and these were elaborated with remarkable speed. Elements 95 and 96, named americium and curium, respectively, were first prepared in 1944 by bombardment of ^{239}Pu; curium was synthesized by irradiation of plutonium with helium ions (alpha particles), and soon thereafter americium was synthesized by multiple neutron capture in plutonium in a nuclear reactor. As was the case for neptunium and plutonium, chemical identification was essential; it was not until these elements were predicted to be part of an actinide (5f) transition series with +3 oxidation states that they were isolated and identified. By 1946 the chemical properties of americium and curium were already well defined, and by 1949 sufficient amounts of americium-241 and curium-242 had been accumulated to make it possible to undertake a search for the next members of the actinide series. Bombardment of elements 95 and 96 by helium ions accelerated in the 60 in. Berkeley cyclotron produced alpha-particle-emitting species that could be identified as isotopes of elements 97 and 98. These in turn were named berkelium and californium after their place of discovery. Again, prediction of their behavior as +3 ions in aqueous solution was essential. During this same period of time, magnetic and spectroscopic evidence confirmed that the transuranium elements were indeed members of a 5f series of elements; see the review by Gruen (1992).

The detonation of a thermonuclear device is capable of producing enormously high fluxes of neutrons. The first test thermonuclear explosion was set off at Eniwetok Atoll by the United States at the end of 1952. The huge numbers of neutrons produced by the explosion resulted in multineutron captures in the uranium-238 that was a part of the device. The capture of no fewer than 15 neutrons by a ^{238}U nucleus yielded an isotope of element 98:

$$^{238}_{92}\mathrm{U} + 15^{1}_{0}\mathrm{n} \rightarrow {}^{253}_{92}\mathrm{U} \xrightarrow{\text{multiple } \beta^- \text{ decays}} {}^{253}_{98}\mathrm{Cf} \tag{1.6}$$

Capture of the 15 neutrons must have been accomplished in a fraction of a microsecond, and the subsequent radioactive decay of uranium-253 via a series of beta-particle emissions to form californium-253 must have been completed in a short time. Californium-253 then undergoes decay by beta-particle emission (with a half-life of 17.8 days) to form einsteinium-253. Close examination of the debris from the nuclear explosion revealed another alpha-particle-emitting radioactive species that was identified as an isotope of element 100 with the mass number 255. The new elements were named einsteinium and fermium in honor of two of the most important progenitors of the nuclear age. The unexpected consequences of the vast numbers of neutrons released by the nuclear chain reaction thus led to the synthesis of two new elements and revealed the potential utility of high-flux nuclear reactors in the production of transplutonium elements. Following the earlier use of other reactors in the 1950s, the High-Flux Isotope Reactor (HFIR) and the transuranium processing facility, currently named Radiochemical Engineering Development Center (REDC) were built at Oak Ridge National Laboratory in the 1960s for the production of transcurium elements. The HFIR starting material is highly irradiated plutonium-239 already containing substantial amounts of heavier isotopes of plutonium. Prolonged exposure to the intense neutron flux of HFIR produces considerable amounts of plutonium-242, americium-243, and curium-244, which have been isolated and refabricated into new targets for irradiation in the HFIR. Work-up of these targets, a task of no mean proportions because of the intense radioactivity from fission products and the newly formed transcurium elements, yields heavy isotopes of curium, berkelium, and californium plus smaller quantities of einsteinium and fermium.

The discovery of elements 99 and 100 in a sense was a watershed in the search for elements of ever higher atomic number. The experimental methods developed to isolate and identify neptunium and plutonium, refined and elaborated, were adequate for the task of isolation and characterization of the transplutonium elements up to element 100. With the transfermium elements, matters became much more difficult. Among the isotopes of the elements uranium, neptunium, plutonium, and curium, there is at least one that has a half-life of 10^6 years or more. For americium and berkelium, the longest-lived isotopes, produced by neutron irradiation, have half-lives of the order of 10^4 years and 1 year, respectively. The most stable californium isotope has a half-life less than

1000 years, einsteinium a half-life less than a year, and fermium a half-life of about 3 months. The elements of atomic number greater than 100 have isotopes with lifetimes measured in days, hours, minutes, seconds, and fractions of a second. The short half-lives severely limit the amount of a heavier isotope that can be made. Whereas the elements up to atomic number 100 could be characterized with amazingly small amounts of material, these, nevertheless, still contained large numbers of atoms. All of the actinides with atomic numbers up to 99 have been studied with weighable amounts (Table 1.1) but there is no prospect for producing weighable amounts of heavier elements. The elements of higher atomic number had to be identified with as little as one atom of a new element. That this feat was achievable was a result of the rapid developments in nuclear systematics, which made it possible to predict the nuclear properties of new isotopes; the actinide concept, which predicted the chemical properties of transuranium elements; and the development of new experimental techniques, which made it possible to isolate a single atom of a new isotope almost simultaneously with its formation in a nuclear reaction, and to measure half-lives in the millisecond range.

On the complex subject of nuclear systematics, it will be sufficient here to mention that the great progress made in the theoretical understanding of the behavior of atomic nuclei allowed predictions about lifetimes and the nature of radioactive emissions and their energetics to be made with considerable confidence, and this played a major role in the search for new elements. The actinide concept similarly played a crucial part. When the first transuranium elements were studied in the laboratory, it soon became apparent that the new members of the periodic table did not have the chemical properties that might be expected of them if they were placed in traditional sequence after uranium. Neptunium did not behave like rhenium, and in no way did plutonium resemble osmium, which would have been positioned directly above plutonium had the first two transuranium elements merely been inserted in the next vacant positions in the periodic table directly after uranium. Because similarities in chemical behavior arise in the periodic table from similarities in electronic configuration of the ions of homologous elements, simple insertion of the transuranium elements into the periodic table would have precluded its use as a reliable guide to the chemistry of the new elements.

The actinide hypothesis advanced by Seaborg systematized the chemistry of the transuranium elements, and thus greatly facilitated the search for new elements. From the vantage point of the actinide concept, the transuranium elements are considered to constitute a second inner transition series of elements similar to the rare-earth elements. In the rare-earth series, successive electrons are added to the inner 4f shell beginning with cerium and ending with lutetium. In the actinide series, fourteen 5f electrons are added beginning, formally, with thorium (atomic number 90) and ending with lawrencium (atomic number 103). Although the regularities are not as pronounced in the actinide as in the lanthanide series, the concept of the actinide elements as members of a 5f transition series is now accepted and has served as a unifying principle in the evolution of the chemistry of the actinide elements. A more detailed discussion of the actinide hypothesis can be found in Chapter 15.

The first chemical studies on neptunium and plutonium were made using classical radiochemical techniques in the 1940s. Amounts far too small to be weighed were studied by tracer methods, where solutions are handled in ordinary-sized laboratory vessels. Concentrations of the order of 10^{-12} mol L^{-1} or less are not unusual in tracer work, and valuable information could be acquired on solutions containing only a few million atoms. The radioactive element is detected by its radioactivity, and the chemistry is inferred from its behavior relative to that of an element of known chemistry present in macro amounts. When weighable amounts were available, ultramicrochemical methods were used. These manipulations were and still are carried out with microgram or even lesser amounts of material in volumes of solution too small to be seen by the naked eye at concentrations normally encountered in the laboratory. Ultramicro methods make possible the isolation of small samples of pure chemical compounds, which can then be identified by X-ray crystallography or electron diffraction in a transmission electron microscope. All of the actinide elements are radioactive, and, except for thorium and uranium, special containment and shielded facilities are mandatory for safe handling of these substances. Gloved boxes are required (Fig. 1.2)

and, where high levels of penetrating radiation (gamma rays or neutrons) are encountered, which is not infrequent, all manipulations may need to be performed by remote control (Figs. 1.3 and 1.4). Even when radiation can easily be shielded, as is the case with alpha-particle emitters, containment to prevent inhalation is still essential because of the toxicity of the transuranium elements. Inhaled transuranium isotopes may be deposited in the lungs and ingested isotopes may be translocated to the bone, where the intense alpha radioactivity over a period of time can give rise to neoplasms. The shorter the half-life, i.e., the higher the specific activity of the radioactive isotope, the more serious are the difficulties of experiments with macro amounts of material. Consequently, every effort has been made to produce long-lived isotopes. There are available isotopes of neptunium, plutonium, and curium with half-lives longer than 10^5 years, and isotopes of americium and californium that have half-lives of the order of 1000 years can be used in chemical studies. These long-lived isotopes greatly reduce the extent of radiolysis of water or other solvents for experiments in the liquid phase, they minimize radiation damage in the solid phase, and they also considerably reduce the health hazards in the experiment. Even with the longest-lived isotopes, most laboratory research with transuranium elements is carried out on the milligram or smaller scale.

The syntheses of the transfermium elements presented an even more challenging set of problems. Because of the short lifetimes of these isotopes, production by successive neutron capture in a high-flux reactor was not possible. Methods

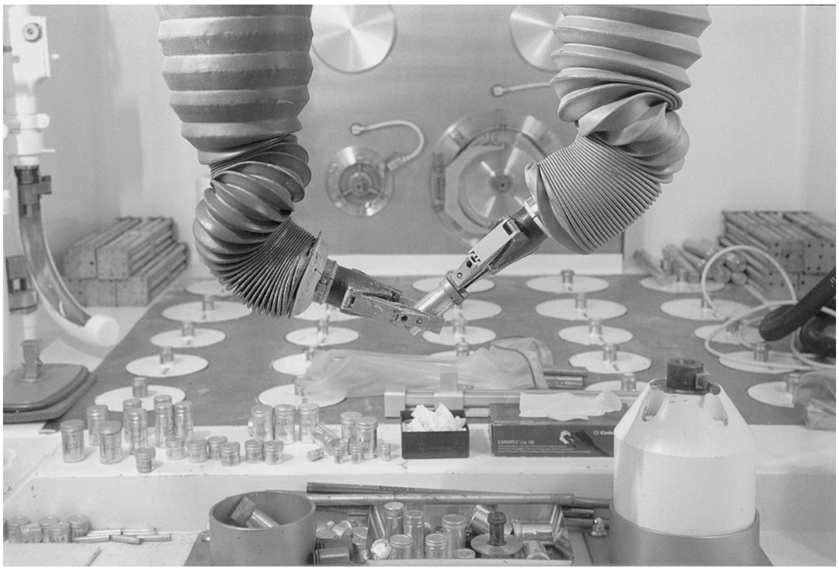

Fig. 1.4 *Example of an experimental setup within a hot-cell facility.* (*Reproduced by permission of Institute for Transuranium Elements, Karlsruhe, part of the Joint Research Centre, European Commission.*)

for the rapid collection of the newly formed isotopes had to be developed and very rapid separation procedures were required to isolate a pure product for identification. Ghiorso (1982) described in fascinating detail how these problems were surmounted. A newly formed nucleus contains sufficient energy to eject it from a target undergoing bombardment; the atom that recoils can be caught on a clean foil placed in close proximity to the target. The catcher foil can then be dissolved and the solution examined. For identification, ion-exchange chromatography proved to be ideal. Elution from an ion-exchange column can be carried out very rapidly. The order of elution is very specific and provides an unmistakable fingerprint for identification. In this way, it was possible to synthesize and identify element 101, subsequently named mendelevium, in experiments in which it was made one atom at a time. Even more highly refined collection procedures were evolved to complete the actinide series of elements by the discovery of nobelium (atomic number 102) and lawrencium (atomic number 103).

The transactinide elements 104 through 112 have been discovered at Berkeley and Darmstadt (see Table 1.1). Scientists at the Dubna Laboratory in Russia also made claims for the discovery of a number of these elements, but their evidence did not meet the accepted criteria for the discovery of new elements (Wilkinson *et al.*, 1991, 1993). No names have been suggested for elements heavier than 111, in conformity with the IUPAC rules for the naming of new elements (Koppenol, 2002). A surprising amount of information has accumulated about the oxidation states of the transfermium and transactinide ions in solution even though only a few atoms of any of these were available at any one time. Evidence for isotopes of elements heavier than 112 has been published by a consortium of scientists from Dubna and Livermore (Table 1.1). The chemistry of transactinide elements, and predicted chemical properties of these elements, is presented in Chapter 14.

One frontier is the synthesis of longer-lived isotopes and determination of chemical properties of additional transactinide elements (Chapter 14 of this work; Schädel, 2003). Numerous theoretical calculations have been made that indicate that there may be more than one "island" of relatively stable nuclei near the presently defined limits of the periodic table. In addition to the island of spherical stability originally predicted to be around atomic number $Z = 114$ and neutron number $N = 184$, other islands of spherical nuclei have been predicted at $Z = 120$ or 126 and $N = 184$ and at $Z = 120$ and $N = 172$. A predicted island of deformed nuclei at $Z = 108$ and $N = 162$ has already been confirmed experimentally. Because of the relatively long half-lives of isotopes conferred by closed nuclear shells, the goal of carrying out chemical studies with the elements at or near these islands is considered to be attainable by some scientists. The new techniques and theoretical understanding required to attain this goal will undoubtedly have profound consequences for nuclear and inorganic chemistry.

There are outstanding questions in actinide chemistry. One is the understanding of the bonding and electronic structure of the 5f electrons in condensed phases containing plutonium and adjacent elements. Another is the bonding and chemical behavior of actinides that may be released into the environment. To advance both of these frontiers, heavy-element chemists utilize modern instrumental techniques – X-ray absorption spectroscopy, laser fluorescence spectroscopy, electron microscopy, mass spectroscopy, neutron scattering, to name only a few – that make it possible to study the elements described in the subsequent chapters as pure materials, at extremely low concentrations, and under many unique conditions. Theoretical actinide and transactinide chemistry is advancing rapidly. Relativistic contributions to electronic properties that incorporate spin–orbit interactions are being calculated for bulk actinide solids, actinide metal surfaces, actinide complexes in solution, and transactinide atoms. Relativistic electronic structure theory utilizes time-dependent density functional theory and relativistic effective core potentials.

The actinide and transactinide elements in the last 65 years have played an important role in inorganic chemistry, in nuclear chemistry and physics, and in many other branches of science and technology. The actinide elements are also of crucial importance in energy resource development and, regrettably, in warfare. These elements are destined to continue to occupy the attention of scientists, engineers, environmentalists, and statesmen. We hope that these volumes will help provide the factual basis so necessary for the important research breakthroughs and technical decisions that will have to be made in future years.

CHAPTER TWO

ACTINIUM

H. W. Kirby and L. R. Morss

2.1 INTRODUCTION

The actinide series of elements encompasses all the 15 chemical elements that have properties attributable to the presence of low-lying 7p, 6d, and 5f orbitals such that their tripositive ions have electronic configurations $7p^06d^05f^n$, where $n = 0,1,2,\ldots,14$. According to this definition, actinium, element 89, is the first member of the actinide series of elements, although it has no 5f electrons in its metallic, gaseous, or ionic forms. As such, its position in group 3 (in current IUPAC terminology) or group 3B (commonly used in some American textbooks) of the periodic table is analogous to that of its homolog, lanthanum, in the lanthanide series. This definition, which includes actinium as the first of the actinides (Seaborg, 1994), parallels the accepted inclusion of lanthanum as the first member of the lanthanide series (Moeller, 1963).

The chemistry of actinium closely follows that of lanthanum. There are no qualitative differences between them; the only quantitative differences are those attributable to the difference in their ionic radii (1.12 Å for Ac^{3+} and 1.032 Å for La^{3+} in six-fold coordination) (Shannon, 1976 and Chapter 15, section 7.5, of this book). Because of this similarity, lanthanum is a nearly ideal surrogate for actinium in the development of preparative or analytical procedures. As a carrier for trace amounts of actinium, lanthanum suffers from only one disadvantage: Once mixed, the two elements behave like any pair of adjacent rare earths and can be separated only by ion-exchange chromatography, solvent extraction, or fractional crystallization.

The most important isotope of actinium is ^{227}Ac, a member of the naturally occurring uranium–actinium ($4n + 3$) family of radioelements. Its applications are derived from its unique radioactive properties. Although ^{227}Ac itself is essentially ($\geq$98%) a weak β^- emitter, with a moderately long half-life (21.773 years), its decay chain includes five short-lived α emitters. The net effect is one of high specific power and long service life, a combination that makes ^{227}Ac suitable as a heat source in thermoelectric generators on space missions to the outer planets and beyond. Recently ^{225}Ac and ^{228}Ac have found applications (see Section 2.9).

The early actinium literature (up to January 1940) was comprehensively reviewed by the staff of the Gmelin Institute, and an English translation is available (Gmelin, 1942). Later reviews and bibliographies have appeared with the waxing and waning of interest in possible applications of actinium (Clarke, 1954, 1958; Hagemann, 1954; Bagnall, 1957; Katz and Seaborg, 1957; Bouissières, 1960; Stevenson and Nervik, 1961; Salutsky, 1962; Sedlet, 1964; Kirby, 1967; Keller, 1977). The most recent monograph on actinium chemistry is the *Gmelin Handbook* supplement (Gmelin, 1981).

2.1.1 Historical

In 1899, André Debierne, in the laboratory of Pierre and Marie Curie, reported that he had found a new radioactive substance, whose chemistry closely followed that of titanium (Debierne, 1899). Six months later, he said that the titanium fraction was no longer very active, but that the radioactive material he was now recovering exhibited the same chemical behavior as thorium (Debierne, 1900). Debierne claimed the right of discovery and named the new substance actinium (*aktis*, ray). His claim was accepted uncritically at the time, but, in the light of what we now know of the chemical and nuclear properties of actinium, it is clear that his 1899 preparation contained no actinium at all and that his 1900 preparation was a mixture of several radioelements, possibly including actinium as a minor constituent (Kirby, 1971; Adloff, 2000).

In 1902, Friedrich Giesel reported a new 'emanation-producing' substance among the impurities he had separated with radium from pitchblende residues (Giesel, 1902). He correctly established many of its chemical properties, including the important fact that it followed the chemistry of the cerium group of rare earths. By 1903, he had concentrated and purified it to a point where lanthanum was the chief impurity and thorium was spectroscopically undetectable (Giesel, 1903). A year later, he proposed the name, emanium, for what was clearly a new radioelement (Giesel, 1904a).

Giesel's claim was vigorously attacked by Debierne (1904), who now had an emanation-producing substance of his own, which, he insisted, was the same as the substance he had originally named actinium, although the 1900 preparation had titanium- or thorium-like properties (Adloff, 2000). Debierne's claim prevailed, and has been propagated by historians (Ihde, 1964; Partington, 1964; Weeks and Leicester, 1968), largely because of the prestige of the Curies and the support of Rutherford (1904). The latter based his conclusion solely on the similarity in the decay characteristics of the "emanations" (i.e. ^{219}Rn) and the "active deposits" (^{211}Pb) given off by the samples supplied to him by the two claimants. Although some historical studies (Weeks and Leicester, 1968; Adloff, 2000) give both Debierne and Giesel credit for the discovery, Kirby (1971), Keller (1977), and the second author of this chapter believe that it is more appropriate to give credit for discovery of actinium to Giesel.

The actinium decay chain was sorted out rather quickly. In 1905, Godlewski (1904–5, 1905) and Giesel (1904b, 1905) independently reported the existence of actinium X (also referred to as "emanium X"), now known as ^{223}Ra, and showed it to be the direct source of the actinium emanation and its active deposit. The following year, Hahn (1906a,b) discovered radioactinium (^{227}Th), the immediate descendant of actinium and the parent of actinium X. ^{231}Pa, the parent of actinium, was discovered independently in 1918 by Soddy and Cranston (1918a,b) and by Hahn and Meitner (1918). The primordial origin of the actinium series ($4n + 3$ or uranium–actinium series, Fig. 2.1) was not finally resolved until 1935, when Dempster (1935) detected the uranium isotope of atomic weight 235 by mass spectroscopy.

2.2 NUCLEAR PROPERTIES

Of the 29 known isotopes of actinium (Table 2.1) only three are of particular significance to chemists. Two of these isotopes are the naturally occurring isotopes, ^{227}Ac (Fig. 2.1, $4n + 3$ or uranium–actinium series) and ^{228}Ac (mesothorium II, Fig. 2.2, $4n$ or thorium series). The third is ^{225}Ac, a descendant of reactor-produced ^{233}U (Fig. 2.3, $4n + 1$ or neptunium series).

2.2.1 Actinium–227

The isotope ^{227}Ac, a β^- emitter, is a member of the naturally occurring ^{235}U (AcU) decay series (Fig. 2.1). It is the daughter of ^{231}Pa and the parent of ^{227}Th (RdAc). It is also the parent, by a 1.38% α branch (Kirby, 1970; Monsecour *et al.*, 1974), of ^{223}Fr, which was discovered in 1939 by Perey (1939a,b). The half-life of ^{227}Ac is (21.772 ± 0.003) years (Jordan and Blanke, 1967; Browne, 2001), as determined by calorimetric measurements made over a period of 14 years. The thermal-neutron-capture cross section σ_t and the resonance integral are (762 ± 29) barn and (1017 ± 103) barn, respectively (1 barn = 10^{-28} m^2) (Monsecour and De Regge, 1975).

The β^- radiation of ^{227}Ac is so weak (0.045 MeV maximum) (Beckmann, 1955; Novikova *et al.*, 1960) that the nuclide was once thought to be 'rayless' (Marckwald, 1909; Rutherford, 1911). Even with modern nuclear spectrometers, neither the β^- nor the γ radiation is useful for analytical purposes because of interference from the rapidly growing decay products. On the other hand, ^{227}Ac is readily identified, even in the presence of its decay products,

by α spectrometry (Fig. 2.4), and a computational technique has been described for its quantitative determination by this method (Kirby, 1970).

The γ spectrum of ^{227}Ac in equilibrium with its decay products is shown in Fig. 2.5. The 235.9-keV γ-ray, which has an intensity of (12.3 ± 1.3)% of ^{227}Th

α decay, can be used for quantitative analysis of ^{227}Ac. For a detailed level scheme, see the most recent critical compilation (Firestone and Shirley, 1996).

2.2.2 Actinium–228 (MsTh II or MsTh$_2$)

The isotope ^{228}Ac (mesothorium II or MsTh$_2$) is a member of the naturally occurring ^{232}Th decay chain. It is the daughter of 5.77-year ^{228}Ra (mesothorium I or MsTh$_1$) and the parent of 1.9116-year ^{228}Th (radiothorium).

All three nuclides were discovered by Otto Hahn (1905, 1907, 1908). The long-accepted half-life of ^{228}Ac (6.13 ± 0.03) h, reported in 1926 (Hahn and Erbacher, 1926), was redetermined to be (6.15 ± 0.02) h in 1985 (Skarnemark and Skalberg, 1985).

^{228}Ac has a complex β$^-$ spectrum (Bjornholm *et al.*, 1957; Arnoux and Giaon, 1969; Dalmasso *et al.*, 1974), but, unlike ^{227}Ac, more than 99% of the β$^-$ particles have maximum energies greater than 0.5 MeV so that its γ-ray spectrum (Novikova *et al.*, 1960) is a useful analytical tool. By contrast, the

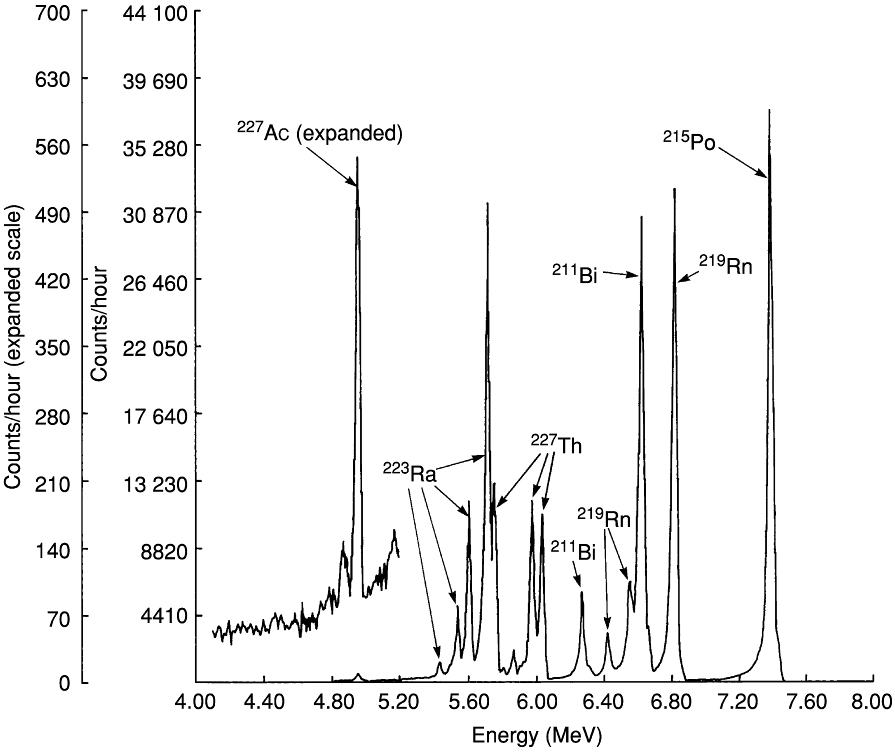

Fig. 2.4 *Alpha spectrum of* ^{227}*Ac in equilibrium with its decay products* (*Kirby,* 1970).

β^- and γ radiations from ^{228}Ra are too weak for routine detection; consequently, nearly all methods for the determination of ^{228}Ra are based on the isolation and counting of ^{228}Ac (Hahn and Erbacher, 1926). ^{228}Ac is frequently used as a tracer for other actinium isotopes (Bhatki and Adloff, 1964; Chayawattanangkur *et al.*, 1973).

A level scheme and a critical compilation of γ-ray energies for ^{228}Ac have been published (Horen, 1973).

2.2.3 Actinium-225

The isotope ^{225}Ac is an α emitter. It is a member of the $4n + 1$ decay series, of which ^{237}Np is the longest-lived member and progenitor (Fig. 2.3). In practice, however, ^{225}Ac is most easily obtained by milking a sample of ^{229}Th that was previously separated from aged ^{233}U (Valli, 1964). The latter isotope is itself produced by neutron bombardment of natural thorium (St. John and Toops, 1958; Hyde *et al.*, 1964):

$$^{232}\mathrm{Th}(\mathrm{n},\gamma)^{233}\mathrm{Th} \xrightarrow[22.3\ \mathrm{min}]{\beta^-} {}^{233}\mathrm{Pa} \xrightarrow[26.967\,\mathrm{d}]{\beta^-} {}^{233}\mathrm{U} \tag{2.1}$$

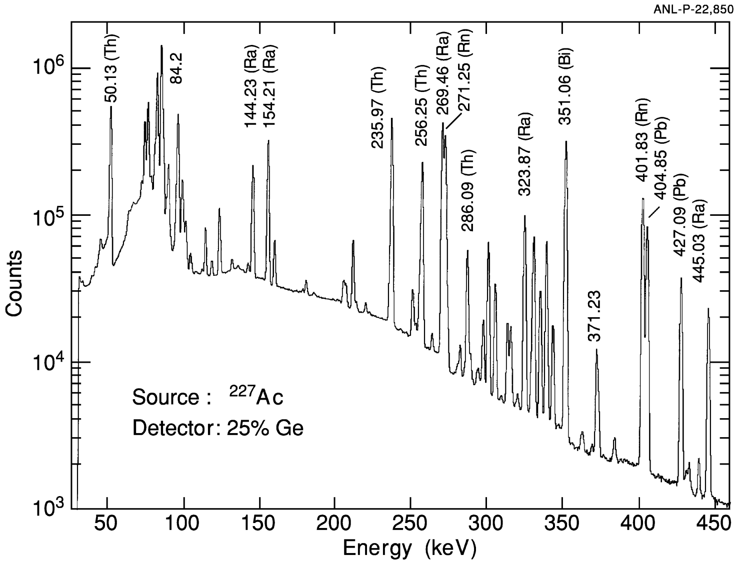

Fig. 2.5 *Gamma spectrum of ^{227}Ac in equilibrium with its decay products* (*I. Ahmad,* 2002).

Unfortunately, ^{229}Th is always more or less contaminated with ^{228}Th because of side reactions during the production of ^{233}U:

$$^{232}\text{Th}(\text{n},2\text{n})^{231}\text{Th} \xrightarrow[25.52\ \text{h}]{\beta^-} {}^{231}\text{Pa} \tag{2.2}$$

$$^{231}\text{Pa}(\text{n},\gamma)^{232}\text{Pa} \xrightarrow[1.31\ \text{d}]{\beta^-} {}^{232}\text{U} \xrightarrow[68.9\,\text{y}]{\alpha} {}^{228}\text{Th} \tag{2.3}$$

To obtain pure samples of ^{225}Ac, the presence of ^{228}Th in ^{229}Th is not a serious problem, because the ^{224}Ra daughter of ^{228}Th can be chemically separated from he ^{225}Ac, together with ^{225}Ra, after its milking from thorium. The ^{224}Ra must be removed to ensure the absence of its progeny ^{208}Tl, which emits a 2.6-MeV γ-ray.

The complex fine structure of the ^{225}Ac α spectrum was thoroughly investigated by Dzhelepov *et al.* (1967) and by Bastin-Scoffier (1967). A level scheme is given in a critical compilation (Maples, 1973).

2.3 OCCURRENCE IN NATURE

The natural occurrence of ^{227}Ac is proportional to that of its primordial ancestor, ^{235}U, which is widely distributed in the Earth's crust (Kirby, 1974). The average crustal abundance of uranium is 2.7 ppm (Taylor, 1964), of which

0.720 mass% is ^{235}U (Holden, 1977). Therefore, the natural abundance of ^{227}Ac (calculated from its half-life and that of ^{235}U) is 5.7×10^{-10} ppm. Based upon a crustal mass of 2.5×10^{25} g (to a depth of 36 km) (Heydemann, 1969), the global inventory of ^{227}Ac is estimated to be 1.4×10^{4} metric tons.

Although the $4n + 1$ family is not ordinarily considered to be 'naturally occurring' because its primordial ancestor has become extinct, both ^{237}Np and ^{225}Ac have been detected in uranium refinery wastes and ^{225}Ac has been found in ^{232}Th isolated from Brazilian monazite (Peppard *et al.*, 1952). These nuclides are believed to be formed continually in nature by the bombardment of natural thorium and uranium with neutrons arising from spontaneous fission of ^{238}U and from neutrons produced by (α,n) reactions on light elements:

$$^{238}\mathrm{U(n,2n)}\ ^{237}\mathrm{U} \xrightarrow[6.75\mathrm{d}]{\beta^-} {}^{237}\mathrm{Np} \tag{2.4}$$

$$^{232}\mathrm{Th}(\mathrm{n},\gamma)\ ^{233}\mathrm{Th} \xrightarrow[22.3\,\mathrm{min}]{\beta^-} {}^{233}\mathrm{U} \tag{2.5}$$

2.4 PREPARATION AND PURIFICATION

Uranium ores always contain large amounts of rare earths, and were thus generally unsatisfactory as sources of actinium before modern methods of rare earth separations were developed. The most concentrated actinium sample ever prepared from a natural raw material consisted of 0.5 mCi (~7 μg) of ^{227}Ac in less than 0.1 mg of La_2O_3 (Lecoin *et al.*, 1950).

In 1949, Peterson reported that ^{227}Ac could be synthesized by irradiating ^{226}Ra with thermal neutrons (Peterson, 1949):

$$^{226}\mathrm{Ra}(\mathrm{n},\gamma)\ ^{227}\mathrm{Ra} \xrightarrow[42.2\,\mathrm{min}]{\beta^-} {}^{227}\mathrm{Ac} \quad (\sigma_\mathrm{t} \cong 20\ \mathrm{barn}) \tag{2.6}$$

This reaction greatly simplified the chemical separations required to prepare macroscopic amounts of pure ^{227}Ac and, in 1950, Hagemann reported the isolation of 1.27 mg of ^{227}Ac from 1 g of neutron-irradiated ^{226}Ra (Hagemann, 1950).

Later work (Kirby *et al.*, 1956; Cabell, 1959; Monsecour and De Regge, 1975) showed that the neutron-capture cross section of ^{227}Ac is many times greater than that of ^{226}Ra (Fig. 2.6). A new problem is introduced, namely that of separating ^{227}Ac from the large amounts of 1.9-year ^{228}Th produced by the second-order reactions:

$$^{227}\mathrm{Ac}(\mathrm{n},\gamma)\ ^{228}\mathrm{Ac} \xrightarrow[6.15\ \mathrm{h}]{\beta^-} {}^{228}\mathrm{Th} \quad (\sigma_\mathrm{t} = 762\ \mathrm{barn}) \tag{2.7}$$

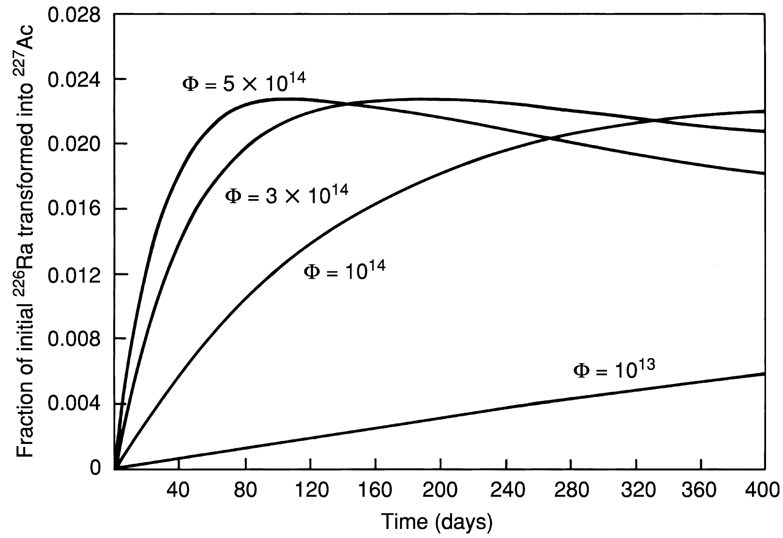

Fig. 2.6 *Growth of* ^{227}*Ac in neutron-irradiated* ^{226}*Ra at various thermal-neutron fluxes* Φ (*in* $\mathrm{cm^{-2}\ s^{-1}}$). *The calculations assume* $\sigma_t(^{226}Ra) = 20$ *barn and* $\sigma_t(^{227}Ac) = 795$ *barn* (*Gomm and Eakins,* 1968).

Nevertheless, neutron irradiation of ^{226}Ra remains the method of choice for the preparation of ^{227}Ac at either the tracer or the macroscopic level.

The isotope ^{225}Ac is best generated by separating it from the generator ^{229}Th (Geerlings *et al.*,1993; Tsoupko-Sitnikov *et al.*, 1996; Khalkin *et al.*, 1997). The ^{229}Th generator must be separated from ^{233}U. The isotope ^{233}U is synthesized by neutron irradiation of ^{232}Th, which contaminates the ^{229}Th with some ^{228}Th and its daughters.

The isotope ^{228}Ac can be generated by separating it from the generator ^{228}Ra, which can be isolated from natural ^{232}Th (Gmelin, 1981). Detailed procedures were given by Sekine *et al.* (1967). Sani (1970) and Mikheev *et al.* (1995) removed ^{228}Ra from aged ^{232}Th by cocrystallization with $Ba(NO_3)_2$. The ^{228}Ac that grew into ^{228}Ra was removed by extraction or by adding $GdCl_3$ to an aqueous solution of the ^{228}Ra in $Ba(NO_3)_2$ and coprecipitating Ac^{3+} with Gd $(OH)_3$ using $NH_3(g)$.

2.4.1 Purification by liquid–liquid extraction

Hagemann (1950, 1954) isolated the first milligram of ^{227}Ac from neutron-irradiated ^{226}Ra by liquid–liquid extraction with 2-thenoyltrifluoroacetone (TTA). Experience has shown (Engle, 1950; Stevenson and Nervik, 1961; Kirby, 1967), however, that TTA is not a suitable reagent for quantitative extraction of actinium because a relatively high pH (≥ 5.5, Fig. 2.7) is required

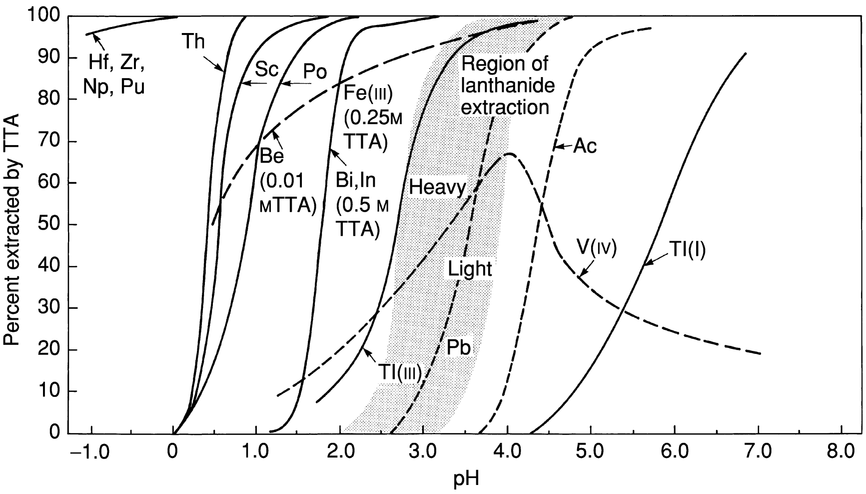

Fig. 2.7 *Extraction of various elements with thenoyltrifluoroacetone* (*TTA*). (*After Stevenson and Nervik,* 1961).

for efficient chelation but Ac^{3+} hydrolyzes above pH 7 and forms inextractable polymeric species when the pH is in the 'desirable' range, 6–7. The recovery of actinium requires tight pH control and speed of operation for satisfactory yields (Allison *et al.*, 1954; Tousset, 1961) that are usually not quantitative. The most effective application of TTA in the purification of ^{227}Ac is to remove ^{227}Th, which can be selectively and quantitatively extracted from moderately acid solutions. For this extraction, the pH_{50} (the pH at which 50% of the Th^{4+} is extracted or partitioned equally between the phases, i.e. $D = 1$) is 0.48 (Poskanzer and Foreman, 1961).

On the other hand, Sekine *et al.* (1967) found that, while the extraction of ^{228}Ac with TTA alone was not quantitative, a mixture of 0.1 M TTA and 0.1 M tri(*n*-butyl)phosphate (TBP) in CCl_4 gave reproducible distribution ratios and quantitative extraction of Ac^{3+} at pH ≥ 4.

Solvent extraction systems that have been applied to other actinide and lanthanide separations have also been applied to actinium separations from thorium and radium. Thus, Karalova *et al.* (1977a) studied the extraction of Ac(III) in aqueous nitrate solution by trioctylphosphine oxide dissolved in cyclohexane, *o*-xylene, carbon tetrachloride, octyl alcohol, or chloroform. Optimum extraction conditions were: $[NaNO_3] \geq 2$ M, pH 2, and cyclohexane as the partition solvent. Making the aqueous phase 8 M in lithium chloride appears to facilitate extraction with 0.1 M trioctylphosphine oxide (Karalova *et al.*, 1977b).

Trialkylphosphine oxide in aliphatic hydrocarbon solvents was used by Xu *et al.* (1983) for the solvent extraction separation of Ac(III) from La(III) in nitric acid solution. Amines and quaternary ammonium bases have also been used in solvent extraction systems for the separation of Ac(III) from rare earths and Am(III). Karalova *et al.* (1979a) examined the separation of Ac(III) from Eu(III) by extraction from aqueous solutions containing lithium nitrate at pH 2.5–3 with tri-*n*-octylamine in cyclohexane, and concluded that this partition system shows promise for the separation of Ac(III) from rare earths. A 0.5 M solution of the quaternary ammonium base Aliquat 336 (methyltrioctylammonium chloride) in xylene extracts Ac, Am, and Eu efficiently from aqueous alkaline ($pH > 11$) solutions containing ethylenediaminetetraacetic acid (EDTA) or 2-hydroxydiaminopropanetetraacetic acid; separation factors for Ac(III)/Am(III) and Ac(III)/Eu(III) greater than 100 were attained (Karalova *et al.*, 1978a, 1979b). A mixture of trialkylmethylammonium nitrate and TBP was reported by Mikhailichenko *et al.* (1982) to exert a weak synergistic effect on La(III) extraction and an antagonistic effect on Ac(III) extraction. Bis(2-ethylhexyl) phosphoric acid (HDEHP) has been successfully employed in the solvent extraction separation of ^{227}Ac(III), ^{227}Th(IV), ^{223}Ra(II), and ^{223}Fr(I) (Mitsugashira *et al.*, 1977). Karalova *et al.* (1978b) established that the actinium species extracted from 1 M perchloric acid is $AcX_3{\cdot}2HX$, and at higher perchloric acid concentrations is $HAc(ClO_4)_4{\cdot}2HX$.

The use of bis(2-ethylhexyl)phosphoric acid (HDEHP) as an extractant for Ac^{3+} has been little explored. Two studies have explored the fundamental mechanism of this extractant with Ac^{3+} (Szeglowski and Kubica, 1991) and the influence of colloidal rare earth particles on this extraction (Szeglowski and Kubica, 1990).

An unusual purification procedure is one in which actinium must be removed from rare earths on a commercial scale to minimize the level of radioactive contamination of the rare earth products (Kosynkin *et al.*, 1995). Uranium–rare earth phosphorites [fibrous apatites, generic formula $Ca_5(PO_4)_3(OH,F,Cl)$] have been processed commercially to remove both uranium and rare earths. After uranium was extracted from the dissolved phosphorite, cerium was removed by oxidation and precipitation from dilute acid. The trivalent rare earths and actinium remained in the aqueous phase and the actinium was removed from the rare earth fraction using mixer-settlers with mixtures of TBP and trialkyl amine (TAA) extractants in kerosene. Decontamination from a level of $\sim 10^{-8}$ Ci/(g rare earth oxides) to a level of $\sim 2 \times 10^{-11}$ Ci/(g rare earth oxides) has been achieved on an industrial scale.

2.4.2 Purification by ion-exchange chromatography

Cation-exchange chromatography is the simplest and most consistently effective method of separating sub-milligram amounts of ^{227}Ac from its principal decay products, 18.68-day ^{227}Th and 11.43-day ^{223}Ra (Gmelin, 1981). The resin most commonly employed is a strong cation-exchange resin such as Dowex 50 (Andrews and Hagemann, 1948; Cabell, 1959; Farr *et al.*, 1961; Eichelberger *et al.*, 1964; Nelson, 1964; De Troyer and Dejonghe, 1966; Baetslé *et al.*, 1967;

Baetslé and Droissart, 1973; Kraus, 1979; Boll *et al.*, 2005), but inorganic ion exchangers have also been used successfully (Huys and Baetslé, 1967; Monsecour and De Regge, 1975). The method is applicable to milking of ^{228}Ac tracer from its parent, 5.76 year ^{228}Ra (Bjornholm *et al.*, 1956, 1957; Duyckaerts and Lejeune, 1960; Bryukher, 1963; Bhatki and Adloff, 1964; Gomm and Eakins, 1966; Arnoux and Giaon, 1969; Monsecour *et al.*, 1973). A typical separation is illustrated in Fig. 2.8.

Anion-exchange chromatography is now used for bulk separation of ^{225}Ac and ^{223}Ra from ^{229}Th. The ^{225}Ac and ^{223}Ra are eluted in 2–4 bed volumes of 8 M HNO_3 and then ^{229}Th is stripped from the resin in 0.1 M HNO_3, after which the ^{229}Th can be recycled (Boll *et al.*, 2004).

Partition chromatography by reverse-phase and ion-exchange chromatography has been explored (Sinitsyna *et al.*, 1977, 1979). The radioisotopes of actinium were separated from other elements using trioctylamine, bis(2-ethylhexyl)phosphoric acid, and TBP as stationary phases on Teflon. Chromatography on a Teflon support was also investigated by Korotkin (1981). He used a mixture of TTA and TBP impregnated in Teflon to sorb the metal ions. Elution

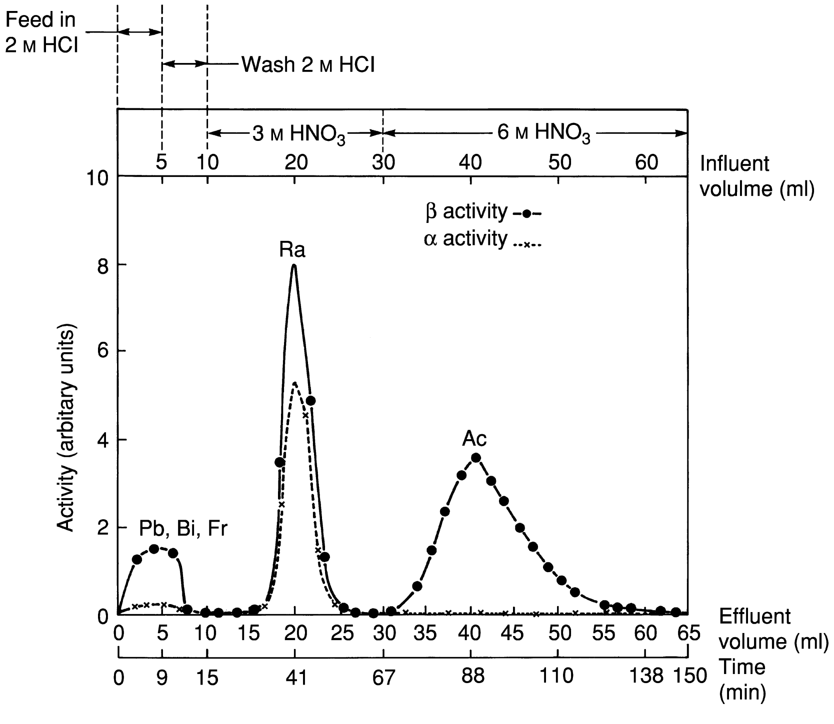

Fig. 2.8 *Separation of* ^{227}Ac *from its decay products by cation-exchange chromatography on Dowex* 50, *hydrogen form,* 200–400 *mesh,* 60°C (*Cabell,* 1959).

was by oxalate in a phthalate buffer. The procedure appears to have general utility for the rapid separation of actinides, lanthanides, and other metal ions. ^{227}Ac was separated from irradiated radium samples containing Pb, Tl, Bi, Po, and Th, and ^{225}Ac was separated from ^{233}U containing the same elements.

The inorganic cation exchanger, cryptomelane MnO_2 [a sorbent for large cations related to the mineral cryptomelane, $K(Mn^{4+},Mn^{2+})_8O_{16}$] is highly radiation-resistant and has distribution ratios (K_d values) for trivalent lanthanides and actinides that are orders of magnitude smaller than for Ra^{2+}. This ion exchanger has been used to separate $^{225}Ac^{3+}$ or $^{228}Ac^{3+}$ from $^{225}Ra^{2+}$ or $^{228}Ra^{2+}$ in radioisotope generators (Włodzimirska *et al.*, 2003).

2.4.3 Isolation of gram quantities of actinium

The history of large-scale actinium production is littered with the mutilated corpses of carefully designed processes, developed at the laboratory scale, which failed utterly, or required innumerable *ad hoc* modifications, when they were applied to the recovery of multi-Curie amounts of ^{227}Ac and ^{228}Th from multigram quantities of neutron-irradiated ^{226}Ra (Andrews and Hagemann, 1948; Engle, 1950; Kirby, 1951, 1952; Eichelberger *et al.*, 1964, 1965; De Troyer and Dejonghe, 1966; Foster, 1966; Baetslé *et al.*, 1967; Huys and Baetslé, 1967; Baetslé and Droissart, 1973).

Not the least of the problems is that posed by 3.824-day ^{222}Rn, a noble gas, which is evolved copiously and continuously by the decay of ^{226}Ra. The radioactive gaseous exhaust from the facility must be trapped and immobilized for several weeks while it decays to levels at which it can safely be released to the environment. (The maximum permissible concentration [inhalation derived air concentration (DAC)] of ^{222}Rn and its progeny in air in the workplace is very low, 3×10^{-8} μCi mL^{-1}) (U.S. Nuclear Regulatory Commission, 2005) Until now, this low level has been achieved by adsorbing the radon on activated charcoal at −75 to −180°C (Baetslé *et al.*, 1972), or by replacing the air at a sufficiently high rate, but chemical methods for removing radon and its daughters from the air by reaction with powerful fluorination reagents were also shown to bear promise for the removal of radon from air (Stein and Hohorst, 1982).

At the Belgian Nuclear Research Center (SCK-CEN, Mol), the irradiated $RaCO_3$ was dissolved in dilute nitric acid, and then precipitated as $Ra(NO_3)_2$ from 80% HNO_3, leaving nearly all the ^{227}Ac and ^{228}Th in solution. This step made the ^{226}Ra immediately available for recycling to the reactor; it also eliminated many of the severe radiolytic problems that develop when organic solvents or ion-exchange resins are in contact with large amounts of ^{226}Ra for extended periods of time.

The solution was then filtered, adjusted to 5 M HNO_3, and passed through a column of Dowex AG 1 × 8, an anion-exchange resin. ^{228}Th was quantitatively adsorbed (Danon, 1956, 1958), while the non-complexing cations (Fe, Ni, Cr) passed through the column unimpeded. ^{227}Ac, which appeared to be adsorbed to a slight extent by the resin, followed after a brief delay. The actinium was finally purified by oxalate precipitation (Salutsky and Kirby, 1956) and ignited to Ac_2O_3 at 700°C. The process gave excellent Ac/Th separations ($<0.01\%$ ^{228}Th) and 'reasonable' Ac purifications (Baetslé *et al.*, 1972; Baetslé, 1973).

The production capacity at Mol was about 20 g ^{227}Ac and 4 g ^{228}Th per year. As of the end of 1972, 2 g of Ac_2O_3 had been encapsulated as a prototype 30 W heat source and about 700 mg had been purified for the preparation of Ac–Be neutron sources. The ^{227}Ac production and separation facility at Mol was dismantled a few years later (Deworm *et al.*, 1979).

2.5 ATOMIC PROPERTIES

Meggers, Fred, and Tomkins (Meggers *et al.*, 1951, 1957; Meggers, 1957; Sugar, 1984) examined the emission spectra of actinium excited in a hollow cathode and in arcs and sparks between copper or silver electrodes. They reported some 500 lines characteristic of actinium in the spectral range 2062.00–7886.82 Å. Of these about 140 lines were assigned to the neutral atom, Ac I, more than 300 to singly ionized actinium, Ac II, and eight to doubly ionized actinium, Ac III. The lowest energy levels for identified configurations are given in Chapter 16 of this work (Table 16.1). The electron configuration of the Ac I (neutral Ac) ground state was found to be [Rn]($6d7s^2$) $^2D_{3/2}$; that of Ac II (Ac^+), ($7s^2$) $^1S_0$; and that of Ac III (Ac^{2+}), (7s) $^2S_{1/2}$. The first two ionization potentials were estimated to be 5.17 and 11.87 eV (Sugar, 1973, 1984). Similar values were calculated by Eliav *et al.* (1998), who also calculated the third ionization potential to be 17.518 or 17.512 eV by relativistic coupled-cluster methods. The first ionization potential was recently measured to be 5.3807(3) eV by resonant excitation of ^{227}Ac by laser spectroscopy in an external electric field (Backe *et al.*, 2002).

Analysis of interference spectrograms of the ^{227}Ac nucleus yielded the nuclear spin $I = 3/2$ (Tomkins *et al.*, 1951), and values of $\mu = (1.1 \pm 0.1)$ nuclear magnetons and $Q = +1.7$ barns for the magnetic and electric quadrupole moments, respectively (Fred *et al.*, 1955).

The foregoing comprises essentially all the experimentally determined data presently available on the properties of isolated actinium atoms and ions in the gas phase (see also Chapters 16 and 19). Theoretical calculations on such properties as energy levels (Brewer, 1971a,b; Nugent and Vander Sluis, 1971; Vander Sluis and Nugent, 1972, 1974; Nugent *et al.*, 1973b), ionization potentials (Carlson *et al.*, 1970; Sugar, 1973; Eliav *et al.*, 1998), and electron affinities (Eliav *et al.*, 1998) of actinium atoms and its free ions have also been made. There remain some discrepancies among some of these calculations or estimates that will only be resolved by better theoretical treatments and experimental measurements.

Consistent with the difference between the ionic radii of La^{3+} and Ac^{3+} (0.088 Å = 8.8 pm) (Shannon, 1976 and Section 15.7.5, Chapter 15), *ab initio* nonrelativistic and quasi-relativistic calculations of the bond lengths in monohydrides, monoxides, and monofluorides of all the lanthanide and actinide elements indicated a difference between La–X and Ac–X bond lengths of 10 pm (Küchle *et al.*, 1997). Another set of fully relativistic *ab initio* calculations of the bond lengths in monofluorides, monohydrides, and trihydrides revealed similar La–X and Ac–X bond-length differences; for LaH_3 and AcH_3 the bond-length difference calculated was also 10 pm (Laerdahl *et al.*, 1998).

2.6 THE METALLIC STATE

In 1953, Farr *et al.* (1953, 1961) prepared 10 μg of ^{227}Ac metal in an X-ray capillary by reduction of $AcCl_3$ with potassium vapor at 350°C. The diffraction pattern yielded two face-centered cubic (fcc) structures, which were attributed (by analogy to a parallel experiment with lanthanum) to actinium metal (a_0 = 5.311 ± 0.010 Å) and actinium hydride (a_0 = 5.670 ± 0.006 Å). The calculated densities were 10.07 and 8.35 g cm^{-1}, respectively. (The hydrogen in the 'actinium hydride' was of unknown origin.)

Milligram amounts of actinium metal were prepared by reduction of AcF_3 with lithium vapor in a molybdenum crucible (Stites *et al.*, 1955). The temperature range, 1100–1275°C, was critical for the reduction of AcF_3; at lower temperatures reduction was incomplete because the product metal did not melt, whereas at higher temperatures the yield was low because some of the AcF_3 was lost by volatilization.

The metal was reported to be silvery white in color, sometimes with a golden cast. It oxidizes rapidly in moist air to form a white coating of Ac_2O_3, which is somewhat effective in preventing further oxidation. Stites *et al.* (1955) estimated the melting point to be (1050 ± 50)°C. This melting point has been criticized as 'unreasonably low' (Matthias *et al.*, 1967) but is accepted in this work. A melting point of 1227°C has been estimated more recently (Arblaster, 1995). Based upon bonding contributions to the cohesive energy by 7s, 7p, and 6d electrons, Fournier (1976) estimated the melting point to be 1430°C and the enthalpy of sublimation ($\Delta_f H°$, Ac, g, 298 K) to be 396 kJ mol^{-1}. Other estimates of the enthalpy of sublimation are 406 kJ mol^{-1} (Wagman *et al.*, 1982) and 418 kJ mol^{-1} (David *et al.*, 1978; Ward *et al.*, 1986). The boiling point, estimated by extrapolation from vapor pressure measurements, is (3200 ± 300)°C (Foster and Fauble, 1960).

Subsequently, two metal preparations were made by the reduction of Ac_2O_3 with metallic thorium in high vacuum at 1750°C (Baybarz *et al.*, 1976), subliming the metal onto a tantalum condenser, and resubliming the metal to further purify it. X-ray data on these preparations of Ac metal suggest an fcc lattice with a_0 parameter of (5.317 ± 0.009) and (5.314 ± 0.001) Å in the two preparations (Baybarz *et al.*, 1976). Arblaster (1995) predicted that actinium metal should parallel metallic lanthanum and americium, with a double close-packed hexagonal allotrope at lower temperature and a body-centered cubic (bcc) allotrope at higher temperature.

Farr *et al.* (1953, 1961) reported that the metallic radius of actinium is 1.88 Å, but Zachariasen (1961, 1973) regarded this value as unreasonably similar to that of lanthanum (1.87 Å), because, in all isostructural compounds, the bond distances for actinium compounds are approximately 0.1 Å greater than those for the corresponding lanthanum compounds. By interpolation between the metallic radii of Ra and Th (2.293 and 1.798 Å, respectively), he predicted a value of 1.977 Å for Ac. On the other hand, Hill (1972) suggested that the lack of an appreciable increase in the metallic radius is a manifestation of a pronounced relativistic shrinkage in the 7s orbital of the neutral Ac atom, relative to such an effect on the 6s orbital of lanthanum. The fcc Ac prepared by Baybarz *et al.* (1976) corresponded to a metallic radius of 1.878 Å, supporting Hill's argument.

2.7 COMPOUNDS

With the sole exception of the questionable hydride mentioned in Section 2.6, almost all the compounds of actinium that have been positively identified by X-ray diffraction analysis are the result of a single study by Fried, Hagemann, and Zachariasen (Fried *et al.*, 1950). Each of the compounds was prepared from 10 μg of actinium or less, which was purified by TTA extraction (Hagemann, 1950) immediately before the start of the preparation. The small sample size was chosen to minimize the radiation health hazard and to reduce the fogging of the X-ray film by γ radiation from the rapidly growing actinium decay products. Even, so, it was necessary to prepare and photograph the compound within 24 h after purification. After purification of actinium from neutron-irradiated ^{226}Ra (Baetslé and Droissart, 1973) by ion exchange, Weigel and Hauske (1977) precipitated actinium oxalate on the 10 μg scale and identified it as the decahydrate from its X-ray powder pattern. It is isomorphous with similar compounds of the rare earths, plutonium, and americium.

Table 2.2 summarizes the preparative work and some of the properties of the ten known compounds of actinium. In addition, compounds thought to be the iodide, hydroxide, oxalate, oxyiodide, phosphate, and double salt with potassium sulfate were prepared but could not be identified (Fried *et al.*, 1950). Other unidentified compounds, suggested by chemical or thermogravimetric evidence, include the basic carbonate (Butterfield and Woollatt, 1968), the 8-hydroxyquinolate (Mosdzelewski, 1966; Keller and Mosdzelewski, 1967), and a double salt with ammonium nitrate (Kirby, 1969).

Table 2.2 *Preparation and properties of actinium compounds* (*Fried* et al., 1950; *Weigel and Hauske*, 1977; *Gmelin*, 1981).

2.8 SOLUTION AND ANALYTICAL CHEMISTRY

All available evidence supports the conclusion (Moeller and Kremers, 1945), derived primarily from tracer and coprecipitation studies, that actinium is a homolog of lanthanum, fitting into the 7th period in the periodic table. The Ac^{3+}(aq) ion is more basic (less subject to hydrolysis) than the La^{3+}(aq) ion. As such, Ac^{3+} is the most basic tripositive ion known.

Aqueous solutions of actinium are colorless. In the only reported spectrophotometric study (Hagemann, 1954), no absorption was observed over the range 400–1000 nm. There was a slight amount of absorption between 300 and 400 nm, and a pronounced absorption maximum at 250 nm.

There has been limited work on the fundamental properties of Ac^{3+}(aq). Abramov *et al.* (1998) calculated the hydration Gibbs energy of Ac^{3+} to be -3034.7 kJ mol^{-1}.

2.8.1 Redox behavior

The only stable oxidation state of actinium in aqueous solution is 3+. A transitory Ac(ii) ion has been postulated by Bouissières, David, and coworkers (Bouissières *et al.*, 1961; Bouissières and Legoux, 1965; David and Bouissières, 1965, 1968; David, 1970a) to account for the amalgamation behavior of actinium, which resembled that of Eu(ii) and Sm(ii) more than that of La(iii). This hypothesis was reinforced by polarographic evidence: David (1970b,c) reported two waves in the polarogram of ^{228}Ac in $HClO_4$ at pH 1.9–3.1. He attributed the first wave to the reversible reaction:

$$Ac^{2+} + 2e^- + Hg \leftrightarrows Ac(Hg) \tag{2.8}$$

and the second to the irreversible reaction:

$$Ac^{3+} + 3e^- + Hg \rightarrow Ac(Hg) \tag{2.9}$$

From the half-wave potentials, he estimated the formal potential of the Ac(iii)/Ac(ii) couple to be -1.6 V and that of the Ac(iii)/Ac(0) couple to be -2.62 V. A later estimate was $E°(Ac^{3+}/Ac) = -2.13$ V (David *et al.*, 1978). However, Maly (1969) performed extractions of actinium and other elements from sodium amalgam in sodium acetate solutions as a function of pH and found that actinium extraction behavior was similar to that of the elements thorium to berkelium, i.e. that actinium reduction did not show evidence of the Ac(ii) ion.

Yamana *et al.* (1983) attempted to increase the stability of Ac^{2+}(aq) by complexing it with 18-crown-6. They noted a shift of the half-wave potential of about 0.15 V due to a complex, which they attributed to formation of an Ac^{2+}–crown complex and an Ac^{2+}(aq) ion with electronic configuration $[Rn]6d^1$ and ionic radius 1.25 Å. The $[Rn]6d^1$ configuration lies only 801 cm^{-1} above the [Rn]7s state in the free ion, so that the change of configuration is plausible.

However, Mikheev *et al.* (1995) noted that Nugent *et al.* (1973a) and Bratsch and Lagowski (1986) had calculated $E^\circ(\mathrm{Ac}^{3+}/\mathrm{Ac}^{2+})$ to be −4.9 and −3.3 V, respectively; the value $E^\circ(\mathrm{Ac}^{3+}/\mathrm{Ac}^{2+}) = -4.9$ V is adopted in Chapter 19 of this work. Either of these much more negative E° values would preclude the observation of Ac^{2+}(aq). Mikheev *et al.* (1994) found no evidence for Ac^{2+} in cocrystallization experiments with $\mathrm{Gd_2Cl_3}$ clusters or with Sm^{2+} in aqueous ethanol solution, a medium that should enhance the stability of Ac^{2+}. They recommended that the polarographic reduction of Ac^{3+}(aq) (David, 1970b,c) was actually reduction of water but they recommended further research on the $\mathrm{Ac}^{3+}/\mathrm{Ac}^{2+}$ couple.

The electrolysis of actinium at a mercury cathode has been used to separate tracer amounts of ^{228}Ac and 1.24 μg of ^{227}Ac from 3.10 mg of ^{231}Pa and an equilibrium amount of ^{227}Th. After 50 min of electrolysis in 0.17 M lithium citrate solution at a current density of 15 mA cm^{-2} the actinium was recovered by washing the amalgam with 0.1 M HCl. The overall yield was 85% and the decontamination factor was greater than 10^8 with respect to protactinium and thorium (David and Bouissières, 1966; Monsecour *et al.*, 1973).

2.8.2 Solubility

At the tracer level, actinium is carried quantitatively by any quantitative lanthanum precipitate, as well as by a wide variety of isomorphous and nonisomorphous carriers. The coprecipitation behavior of actinium was summarized in a useful table by Kahn (1951) and was exhaustively discussed in reviews (Bouissières, 1960; Sedlet, 1964; Kirby, 1967; Gmelin, 1981).

The relative amounts of actinium in partial precipitations of actinium tracer with lanthanum or other carriers are consistent with the relative solubilities of the compounds precipitated, where these are known or predictable. Unfortunately, however, with only two exceptions, quantitative solubility information is generally unavailable, because the dissolutions and precipitations that have been reported were usually incidental to some other objective, e.g. the preparation of compounds for crystallographic analysis (Table 2.2) (Weigel and Hauske, 1977).

Salutsky and Kirby (1956) precipitated tens of milligrams of ^{227}Ac from homogeneous solution with dimethyl oxalate and estimated the solubility of $\mathrm{Ac_2(C_2O_4)_3}$ in 0.25 M $\mathrm{H_2C_2O_4}$ (pH 1.2) to be 24 mg L^{-1}. That result is consistent with a more detailed study by Ziv and Shestakova (1965a), which shows, as expected, that the solubility of $\mathrm{Ac_2(C_2O_4)_3}$ varies with both the acidity and the oxalate concentration (Table 2.3). In a parallel study, the authors found that the solubility of $\mathrm{La_2(C_2O_4)_3}$ in 0.01 M $\mathrm{HNO_3}$ (pH 2.2) was 4.28×10^{-5} M, about half that of $\mathrm{Ac_2(C_2O_4)_3}$ under the same conditions. This unusual solubility of $\mathrm{Ac_2(C_2O_4)_3}$ may be due to radiolysis.

Ziv and Shestakova (1965b) also studied the solubility of $\mathrm{Ac(OH)_3}$ in $\mathrm{NH_4NO_3}$ solutions ($\mu = 0.001$ M). They observed a pronounced aging effect

Table 2.3 *Solubility of actinium oxalate in aqueous media at* 25°C (*Ziv and Shestakova,* 1965a).

Solvent	*pH*	*Solubility*		*Activity product*
		Ac^{3+} (mg L^{-1})	$Ac_2(C_2O_4)_3$ (M)	
0.01 M HNO_3	1.85	41.0	9.0×10^{-5}	7.5×10^{-27}
0.01 M HNO_3	2.00	40.0	8.8×10^{-5}	6.7×10^{-27}
0.01 M HNO_3	2.00	34.0	7.5×10^{-5}	2.1×10^{-27}
0.01 M HNO_3	2.00	30.0	6.5×10^{-5}	1.5×10^{-27}
H_2O	–	0.86	1.9×10^{-6}	2.7×10^{-27}
H_2O	–	1.5	3.3×10^{-6}	4.2×10^{-26}
H_2O	–	1.7	3.7×10^{-6}	8.0×10^{-26}
5×10^{-5} M $H_2C_2O_4$	3.4	2.5	5.5×10^{-6}	–
5×10^{-4} M $H_2C_2O_4$	3.0	1.2	2.6×10^{-6}	–
5×10^{-3} M $H_2C_2O_4$	2.3	0.96	2.1×10^{-6}	–
5×10^{-1} M $H_2C_2O_4$	0.9	7.85	1.73×10^{-5}	–

on both its solubility and the pH of its saturated solutions. For example, 1 h after precipitation the solubility was 3.6×10^{-8} g L^{-1} (1.59×10^{-8} M) and the pH was 10.4; 15 h later, the solubility had increased to 1.73×10^{-4} g L^{-1} and the pH had decreased to 9.1. After 27 days, the pH was 4.2. The authors attributed this decrease in pH to radiolysis of the solution by adsorbed ^{227}Th. Gamma radiation of aerated water also causes the pH to decrease: radiolysis by γ-rays produces nitric acid from dissolved O_2 and N_2 (Barkatt *et al.*, 1982). Another reason for the decrease of pH is that radiolysis of air by α particles at an air–water interface (Burns *et al.*, 1982) oxidizes nitrogen to acidic nitrogen oxides, which slowly acidifies the adjacent aqueous solution.

When ^{227}Ac was radiochemically purified before precipitation, the pH declined from 10.4 to only 8.3 in 166 days. From the activity product in various concentrations of NH_4NO_3, the solubility of aged $Ac(OH)_3$ was calculated to be 0.74 mg L^{-1}, which is higher than that for $La(OH)_3$. The corresponding equilibrium constants

$$M(OH)_3(s) + 3H^+(aq) \rightarrow M^{3+}(aq) + 3H_2O \ {}^*K_{s,0} \qquad (2.10)$$

(see Chapter 19, section 9, this book, for further discussion of $^*K_{s,0}$) at ionic strength 0.1 are $(1.26 \pm 0.04) \times 10^{24}$ for $Ac(OH)_3$ and 2.0×10^{20} for $La(OH)_3$. The higher solubility of $Ac(OH)_3$ can be attributed to the more basic character of the large Ac^{3+} ion, radiation damage of the crystallites, and/or to the tendency of radiolysis to produce more acidic conditions (Barkatt *et al.*, 1982; Burns *et al.*, 1982). A comparison of some solubility products for rare earth and actinide hydroxides is given in Chapter 19. The above evidence that $Ac(OH)_3$ is the most soluble of all f-element trihydroxides is consistent with Ac^{3+} being the most basic tripositive cation.

More recently, Kulikov *et al.* (1992) used electromigration to determine that ^{225}Ac is unhydrolyzed in aqueous solution of ionic strength 0.1 at 298 K until pH > 10. They determined the $*K_{s,0}$

$$\mathrm{Ac(OH)_3(s) + 3H^+(aq) \rightarrow Ac^{3+}(aq) + 3H_2O} \quad *K_{s,0} \tag{2.11}$$

to be 7.9×10^{31}. This value is much higher than that derived by Ziv and Shestakova or that expected by extrapolating from trivalent rare earths and actinide hydroxides.

2.8.3 Complexation

As in all its reactions, actinium closely resembles lanthanum in its behavior toward complexing agents. To the extent that they have been determined experimentally, the stability constants of actinium complexes (a selection is given in Table 2.4) are the same as, or slightly smaller than, those of the corresponding lanthanum complexes (Rao *et al.*, 1968, 1970; Shahani *et al.*, 1968; Sekine *et al.*, 1969; Sekine and Sakairi, 1969; Gmelin, 1981), in agreement with prediction from the similarity in their electronic configurations and their ionic radii (Kirby, 1967; Section 15.7.5). There is a linear dependence of log (formation constant) upon ionic radius, with Ac^{3+} always having the extreme position of largest ionic radius (Gmelin, 1981 and Section 15.7.5).

The hydrolysis of $Ac^{3+}(aq)$ is the smallest of all 3+ ions. Moutte and Guillaumont (1969) determined the equilibrium constant for the reaction

$$\mathrm{AcOH^{2+}(aq) + H_2O \rightarrow Ac(OH)_2^+(aq) + H^+(aq)} \tag{2.12}$$

to be 3.5×10^{-9} mol L^{-1}. Using the isotope ^{228}Ac, they determined that, at pH 8, 74% of the actinium in solution exists as $Ac(OH)^{2+}$ and 26% exists as $Ac(OH)_2^+$.

The Ac^{3+}–citrate complexes are sufficiently strong that citrate complexes almost all Ac^{3+} in 0.001 M citrate even at pH 8.1 (Moutte and Guillaumont, 1969). In addition to the complexes listed in Table 2.4, Ac^{3+} complexes have been studied with *trans*-1,2-diaminocyclohexanetetraacetic acid (DCTA), TTA and other diketones, arsenazo III, and other organic ligands (Gmelin, 1981).

Fukusawa *et al.* (1982) determined stability constants for chloro and bromo complexes of Ac(III), among many others, by a solvent extraction procedure. A much larger contribution from inner-sphere complex formation was observed in chloro than in bromo complexes for tripositive actinide ions. An empirical approach for predicting the stability of metal-ion complexes has been applied to actinium (Kumok, 1978).

On the basis of known and estimated ionic radii, Abramov *et al.* (1998) calculated the extraction constant K_{ex} of Ac^{3+} with bis(2-ethylhexyl)phosphoric acid (HDEHP) into toluene. The calculated K_{ex} value for Ac^{3+} is nearly an order of magnitude smaller than that for La^{3+}.

Table 2.4 *Cumulative stability constants of selected actinium complexes.*

Ligand	*Ionic strength* (μ)	$[H^+]$ (M)	*Stability constant*[a]	*Reference*
F^-	0.5	0.00025	$\beta_1 = 529 \pm 8$ $\beta_2 = (1.67 \pm 0.09) \times 10^5$ $\beta_3 = 8 \times 10^7$	Aziz and Lyle (1970)
F^-	0.1	0.016	$\beta_1 = 885$	Makarova *et al.* (1973)
Cl^-	1.0	1.0	$\beta_1 = 0.80 \pm 0.09$ $\beta_2 = 0.24 \pm 0.08$	Shahani *et al.* (1968)
Cl^-	4.0	0.01	$\beta_1 = 0.9$ $\beta_2 = 0.09$ $\beta_3 = 0.05$	Sekine and Sakairi (1969)
Br^-	1.0	1.0	$\beta_1 = 0.56 \pm 0.07$ $\beta_2 = 0.30 \pm 0.06$	Shahani *et al.* (1968)
NO_3^-	1.0	1.0	$\beta_1 = 1.31 \pm 0.12$ $\beta_2 = 1.02 \pm 0.12$	Shahani *et al.* (1968)
SO_4^{2-}	1.0–1.16	1.0	$\beta_1 = 15.9 \pm 1.3$ $\beta_2 = 71.4 \pm 7.3$	Shahani *et al.* (1968)
SO_4^2	1.0	pH 3–3.5	$\beta_1 = 22.9$ $\beta_2 = 479$	Sekine and Sakairi (1969)
SCN^-	1.0	pH 2	$\beta_1 = 1.11 \pm 0.07$ $\beta_2 = 0.82 \pm 0.08$	Rao *et al.* (1968)
SCN^-	5.0	pH 3–3.5	$\beta_1 = 0.18$ $\beta_2 = 0.35$	Sekine and Sakairi (1969)
$C_2O_4^{2-}$	1.0	pH 3–3.5	$\beta_1 = 3.63 \times 10^3$ $\beta_2 = 1.45 \times 10^6$	Sekine and Sakairi (1969)
$H_2PO_4^-$	0.5	pH 2–3	$\beta_1 = 38.8 \pm 5$	Rao *et al.* (1970)
Citrate	0.1	pH 2–3	$\beta_1 = 9.55 \times 10^6$	Makarova *et al.* (1974)
NTA^{-}[b]	0.1	pH $\approx$ 5	$\beta_3 = 4.3 \times 10^{14}$	Keller and Schreck (1969)
EDTA[c]	0.1	pH 2.8	$\beta_1 = 1.66 \times 10^{14}$	Makarova *et al.* (1972)

[a] $\beta_n = [MLn]/[M][L]^n$.

[b] HNTA, 2-naphthoyltrifluoroacetone.

[c] EDTA, ethylenediaminetetraacetic acid.

2.8.4 Radiocolloid formation

Kirby (1969) noted that when acidic aqueous solutions containing tracer amounts of Ac^{3+} and its progeny $^{227}Th^{4+}$ and $^{223}Ra^{2+}$ are dried on platinum disks, the actinium can be separated by redissolution in dilute NH_4NO_3(aq) and the radium by redissolution in dilute HF(aq), leaving the thorium on the disk. He described this separation as an application of ‘residue adsorption’; it may represent radiocolloid formation and selective redissolution at the metal surface.

Rao and Gupta (1961) studied the adsorption of ^{228}Ra and ^{228}Ac onto sintered glass and paper, and found that the adsorption of ^{228}Ac onto the glass increased with pH and time of aging. They studied the phenomenon by centrifugation; the ^{228}Ac fraction could be centrifuged at pH ≥ 5. Paper chromatography showed that the ^{228}Ac was immobile at a pH of 3 and higher, whereas Ba remained in solution. They concluded that the ^{228}Ac formed radiocolloids at pH ≥ 5.

2.8.5 Analytical chemistry of actinium

Sedlet (1964) published a complete set of procedures for analytical chemistry of actinium, primarily radiochemical procedures for ^{227}Ac. Kirby (1967) published a review that selected published and unpublished procedures that "will be of most value to the modern analytical chemist." Kirby also wrote the section on analytical chemistry in Gmelin (1981). Karalova (1979) reviewed the analytical chemistry of actinium. The analytical procedures that they described were based upon separation of actinium from other radioelements and then determination by measurement of the α, β, or γ radioactivity of a sample that has reached secular equilibrium with its daughters. The techniques suitable for tracer-level determination of ^{227}Ac are neutron activation analysis, by which ^{227}Ac can be determined at the level of 10^{-17} g, and total α, β, and γ radioactivity of a sample that has reached secular equilibrium with its daughters, by which ^{227}Ac can be determined at the level of 10^{-20} g. Recently a procedure for determination of ^{227}Ac in environmental samples by coprecipitation with lead sulfate, ion exchange, and α spectrometry after allowing the daughter isotopes ^{227}Th and ^{223}Ra to reach secular equilibrium (2–3 months) has been published (Martin *et al.*, 1995). The method requires the use of a short-lived actinium yield tracer, ^{225}Ac or ^{228}Ac. The lower limit of detection is $\sim$0.2 mBq per sample (7.5×10^{-16} g) at 95% confidence level.

The isotope ^{225}Ac, which is useful for tumor radiotherapy (see below), can be determined by α-spectrometric measurement of its α-emitting progeny ^{217}At (Martin *et al.*, 1995) or by γ spectrometry of the progeny ^{221}Fr and ^{213}Bi (McDevitt *et al.*, 2001).

2.9 APPLICATIONS OF ACTINIUM

2.9.1 Heat sources for radioisotope thermoelectric generators

The first practical use of actinium was to produce multi-Curie amounts of ^{227}Ac in order to take advantage of the energy released from the five α particles that are generated during its decay (Fig. 2.1) to produce electrical power for spacecraft and other devices that must operate for long periods of time in remote locations. An ambitious radioisotope thermoelectric generator (RTG) program was undertaken in Belgium to produce a 250 W_{th} thermoelectric generator fueled with 18 g of ^{227}Ac (Baetslé and Droissart, 1973). A prototype heat source that contained 2 g of ^{227}Ac was prepared but was not put into use (Baetslé and

Droissart, 1973). Kirby (Gmelin, 1981) listed the radioisotopes that can be used as thermoelectric heat sources. Of these, ^{238}Pu has been the most suitable; it has been used in almost all U.S. spacecrafts that utilized RTGs, beginning with 2.7-W SNAP–3B (Space Nuclear Auxiliary Power) generators for Transit 4A and 4B satellites in 1961 (Lange and Mastal, 1994; U.S. Department of Energy, 1987) and continuing to the three 276-W general purpose heat source (GPHS) RTGs in the Cassini probe, which was launched in 1997 and reached Saturn in 2004. (See also relevant sections in Chapter 7 and Chapter 15, section 11.2, this book.)

2.9.2 Neutron sources

Isotopes of elements with $Z \leq 20$ emit neutrons when they are bombarded by ~5 MeV α particles. Kirby (Gmelin, 1981) listed the properties of important (α,n) generators. The advantages of ^{227}Ac as a heat source are also those that make it attractive as an (α,n) generator. A few ^{227}Ac (α,n) generators have been constructed and used (Gmelin, 1981).

2.9.3 Alpha-particle generators for tumor radiotherapy

The 10-day α emitter ^{225}Ac has desirable properties for destroying rapidly growing cancer cells. After decay of ^{225}Ac to ^{221}Fr, four additional high-energy α decays and two β^- decays occur rapidly (Fig. 2.3), delivering ~40 MeV of high linear-energy-transfer radiation over a range of less than 100 μm. None of the decay events emits hard γ-rays, so that ^{225}Ac can deliver large doses to a tumor cell and negligible doses to surrounding healthy tissue (Tsoupko-Sitnikov *et al.*, 1996; Khalkin *et al.*, 1997; Boll *et al.*, 2005). To utilize this isotope for therapy, the principal challenges are to generate the isotope free of other radioisotopes, to deliver it to the cancer cell for a long enough period of time, to bind it firmly to the target call, and to retain the daughter radioisotopes (especially the ^{221}Fr$^+$ ion) at the target site. The *in vivo* stability of several macrocyclic complexes of ^{225}Ac have been evaluated. Deal *et al.* (1999) found the most promising complex to be that with 1,4,7,10,13,16-hexaazacyclohexadecane-*N*,*N*′,*N*″,*N*‴,*N*⁗-hexaacetic acid (HEHA); Ouadi *et al.* (2000) bifunctionalized an isothiocyanate derivative of HEHA for good covalent bonding to biomolecules. A procedure for delivering ^{225}Ac to tumors via bifunctional chelators related to the ligand 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) has been described (McDevitt *et al.*, 2001). Kennel *et al.* (2000, 2002) evaluated radioimmunotherapy of mice with lung and other tumors using ^{225}Ac–HEHA conjugates with monoclonal antibodies; their studies concluded that the radiotoxicity of ^{225}Ac can only be controlled if conjugates that bind strongly with the daughters as well as with Ac$^+$ can be discovered.

As described in the earlier paragraph and in Section 2.2.3, ^{229}Th (α, $t_{1/2} = 7340$ years) is an appropriate generator from which ^{225}Ac can be removed periodically. At the time of writing, Oak Ridge National Laboratory is producing

50–60 mCi of ^{225}Ac from ^{229}Th every 8 weeks. Additional shipments of 5–20 mCi of ^{225}Ac are produced by ORNL every 2 weeks from the decay of the ^{225}Ra parent. The ^{225}Ac is shipped to hospitals and other research facilities (Boll *et al.*, 2005).

The isotope ^{225}Ac can also serve as a ^{213}Bi generator, which decays with a 45.6-min half-life (97.8% β, 2.2% α). The decay is accompanied by a 440-keV γ-ray, so that ^{213}Bi can be delivered to tumors with a bifunctional chelating agent for radioimmunotherapy as well as for imaging (Pippin *et al.*, 1995; Nikula *et al.*, 1999). Generators have been delivered to hospitals, where radioisotopically pure, chemically active ^{213}Bi can be eluted for radiotherapy, with minimum shielding every 5–6 h for at least 10 days. At the time of writing, the Institute for Transuranium Elements (Joint Research Centre of the European Commission, located at Karlsruhe, Germany) is producing and distributing ^{225}Ac/^{213}Bi generators.

2.9.4 Actinium-227 as a geochemical tracer

Nozaki (1984) demonstrated that the concentration of ^{227}Ac is higher than that of its progenitor ^{231}Pa in deep seawater; he proposed the use of natural ^{227}Ac as a tracer for circulation and mixing of seawater in deep ocean basins. Geibert *et al.* (2002) confirmed this phenomenon in several other oceanic locations and proposed that ^{227}Ac be used as a tracer for deep seawater circulation (diapycnal mixing, i.e. mixing across lines of equal density).

CHAPTER THREE

THORIUM

Mathias S. Wickleder, Blandine Fourest, and Peter K. Dorhout

3.1 HISTORICAL

In 1815 Berzelius analyzed a rare mineral from the Falun district. He assumed that the mineral contained a new element, which he named thorium after the ancient Scandinavian god of thunder and weather, Thor (Weeks and Leicester, 1968).

Unfortunately, 10 years later the mineral turned out to be simply xenotime, e.g. yttrium phosphate. However, in 1828, Berzelius was given a mineral by the Reverend Hans Morten Thrane Esmark. In that mineral Berzelius really discovered a new element and gave it the same name (Berzelius, 1829; Gmelin, 1955, 1986a; Weeks and Leicester, 1968). Consequently, he called the mineral from which he isolated the new element thorite. It is a silicate that contains significant amounts of uranium and should therefore be written as $(Th,U)SiO_4$. Although thorium was discovered in 1828, it virtually had no application until the invention of the incandescent gas mantle in 1885 by C. Auer von Welsbach. Thereafter the application of thorium developed into a wide array of products and processes (Gmelin, 1988b). Besides the above-mentioned incandescent gas mantles, the production of ceramics, carbon arc lamps, and strong alloys may serve as examples. To be mentioned is also its use as coating for tungsten welding rods, because it provides a hotter arc. Furthermore, when added to refractive glass, it allows for smaller and more accurate camera lenses. As minor important applications, the use of ThO_2 in producing more heat-resistant laboratory crucibles and its occasional use as a catalyst for the oxidation of ammonia to nitric acid and other industrial chemical reactions can be mentioned. Nevertheless, during the last decade the demand for thorium in non-nuclear applications has sharply decreased due to environmental concerns related to its radioactivity. The radioactivity of thorium is helpful for the dating of very old materials, e.g. seabeds or mountain ranges. Maybe the largest potential for thorium is its usage in nuclear energy. This is because ^{232}Th can be converted by thermal (slow) neutrons to the fissionable uranium isotope ^{233}U via the following reaction sequence:

$$^{232}\mathrm{Th(n,\gamma)} \rightarrow {}^{233}\mathrm{Th} \xrightarrow{\beta^-} {}^{233}\mathrm{Pa} \xrightarrow{\beta^-} {}^{233}\mathrm{U}$$

Fission of the ^{233}U can provide neutrons to start the cycle again. This cycle of reactions is known as the thorium cycle (Seaborg *et al.*, 1947; Katzin, 1952).

Conversion of ^{232}Th into ^{233}U provides the possibility to gain large amounts of slow-neutron-fissile material, several times the amount of uranium naturally present on Earth, and several hundred times the amount of the naturally occurring fissile uranium isotope ^{235}U (Seaborg and Katzin, 1951).

A number of advantages of thorium-based nuclear fuels exist in comparison with the presently utilized uranium–plutonium fuels (Rand *et al.*, 1975; Trauger, 1978). These include the inherent detectability of ^{233}U, its higher neutron yield, the fact that ^{233}U, unlike ^{239}Pu, can be mixed with ^{238}U so that it cannot directly be used in weapons manufacture, and the superior physical properties of thorium-based fuels that enhance reactor core safety and performance. The disadvantage of the use of thorium-based fuels is that thorium must be irradiated and reprocessed before the advantages of ^{232}Th can be realized. This reprocessing step, requiring more advanced technology than that needed for uranium fuels, and other factors have projected greater costs for thorium fuels. The nuclear technology has nevertheless matured with the development of high-temperature gas-cooled reactors.

3.2 NUCLEAR PROPERTIES

Thorium refined from ores free of uranium would be almost monoisotopic ^{232}Th, with less than one part in 10^{10} of ^{228}Th (radiothorium) produced by its own radioactivity decay chain (4*n* family). If the ore contains uranium, as is usually the case, practically undetectable concentrations of ^{231}Th (uranium Y) and ^{227}Th (radioactinium) are present, products of the $(4n + 3)$ decay chain that starts with ^{235}U. Also present are greater quantities of ^{230}Th (ionium), as well as lesser amounts of ^{234}Th (uranium X_1), which originate from the $(4n + 2)$ decay chain whose progenitor is ^{238}U. ^{229}Th is the first product in the $(4n + 1)$ decay series (English *et al.*, 1947; Hagemann *et al.*, 1947, 1950) derived from man-made ^{233}U formed as indicated in Section 3.1. The remaining thorium isotopes listed in Table 3.1 (see also Appendix II) are also synthetic, being formed directly by bombardment of lead or bismuth targets with energetic

Table 3.1 *Nuclear properties of thorium isotopes.*[a]

Mass number	*Half-life*	*Mode of decay*	*Main radiations* (MeV)	*Method of production*
209	3.8 ms	α	α 8.080	^{32}S + ^{182}W
210	9 ms	α	α 7.899	^{35}Cl + ^{181}Ta

multi-nucleon projectiles, by decay of lightweight uranium isotopes, which are themselves synthetic and formed by nuclear bombardment, or by other miscellaneous nuclear reactions. Uranium ores that are relatively thorium-free can be processed to prepare multigram amounts of material with significant proportions of ionium, ^{230}Th. From one unselected ore residue, after removal of uranium, thorium was obtained (Hyde, 1952, 1960) that was 26.4% ionium and 73.6% ^{232}Th (Roll and Dempster, 1952).

3.3 OCCURRENCE OF THORIUM

Two volumes of the *Gmelin Handbook of Inorganic Chemistry* deal with the natural occurrence of thorium and give a comprehensive review of known thorium minerals (Gmelin, 1990a, 1991a). So only the most important features will be emphasized here. Thorium has a much wider distribution than is generally thought. In the Earth's crust it is three times as abundant as Sn, twice as abundant as As, and nearly as abundant as Pb and Mo. It occurs in the tetravalent state in nature and is frequently associated with U(IV), Zr(IV), Hf(IV), and Ce(IV) but also with the trivalent rare earth elements that are relatively close in ionic radii (Cuthbert, 1958; Frondel, 1958; Shannon, 1976).

Due to the isotypism of ThO_2 and UO_2 solid state solutions can be formed and depending on the uranium content the mixtures are named thorianite (75–100 mol% ThO_2), uranothorianite (25–75 mol% ThO_2), thorian uraninite (15–25 mol% ThO_2) and uraninite (0–15 mol% ThO_2). A second mineral with a high thorium content is thorite, $ThSiO_4$, from which the element has originally been discovered. Thorite has the tetragonal zircon-type of structure but also a monoclinic variant of $ThSiO_4$ is known, which is called huttonite (Taylor and

Table 3.2 *Thorium content of various minerals.*

Accessory mineral	*Th* (ppm)
monazite	25000 to 2×10^5
allanite	1000 to 20000
zircon	50 to 4000
titanite	100 to 600
epidote	50 to 500
apatite	20 to 150
magnetite	0.3 to 20
xenotime	Low

Ewing, 1978). In both modifications of $ThSiO_4$, substitution of PO_4^{3-} for SiO_4^{4-} is frequently observed with additional replacement of Th^{4+} by trivalent rare earth ions for charge compensation. SiO_4^{4-} ions may be also replaced by OH^- groups according to $Th(SiO_4)_{1-x}(OH)_{4x}$ leading to a new mineral, thorogummite.

However, in all the minerals given in Table 3.2, Th occurs as the minor constituent. From these minerals, monazite is of significant commercial interest because it is distributed throughout the world, and some of the deposits are very large. Monazite is a phosphate of high specific gravity that is found in the form of yellow to brown sand in nature (monazite sand). The chemical inertness of monazite makes it hard to process.

3.4 THORIUM ORE PROCESSING AND SEPARATION

Monazite can be only attacked by strong acid, which essentially transforms the phosphate ion to $H_2PO_4^-$ and H_3PO_4 and leaves the metal ions as water-soluble salts, or by strong alkali, which transforms the insoluble phosphates to insoluble metal hydroxides that can easily be dissolved in acid after removal from the supernatant solution of alkali phosphates.

Thorium in monazite follows the rare earths in either the acid or the alkali processes. Thorium can be separated from the rare earths in strong sulfuric acid solution (Fig. 3.1) by partial dilution and reduction of acidity (by ammonia addition) to about pH 1.0, at which point hydrated thorium phosphates, containing only small amounts of entrained rare earths, precipitate (Fig. 3.2). The acidity must be reduced to about pH 2.3 to ensure precipitation of the bulk of the rare earths. (Any uranium present in the process solution is separated from the rare earths at this step.) The crude precipitate of thorium phosphate is then treated with alkali to remove undesired sulfate and phosphate anions, and the thorium hydroxide residue may then be dissolved in nitric acid for subsequent

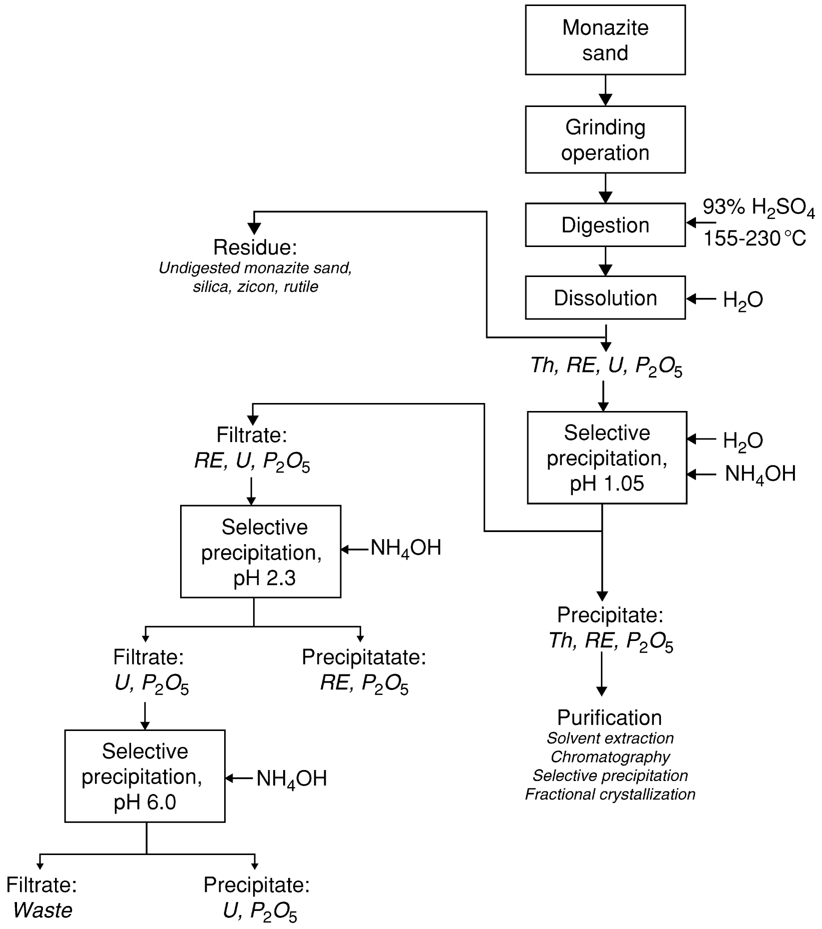

Fig. 3.1 *Simplified schematic diagram of sulfuric acid digestion of monazite sand and recovery of thorium, uranium, and the rare earths.*

purification. Purification is achieved efficiently by solvent extraction of the thorium with tri(*n*-butyl)phosphate (TBP) dissolved in kerosene, a procedure that separates thorium nitrate from rare earths and other non-extractable species. Numerous further extractants have been employed as pointed out in the *Gmelin Handbook* (Gmelin, 1985a).

The solid reaction product of the alkaline digestion of monazite (Fig. 3.3) may be dissolved in acid after separation from the supernatant solution. The solubility of the thorium-containing fraction, however, is a function of the conditions under which the alkaline digestion is performed. Too prolonged

digestion at too high temperature may produce a product in which a large fraction of the thorium will not react readily with the acid used to dissolve the hydroxide cake. Presumably this is a consequence of the formation of ThO_2. Depending on whether hydrochloric, nitric, or sulfuric acid is used to dissolve the hydroxide cake, different procedures may be used in subsequent purification. Assuming the use of hydrochloric acid, which involves the fewest complications, a solution of thorium and rare earth chlorides is obtained. Differential precipitation of thorium from this solution again offers several choices: hydroxide (preferred), peroxide, or phosphate may be used to precipitate the thorium, or precipitation by carbonate may be used to separate the rare earths from thorium (and uranium), which form soluble anionic complexes. Final purification of thorium, again, is preferably made by solvent extraction (Marcus and Kertes, 1969; Gmelin, 1985a), but also chromatographic methods are applied (Kiriyama and Kuroda, 1978; Mayankutty *et al.*, 1982; Gmelin, 1990c, 1991b).

Thorium may also be recovered as a by-product from the treatment of uraninite or uranothorianite to obtain uranium. The thorium remaining in the solution of sulfuric acid after removal of the uranium is extracted into kerosene with the aid of long-chain amines. The thorium is part of a complex sulfate anion, which accompanies the protonated cationic amine into the organic phase. Neutralization of the quaternary ammonium cation precipitates the thorium from the organic phase or allows it to be back-extracted into an aqueous phase.

3.5 ATOMIC SPECTROSCOPY OF THORIUM

The atomic spectroscopy of thorium provides not only information about the electronic states of thorium but also clues to the properties expected for elements of higher atomic number. The electronic structure of thorium and the related spectra will be discussed in more detail in Chapter 16 and are only summarized briefly here. Further details are also given in a volume of *Gmelin's Handbook* (Gmelin, 1989).

The four valence electrons of the neutral atom have available to them, in principle, the 5f, 6d, 7s, and 7p orbitals. The stable ground state configuration of the neutral thorium atom turns out to be $6d^27s^2$ ($^3F_2$) (Giacchetti *et al.*, 1974).

The $6d^37s$ ($^5F_1$) level is at higher energy by 5563.143 cm^{-1} and it is only at 7795.270 cm^{-1} that one encounters $5f6d7s^2$ ($^3H_4$). Still higher lie $6d7s^27p$ (10783.153 cm^{-1}), $6d^27s7p$ (14465.220 cm^{-1}), and $5f6d^27s$ (15618.98 cm^{-1}) (Zalubas, 1968).

The ionization potential of neutral Th was recently measured by resonance ionization mass spectrometry (RIMS) (Köhler *et al.*, 1997) as 6.3067(2) eV. The value obtained earlier (Sugar, 1974; Ackermann and Rauh, 1972) by extrapolation of spectroscopic data was 6.08 eV. The ground level of singly ionized Th is d^2s, followed by ds^2 (1859. 938 cm^{-1}), fs^2 (4490.256 cm^{-1}), fds (6168.351 cm^{-1}), d^3 (7001.425 cm^{-1}), and fd^2 (12485.688 cm^{-1}) (Zalubas and Corliss, 1974). It is a major step up in energy to configurations with either p contribution or to configurations that contain paired f-electrons: dsp is at 23372.582 cm^{-1}, followed by f^2s (24381.802 cm^{-1}), fsp (26488.644 cm^{-1}), d^2p (28243.812 cm^{-1}), fdp (30452.723 cm^{-1}), s^2p (31625.680 cm^{-1}), and f^2d (32620.859 cm^{-1}).

The ground state of doubly ionized thorium is 5f6d but the $6d^2$ configuration is only 63.267 cm^{-1} and the 5f7s is 2527.095 cm^{-1} higher (Racah, 1950). These are followed by 6d7s (5523.881 cm^{-1}), $7s^2$ (11961.133 cm^{-1}), $5f^2$ (15148.519 cm^{-1}), 5f7p (33562. 349 cm^{-1}), 6d7p (37280.229 cm^{-1}), and 7s7p (42259.714 cm^{-1}). These trends are continued in the triply ionized form (Klinkenberg and Lang, 1949), in which the ground level is 5f, and 6d is at 9193.245 cm^{-1}, 7s at 23130.75 cm^{-1}, and 7p at 60239.10 cm^{-1}.

Thus, with increasing ionic charge, configurations that include 5f electrons are stabilized with respect to others and the configurations containing 7p electrons become grossly destabilized. Effects in 7s and 6d systems are less but are still significant. The stabilization of the 5f electron in the triply charged ion is not sufficient however to make triply charged thorium a stable chemical species. The stable form is tetrapositive Th^{4+}, in which only the radon core of electrons is present.

Solid metallic thorium with the ground state configuration d^2s^2 has the 5f electrons in a reasonably broad energy band (Koelling and Freeman, 1971), about 5 eV above the Fermi level of 7.5–8.0 eV. This presumably is because the fds^2 level lies so low and interacts with the d^2s^2 level. Electron-binding energies for the various core levels of the atom have been determined (Nordling and Hagström, 1964), and the X-ray transitions have been determined with precision (Bearden, 1967; Bearden and Burr, 1967; Murthy and Redhead, 1974).

3.6 THORIUM METAL

A comprehensive treatment of the physical and chemical properties of thorium metal is given in the *Gmelin Handbook* (Gmelin, 1989, 1997). A brief summary on the most important properties shall be given here.

The preparation of thorium has been done by reducing halides or double halides by sodium, potassium, or calcium (Berzelius, 1829; Chydenius, 1863;

Nilson, 1876; Chauvenet, 1911). Furthermore, $ThCl_4$ can be reduced by sodium or electrolysis can be applied to a melt of thorium chloride or fluoride in sodium chloride or potassium chloride (Matignon and Delepine, 1901; Moissan and Hönigschmid, 1906; von Bolton, 1908; von Wartenberg, 1909; Chauvenet, 1911; Kaplan, 1956). Also, ThO_2 can be used as starting material and various reductants may be used (Ruff and Brintzinger, 1923; Marden and Rentschler, 1927). Care has to be taken when carbon or silicon is used because the formation of carbides and silicides may occur (Berzelius, 1829; Moissan and Étard, 1896, 1897; Hönigschmid, 1906a,b). In the so-called 'Sylvania process' calcium is used as the reducing agent (Dean, 1957; Smith *et al.*, 1975). Other reduction processes involve ThO_2 and aluminum or magnesium (Winkler, 1891; Leber, 1927). Both reactions are preferably carried out in the presence of zinc, making the reduction process thermodynamically favorable due to the formation of the intermetallic compound Th_2Zn_{17} (Spedding *et al.*, 1952). Zinc can easily be removed by vacuum distillation and leaves the metal mainly as a powder (Meyerson, 1956; Fuhrman *et al.*, 1957). Zinc is usually introduced as chloride or fluoride in the process (Briggs and Cavendish, 1971), but attempts have been made to use a zinc–magnesium alloy as reductant (Capocchi, 1971).

Unusual reductions include, for example, the reaction of $ThCl_4$ with $DyCl_2$ (Mikheev *et al.*, 1993). A method leading to high-purity thorium is the thermal decomposition of ThI_4 on a hot tungsten filament, known as the van Arkel–de Boer process (van Arkel and de Boer, 1925). This reaction is also used for the purification of thorium because the iodine formed in the reaction can be used to transport the crude metal from the low-temperature source to the hot wire. Another method to gain very pure thorium is the electrotransport that refines the high-grade thorium from the van Arkel–de Boer process further to a material containing less than 50 ppm impurities in total (Peterson and Schmidt, 1971).

Thorium appears as a bright silvery metal that has the highest melting point among the actinide elements while its density is the lowest one in the series except for Ac. Under ambient conditions, Th adopts the face-centered cubic (fcc) structure of copper that transforms to the body-centered cubic (bcc) structure of tungsten above 1360°C. Under high pressure, a third modification with a body-centered tetragonal lattice has been observed (Bridgman, 1935; Vohra, 1991, 1993; Vohra and Akella, 1991, 1992). Note that the transition conditions between the modifications depend remarkably on the amount of impurities in the metal (Smith *et al.*, 1975; Oetting *et al.*, 1976). The same is true for the properties like melting point, density (James and Straumanis, 1956), resistance, and others shown in Table 3.3, which summarizes selected properties of thorium as reported in two monographs (Smith *et al.*, 1975; Oetting *et al.*, 1976), and in the *Gmelin Handbook* (Gmelin, 1997).

Thorium metal is paramagnetic (ground state $6d^27s^2$) and shows a specific magnetic susceptibility of $0.412 \times 4\pi \times 10^{-9}$ m^3 kg^{-1} at room temperature (Greiner and Smith, 1971). The magnetic susceptibility is nearly

[a] Cox *et al.* (1989).

temperature-independent but it depends on the amount of impurities or dopants, respectively (Sereni *et al.*, 1987). Thorium is superconducting at low temperature (Meissner, 1929; de Haas and van Alphen, 1931). The transition temperature T_c is between 1.35 and 1.40 K, the critical magnetic field H_c has been found to be (159.22 ± 0.10) G for a high-purity sample (Decker and Finnemore, 1968). Thorium is an excellent example of a weakly coupled type-I superconductor that exhibits a complete Meissner effect and whose critical field curve $H_c(T)$ has a parabolic temperature dependence and is in good agreement with the predictions of the theory of Bardeen, Cooper, and Schrieffer (Bardeen *et al.*, 1957). The pressure dependence of H_c has been determined (Fertig *et al.*, 1972) and the specific heat discontinuity at T_c has been reported by several authors to be around 8.4 mJ mol^{-1} K^{-1} (Gordon *et al.*, 1966; Satoh and Kumagai, 1971, 1973; Luengo *et al.*, 1972a,b). Calculations on electron–phonon coupling have been also reported (Winter, 1978; Skriver and Mertig, 1985; Allen, 1987; Skriver *et al.*, 1988). The pressure dependence of the critical temperature has been followed up to 20 GPa (Palmy *et al.*, 1971; Rothwarf and Dubeck, 1973). Below 2.5 GPa T_c decreases linearly with pressure. The decrease flattens to a minimum around 7.4 GPa, increases slightly up to 10 GPa, before it smoothly decreases again. The pressure dependence of T_c has also been recently examined theoretically (Rosengren *et al.*, 1975; Mahalingham *et al.*, 1993). Furthermore, the dependence of T_c on impurities has been investigated (Guertin *et al.*, 1980).

The chemical reactivity of thorium is high. It is easily attacked by oxygen, hydrogen (Winkler, 1891; Matignon and Delepine, 1901; Sieverts and Roell, 1926; Nottorf *et al.*, 1952), nitrogen (Matignon, 1900; Kohlschütter, 1901; Matignon and Delepine, 1901), the halogens (Nilson, 1876; Moissan and Étard, 1896, 1897; von Wartenberg, 1909), and sulfur (Berzelius, 1829; Nilson, 1876; von Wartenberg, 1909) at elevated temperatures. Also carbon and phosphorus are known to form binary compounds with thorium (Strotzer *et al.*, 1938; Meisel, 1939; Wilhelm and Chiotti, 1950). Finely divided thorium is even pyrophoric (Raub and Engles, 1947). The reaction of bulky thorium with air under ambient conditions is low, but nevertheless corrosion is observed according to the investigations of several authors. Thorium reacts vigorously with hydrochloric acid. The reaction with hydrochloric acid always leaves a certain amount of a black residue (12 to 15%) behind, which was first thought to be ThO_2 that was originally present in the metal (Matignon and Delepine, 1901; Meyer, 1908; von Wartenberg, 1909). As discussed in Section 3.7.3, other studies have suggested that a lower-valent thorium oxide hydrate, $ThO{\cdot}H_2O$, is formed but it is much more likely that this compound is in fact an oxide hydride containing hydroxide and chloride ions according to ThO(X)H (X = combination of OH^- and Cl^-) (von Bolton, 1908; Karstens, 1909, Katzin, 1944, 1958; Karabash, 1958; Katzin *et al.*, 1962). This assumption is also supported by mass spectroscopic investigations that show Cl^- to be present in the residue (Ackermann and Rauh, 1973a). The reaction of thorium with other acids occurs slowly, with nitric acid even passivation is observed (Smithells, 1922; Schuler *et al.*, 1952). The latter can be overcome by adding small amounts of fluoride or fluorosilicate ions.

A great number of thorium alloys are known, including those with iron, cobalt, nickel, copper, gold, silver, platinum, molybdenum, tungsten, tantalum, zinc, bismuth, lead, mercury, sodium, beryllium, magnesium, and aluminum. Other systems, like Th/Cr and Th/U, are simply eutectics, and complete miscibility is found in the liquid and solid states with cerium. An overview of thorium alloys with main group metals can be found in the *Gmelin Handbook* (Gmelin, 1992a, 1997).

3.7 IMPORTANT COMPOUNDS

As Chapter 19 is devoted to the thermodynamic properties of the actinides and their compounds, data such as enthalpies of formation or entropies will not be given here, except when needed for the clarity of the discussion.

3.7.1 Hydrides

Reaction of thorium with hydrogen, and formation of two hydrides, ThH_2 and Th_4H_{15}, has been known for more than a century (Winkler, 1891). A substoichiometric dihydride with the fluorite-type of structure was observed by X-ray diffraction (XRD) along with the tetragonal ThH_{2-x} in a preparation of overall composition $ThH_{1.73}$ (Korst, 1962) as well as in dihydrides containing some ThO_2 (Peterson *et al.*, 1959). The well-known dihydride, which can be significantly substoichiometric, has a tetragonal structure (Nottorf *et al.*, 1952; Rundle *et al.*, 1952; Flotow and Osborne, 1978). The compound contains two metal atoms in the unit cell and is isotypic with ZrH_2 (Rundle *et al.*, 1948a; Nottorf *et al.*, 1952). The higher hydride (Matignon and Delepine, 1901; Sieverts and Roell, 1926; Rundle *et al.*, 1948a, 1952; Nottorf *et al.*, 1952; Zachariasen, 1953; Mueller *et al.*, 1977), Th_4H_{15} (= $ThH_{3.75}$), has a unique cubic structure, with the Th atom in 12-fold coordination of hydrogen atoms. The hydrogen atoms are coordinated by three and four thorium atoms as may be expressed by the formula $ThH_{9/3}H_{3/4}$ according to Niggli's formalism. The structure has also been determined for the deuterated analog Th_4D_{15} (Mueller *et al.*, 1977). Th_4H_{15} was the first metal hydride to be found to show superconductivity (Satterthwaite and Toepke, 1970; Satterthwaite and Peterson, 1972; Dietrich *et al.*, 1974). The transition temperature for superconductivity is 7.5–8 K, which is narrow, but not isothermal. Metallic conduction is exhibited at room temperature. Both the hydride and the deuteride are superconducting, with no apparent isotope effect. The existence of another crystalline form, with a 1% tetragonal distortion, that is non-superconducting has been suggested (Caton and Satterthwaite, 1977). The transition temperature is reversibly pressure-sensitive, with a slope of about 42 mK $kbar^{-1}$, up to a pressure of about 28 kbar. The heat capacities of ThH_2 and Th_4H_{15} have been measured from 5 to 350 K (Schmidt and Wolf, 1975; Miller *et al.*, 1976; Flotow and Osborne, 1978). As pointed out in more detail in Chapter 19, experimental values have been extrapolated to 800 K by Flotow *et al.* (1984).

The electronic structure of these binary thorium hydrides has been investigated by photoelectron spectroscopy (Weaver *et al.*, 1977) and nuclear magnetic resonance (NMR) spectroscopy (Schreiber, 1974; Lau *et al.*, 1977; Peretz *et al.*, 1978; Maxim *et al.*, 1979).

Powdered or sintered thorium metal reacts immediately and exothermically with hydrogen at room temperature, whereas massive metal may require heating to 300–400°C before reaction takes place. For the reaction with massive metal, an induction period that is a function of the impurity content of the metal was found (Nottorf *et al.*, 1952). In general, it is taken for granted that a consequence of the reaction of hydrogen on massive metal is a crumbling and powdering of the mass. However, it has been found (Satterwaithe and Peterson, 1972) that, at temperatures around 850°C, massive metal yields massive ThH_2, and then massive Th_4H_{15}, whereas even at 500°C the reaction fractures and cracks the massive metal. It is assumed that at high temperature, there is a sufficiently close match between the crystal structures of the metal and the hydride formed at that temperature that the incorporation of hydrogen can proceed without causing disruption of the solid.

At 900°C, in high vacuum, thorium hydride is completely decomposed to its elements. The decomposition product is grey to black, powdered, or in the form of an easily disintegrated mass. When it is desired to prepare thorium metal for some subsequent reaction, formation and decomposition of the hydride is generally used to accomplish this goal. The dissociation pressures of the two hydrides have been reported as (Nottorf *et al.*, 1952):

$$\log p(\mathrm{mmHg}) = -7700\ (T/K)^{-1} + 9.54 \quad (\mathrm{Th/ThH_2\ system})$$

$$\log p(\mathrm{mmHg}) = -4220\ (T/K)^{-1} + 9.50 \quad (\mathrm{ThH_2/Th_4H_{15}\ system})$$

Flotow *et al.* (1984) discuss in greater detail the hydrogen pressures associated with the Th–H_2 system as a function of the hydrogen composition of the solid phases and the temperatures.

Thorium hydride reacts readily with oxygen to form ThO_2. Many hydride preparations are in fact pyrophoric. ThO_2 can also be formed smoothly by reaction of thorium hydride with steam at 100°C. The reactions with oxygen and with steam are typical for the procedures commonly used for the synthesis of binary compounds of thorium. Pure thorium is necessary to prepare thorium hydride that is free of oxygen or moisture. Subsequent manipulation in the absence of air or moisture then assures the formation of pure binary compounds. Thus, in the range of 250–350°C, the hydride reacts smoothly with halogens as well as with hydrogen compounds of the halogens, sulfur, phosphorus, or nitrogen to give the corresponding binary compounds of thorium (Foster, 1945, 1950; Lipkind and Newton, 1952). Methane or carbon dioxide does not react with thorium hydride.

A number of ternary hydrides and deuterides has been reported (Table 3.4). The iron compounds $Th_2Fe_{17}D_x$ are structurally related to the respective alloy Th_2Fe_{17} and show interesting magnetic properties (Isnard *et al.*, 1993). The deuterides $ThZr_2D_x$ can be described as stuffed variant of the cubic Laves phases as it has been shown by neutron diffraction (van Houten and Bartram, 1971; Bartscher *et al.*, 1986). $ThZr_2H_{7+x}$ (and also the hexagonal $ThTi_2H_{6+x}$) combine an extremely large amount of hydrogen per unit volume with relatively low equilibrium vapor pressures of hydrogen at elevated temperatures. Both of

[a] These authors use the F4/mmm setting with a = 5.734 Å. The F-centered cell has the diagonal of the ab-plane as axis, i.e. square root of twice the a axis of the I-centered cell.

these ternary hydrides are apparently stable in air. Unlike thorium hydride itself, the Th–Zr hydride is not superconducting (Satterthwaite and Peterson, 1972). Also the nickel phases $ThNi_2D_x$ are derived from the alloy $ThNi_2$ and show the deuterium atom in tetrahdral interstices of the metal atom network (Andresen *et al.*, 1984). The thorium manganese compounds $Th_6Mn_{23}D_x$ have been investigated frequently with respect to the D atom distribution in the lattice (Hardman *et al.*, 1980, 1982; Jacob, 1981; Carter, 1982; Hardman-Rhyne *et al.*, 1984). Furthermore, the ternary aluminum hydrides Th_2AlD_x have been reported in great detail (Bergsma *et al.*, 1961; Sorby *et al.*, 2000). Other hydrides, for example with cobalt and palladium are known, however not very well characterized in the most cases (Buschow *et al.*, 1975; Oesterreicher *et al.*, 1976).

3.7.2 Borides, carbides, and silicides

Three binary thorium borides are well characterized (du Jassonneix, 1905; Allard, 1932; Stackelberg and Neumann, 1932; Lafferty, 1951; Post *et al.*, 1956; Konrad *et al.*, 1996). ThB_6 contains a network of linked $[B_6]$ octahedra;

in ThB_4, $[B_2]$ dumbbells accompany the octahedra (Brewer *et al.*, 1951; Zalkin and Templeton, 1951; Blum and Bertaut, 1954). Investigations of the thorium–boron system at low boron concentrations showed that non-stoichiometric varieties of ThB_4 can be prepared (Rand *et al.*, 1975; Chiotti *et al.*, 1981). On the other hand, certain impurities (for example ThO_2) have been suggested to be accountable for the non-stoichiometry (Brewer *et al.*, 1951). The third boride, ThB_{12}, is isotypic with UB_{12} (Cannon and Hall, 1977; Cannon and Farnsworth, 1983). Furthermore, the borides ThB_{66} and ThB_{76} have been reported (Naslain *et al.*, 1971; Schwetz *et al.*, 1972), but it was not clear whether they are truly thorium–boron phases or if they are a metal-stabilized form of a boron allotrope.

Various ternary thorium borides have been prepared, especially those containing transition metals. The orthorhombic borides Th_2MB_{10} were obtained from the elements by arc melting and show a structure that is closely related to that of ThB_6 (Konrad and Jeitschko, 1995). Borides of the composition $ThMB_4$ have been recognized for $M = V$, Mo, W, Re, Cr, and Mo (Pitman and Das, 1960; Rogl and Nowotny, 1974; Konrad *et al.*, 1996). The crystal structures have been determined for $M = Cr$ and Mo, in which the boron atoms form infinite layers with the metal atoms in between similar to MgB_2. The chromium compound $ThCr_2B_6$ is isotypic with $CeCr_2B_6$ and shows metallic conduction and Pauli paramagnetism (Konrad and Jeitschko, 1995). The hexagonal borides $ThIr_3B_2$ and $ThRu_3B_2$ have been characterized magnetically and structurally. They contain discrete boride ions in prismatic coordination of the platin metal atoms (Hiebl *et al.*, 1980; Ku *et al.*, 1980). The magnetic properties have also been also determined for the rather complicated borides $R_{2-x}Th_xFe_{14}B$ ($R = Y$, Dy, Er) (Pedziwiatr *et al.*, 1986).

Further boron-containing thorium compounds are the borohydrides $Th(BH_4)_4$, $LiTh(BH_4)_5$, and $Li_2Th(BH_4)_6$ (Ehemann and Nöth, 1971). They contain the tetrahedral BH_4^- ion.

Carbides of thorium have been discussed in great detail in the *Gmelin Handbook* (Gmelin, 1992b). Thus only the most important items shall be given here briefly. Binary thorium carbides were obtained by the reaction of ThO_2 with carbon or the direct fusion of the elements (Troost, 1883; Moissan and Étard, 1896, 1897; Wilhelm and Chiotti, 1949, 1950). Three compositions, ThC_2, Th_2C_3, and ThC, are known (Fig. 3.4). ThC_2 occurs in three different modifications. At room temperature, a monoclinic unit cell is found (Jones *et al.*, 1987). Between 1430 and 1480°C, a rotation of the C_2 dumbbells starts, leading to a tetragonal structure that changes to cubic above 1480°C with complete rotational disorder of the C_2 units (Hunt and Rundle, 1951; Gantzel and Baldwin, 1964; Hill and Cavin, 1964; Langer *et al.*, 1964; Bowman *et al.*, 1968). The monocarbide, ThC, has the cubic NaCl structure. Both ThC_2 and ThC are refractory solids with high melting points (2655 ± 25 and 2625 ± 25, respectively). For ThC, the specific heat has been measured from 1.5 to 300 K (Danan, 1975). The third binary thorium carbide, Th_2C_3, has been observed at pressures

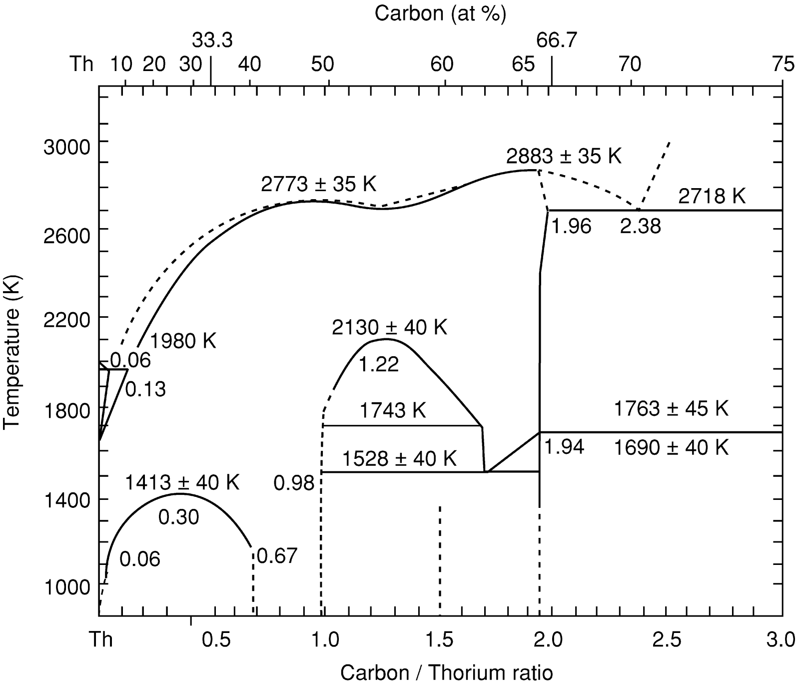

Fig. 3.4 *Phase diagram of the thorium–carbon system* (*Chiotti* et al., 1981).

above 33 kbar in the region of 1200°C (Krupka, 1970). It has the cubic structure of Pu_2C_3 and is a superconductor with T_c decreasing with increasing pressure (Giorgi *et al.*, 1976). Besides these three carbides, several non-stoichiometric phases have been found that can be seen as solid state solutions between α-Th and γ-ThC_2 (Chiotti *et al.*, 1967; Storms, 1967) that have cubic symmetry.

Upon heating ThC_2 to high temperature on a graphite filament, ThC_4^+ ions were observed (Asano *et al.*, 1974). ThC_2 burns in the air to form ThO_2 and reacts with sulfur or selenium vapor (Moissan and Étard, 1896, 1897). Halogens react with the carbide to give anhydrous halides. According to an early study (Lebeau and Damiens, 1913) the hydrolysis of the carbide produces a mixture of almost 60% hydrogen, 3.16% methane, 10.7% ethane, ~15% acetylene, ~3% ethylene, ~8% propylene and propane, and higher products. Other studies on the hydrolysis of ThC and ThC_2 report the formation of methane in the ThC case and the formation of ethane and hydrogen in the ThC_2 case (Kemper and Krikorian, 1962). It seems evident that not only the composition and purity of the carbide but also the actual hydrolysis conditions may be important factors.

A number of ternary carbides have been reported (Table 3.5). The boride carbides have the compositions ThBC, $Th_3B_2C_3$, and ThB_2C (Rogl, 1978, 1979;

Rogl and Fischer, 1989). ThBC and $Th_3B_2C_3$ contain CBBC units; in $Th_3B_2C_3$ additional C atoms are found (Fig. 3.5). For ThB_2C extended layers of connected B and C atoms are found with the thorium atoms located between the layers. In the nitride carbide ThCN (Benz, 1969; Benz and Troxel, 1971), dumbbell-shaped C_2 units and nitride ions are present (Benz *et al.*, 1972).

Several ternary carbide systems have been investigated, Th–M–C, with M being a transition metal element or a lanthanide, and a huge number of compounds are believed to exist (Gmelin, 1992b). However, only a few of them are structurally characterized. Specifically, for ruthenium and nickel, several structure determinations have been performed. In the former case, the compounds $Th_{11}Ru_{12}C_{18}$, $Th_2Ru_6C_5$, and $ThRu_3C$ were investigated (Aksel'rud *et al.*, 1990a,b; Wachtmann *et al.*, 1995). The carbon-rich species contain both C_2 units and single C atoms while $ThRu_3C$ can be regarded as a cubic closest packing of metal atoms with the carbon atoms in octahedral interstices. Two series of thorium iron carbides have been structutrally and magnetically investigated recently. They have the composition $ThFe_{11}C_{1+x}$ $(0 < x < 1)$ and $Th_2Fe_{17}C_x$ $(0 < x < 1)$, respectively (Isnard *et al.*, 1992a,b; Singh Mudher *et al.*, 1995). In the nickel system, three compounds were found: Th_2NiC_2, $Th_3Ni_5C_5$, and $Th_4Ni_3C_6$. According to the structure determination the latter two should be more correctly described as $Th_3Ni_{4.96}C_{4.79}$ and $Th_4Ni_{2.88}C_6$, respectively (Moss and Jeitschko, 1991a,b). Two carbides have been prepared in the system Th–Al–C, namely $Th_2Al_2C_3$ and $ThAl_4C_4$ (Gesing and Jeitschko, 1996). They are both methanides in the sense that they contain isolated carbon atoms. One lanthanide compound that has been structurally characterized is $CeThC_2$ (Stecher *et al.*, 1964).

According to the phase diagram Th–Si (Fig. 3.6) four binary thorium silicides exist (Stecher *et al.*, 1963; Chiotti *et al.*, 1981; Gmelin, 1993b): Th_3Si_5, Th_3Si_2, ThSi, and $ThSi_2$. The latter three are structurally known (Brauer and Mitius, 1942; Jacobson *et al.*, 1956; Brown, 1961). $ThSi_2$ is dimorphic and both the hexagonal (AlB_2 type) and the tetragonal modifications show the thorium atoms in 12-fold coordination of silicon atoms. In ThSi the silicon atoms are linked to zigzag chains (Si—Si distance: 2.49 Å) while Si_2 dumbbells (2.33 Å) are found in Th_3Si_2. Further silicides have been reported, for example Th_6Si_{11} (Brown and Norreys, 1961), but have not be confirmed up to now.

Various ternary silicides of thorium are known (Table 3.5). The largest group among them contains compounds of the composition ThM_2Si_2 with M being a transition metal element. For M = Cr, Mn, Fe, Co, Ni, Cu, and Tc, structure determinations have been performed (Ban and Sikirica, 1965; Leciejewicz *et al.*, 1988; Wastin *et al.*, 1993) and for part of the silicides, magnetic properties are known (Omejec and Ban, 1971; Ban *et al.*, 1975). The compounds are isotypic with each other and have tetragonal symmetry. The stucture consists of layers of edge connected $[ThSi_8]$ cubes that are separated by the transition metal atoms. Other silicides have the composition Th_2MSi_3 (M = M, Fe, Co, Ni, Cu, Ru, Rh, Pd, Os, Ir, Pt, Au) and are derived from the two modifications of $ThSi_2$ by substitution of transition metal atoms for silicon atoms (Ban *et al.*, 1975; Wang *et al.*, 1985; Albering *et al.*, 1994). In the same way, the silicides ThMSi (M = Au, Pd, Ni) are derived from the hexagonal form of $ThSi_2$ (Ban *et al.*, 1975; Wang *et al.*, 1985). Two new silicides of thorium have been reported recently with $ThCo_9Si_2$ and $ThRe_4Si_2$ (Albering and Jeitschko, 1995; Moze *et al.*, 1996).

In a few cases, quaternary compounds have also been investigated. For example the silicide–carbides $Th_2Re_{2.086}Si_xC$ ($x = 1.914$ and 1.904), $ThOs_{2.04}Si_{0.96}C$, and $ThOs_{2.284}Si_{0.716}C$ have been reported (Hüfken *et al.*, 1998, 1999), and the two lanthanide nitride carbides CeThNC and DyThNC are known (Ettmayer *et al.*, 1980).

3.7.3 Oxides, hydroxides, and peroxides

Thorium oxides have received considerable attention in the recent decades. They have been reviewed in the *Gmelin Handbook* (Gmelin, 1976, 1978), but the diverse chemistry of the simple binary oxide of thorium has yielded 435 patents since these days, out of which 53 are related to the catalytic behavior of ThO_2. An recent search of the Chemical Abstract Services database revealed over 540 journal articles and some 50 reports on catalysis. While ThO_2 has been studied as a complement to CeO_2 and HfO_2 in its chemistry, ThO has been postulated as a defect form of the fluorite or a ZnS structure (Katzin, 1958; Ackermann and Rauh, 1973b). Table 3.6 lists the binary oxides and the other chalcogenides (cf. Section 3.7.5) with their lattice constants. Thorium monoxide has been reported to form on the surface of thorium metal exposed to air (Rundle *et al.*, 1948b) but its preparation and isolation as a bulk black suspension was first reported in 1958 by Katzin as a result of the action of 2 to 12 N HCl solutions on thorium metal. The black powder reported appeared later to be a form of low-valent thorium oxide stabilized by HCl and H_2O. XRD studies revealed a cubic phase with a lattice constant of 5.302 Å and a pattern indicative of an fcc lattice – either a defect fluorite or ZnS-type (Ackermann and Rauh, 1973b). However, the 'monoxide' solid state compound appears to be a Th(IV) phase with the formula Th(H)(O)X, where X is a combination of OH^- and Cl^- (Katzin *et al.*, 1962). This seemed to explain the reaction of the black solid upon heating to yield HCl, H_2, H_2O, and ThO_2 under various conditions (Ackermann and Rauh, 1973b). This phase was also reported to be unstable to disproportionation under dynamic vacuum. Until now, however, there is no report on bulk-phase ThO available that is without question. On the other hand, ThO was reported in the vapor phase above a mixture of Th and ThO_2 at high temperatures (Darnell and McCollum, 1961; Ackermann and Rauh, 1973b; Hildenbrand and Murad, 1974a,b; Neubert and Zmbov, 1974).

Thorium dioxide (thoria) is somewhat hygroscopic. Reaction with nitric or hydrochloric acids followed by evaporation yields hydrates that have in the past been thought to resemble the so-called 'metaoxides' of tin and zirconium. The material may be dispersed as a positively charged colloid following evaporation

and the colloid can be 'salted out' by addition of electrolytes. The ignited oxide or the oxide sintered into larger particles is one of the most refractory substances known, showing limited reactivity with hot sulfuric acid or fusion with potassium hydrogen sulfate. Aqueous nitric acid with a few percentage of HF or sodium fluorosilicate provides a reasonable solution of the oxide (Smithells, 1922). Hot aqueous HF or gaseous HF at 250–750°C converts thoria to ThF_4 (Newton *et al.*, 1952b).

Amorphous thoria is said to crystallize from a suitable flux, for example sodium carbonate, potassium orthophosphate, or borax (Nordenskjöld and Chydenius, 1860; Nordenskjöld, 1861; Chydenius, 1863; Rammelsberg, 1873; Troost and Ouvrard, 1889; Duboin, 1909a,b). However, the use of borax as a flux is questionable, because ThO_2 is known to form ThB_2O_5 in the reaction with B_2O_3 (Baskin *et al.*, 1961).

Thorium dioxide has been studied as an active catalyst because of its reactivity with many gases, in addition to water. Dehydration of alcohols (Frampton, 1979; Siddham and Narayanan, 1979), dehydrogenation of alcohols (Thomke, 1977), and the hydration (Frampton, 1979) and hydrogenation of alkenes (Tanaka *et al.*, 1978) have been demonstrated. Other examples include copper–thorium oxide catalysts studied for the selective hydrogenation of isoprene (Bechara *et al.*, 1990a,b), decomposition of isopropanol (Aboukais *et al.*, 1993), and the oxidative coupling of methane (Zhang *et al.*, 2001). Indeed, the development of mixed-metal rare earth/thorium/copper oxides based on a perovskite parent structure have been shown to decompose NO_x (Gao and Au, 2000), to catalyze the reduction of NO by CO (Wu *et al.*, 2000), and to dehydroxylate phenol (Liu *et al.*, 1997). Lastly, thorium oxide, when heated, produces an intense blue light and mixed with ceria at 1%, produces a more intense white light. It is this property that was the basis for the thoriated gas mantle industry (Mason, 1964; Manske, 1965).

Thorium hydroxide is formed as a gelatinous precipitate when alkali or ammonium hydroxide is added to a solution of a thorium salt. This precipitate dissolves in dilute acids and, when fresh, in ammonium oxalate, alkali carbonates, sodium citrate, or sodium potassium tartrate solutions (Chydenius, 1863; Glaser, 1897; Jannasch and Schilling, 1905; Sollman and Brown, 1907). The hydroxide is also precipitated by the action of sodium nitrate (Baskerville, 1901) or potassium azide (Dennis and Kortright, 1894; Glaser, 1897; Wyrouboff and Verneuil, 1898a). Electrolysis of thorium nitrates is also said to yield a precipitate of hydroxide at the anode (Angelucci, 1907). Material dried at 100°C has been reported to correspond closely in composition to $Th(OH)_4$ (Clève, 1874), but other reports claim to find higher hydrates even at higher temperatures (Wyrouboff and Verneuil, 1905). Two forms of $ThO_2{\cdot}2H_2O$ ($=Th(OH)_4$), from precipitation in basic aqueous solution, have been distinguished, one of which is amorphous (Guymont, 1977). Further studies indicate that $Th(OH)_4$ is stable in the temperature range 260–450°C and is converted to the oxide at temperatures of 470°C and higher (Dupuis and Duval, 1949). Thermal analysis has shown that the decomposition of the hydroxide is a continuous process (Tiwari and Sinha, 1980). Thorium hydroxide absorbs atmospheric carbon dioxide very readily (Chydenius, 1863; Dennis and Kortright, 1894; Chauvenet, 1911). When boiled with thorium nitrate, $Th(OH)_4$ forms a positively charged colloid (Müller, 1906). The colloid formation is also observed if thorium hydroxide is treated with hydrous aluminum chloride, ferric chloride, uranyl nitrate, or hydrochloric acid (Szilard, 1907). The solubility product of $Th(OH)_4$ is discussed in Section 3.8.5.

Thorium peroxide had been reportedly known since 1885 as the product of the reaction between hydrogen peroxide and salts of thorium in solution (de Boisbaudran, 1885). The precipitate that forms can be a dense solid or a gelatinous paste. The solid has initially been described in the literature as hydrated thorium peroxide, 'Th_2O_7' (de Boisbaudran, 1885; Pissarsjewski, 1900; Schwarz and Giese, 1928). The existence of peroxide species was confirmed but it was pointed out that the respective anions of the initial thorium salt are part of the solid (Clève, 1885; Wyrouboff and Verneuil, 1898a; Hamaker and Koch, 1952a,b; Johnson *et al.*, 1965; Hasty and Boggs, 1971; Raman and Jere, 1973a,b; Jere and Santhamma, 1977). XRD studies revealed two phases if the precipitation occurs from thorium sulfate solution: $Th(OO)SO_4 \cdot 3H_2O$ precipitated from solutions of high H_2SO_4 concentration and a second phase is obtained from more weakly acidic solutions with a variable sulfate content and 3.0–3.8 peroxide oxygen atoms per thorium atom (Hamaker and Koch, 1952a). A Raman analysis of $Th(OO)SO_4 \cdot 3H_2O$ has been performed (Raman and Jere, 1973a,b) and suggests a formulation of the compound as 'tetraaquo-μ-peroxy-disulfatodithorium(IV)', with two bridging sulfato groups. Raman investigations have been also carried out for the peroxide obtained from a nitrate solution (Raman and Jere, 1973b). According to these measurements thorium peroxide nitrate showed a 'free' (D_{3h}) nitrate anion along with a bridging peroxide molecule between thorium atoms. However, also a nitrate-free peroxide has been obtained from the reaction of a refluxing aqueous solution of $Th(NO_3)_4 \cdot 4H_2O$, urea, and 30% hydrogen peroxide (Gantz and Lambert, 1957). The precipitate, described as a granular light blue-green powder, decomposes at 120°C to yield ThO_2 and water. Chemical analysis revealed a formula of $Th(OH)_3OOH$, equivalent to tin and zirconium analogs. The dried peroxide is insoluble in neutral solutions (aqueous) but is soluble in concentrated mineral acids. Thorium peroxide has also been reported by the action of hydrogen peroxide or sodium hypochlorite on thorium hydroxide, or by anodic oxidation of an alkaline thorium hydroxide suspension containing sodium chloride (Pissarsjewsky, 1902).

Like the double salts of the halides, thorium dioxide will form a similar 'double salt' of oxide with BaO and alkali metal oxides (K_2O, for example) in phases such as $BaThO_3$ and K_2ThO_3 (Brunn and Hoppe, 1977); however, neither the Sr form nor the Li form of these structures have been reported (Hoffmann, 1935; Naray-Szabo, 1951; Scholder *et al.*, 1968; Fava *et al.*, 1971; Nakamura, 1974). No reaction was seen with BeO (Ohta and Sata, 1974) and, although there is solid solution formation with the rare earth oxides, no reaction to form the 'double salt' phase Ln_2ThO_5 has been observed (Diness and Roy, 1969; Sibieude, 1970). Because of the reactivity of ThO_2–CuO mixtures, reactions that have included other transition metal oxides have yielded a number of unique phases including tetragonal perovskite phases such as $La_{1-x}Th_xCoO_3$ (Tabata and Kido, 1987), $La_{1-1.333x}Th_xNiO_3$ (Yu *et al.*, 1992), $Na_{.6667}Th_{.3333}TiO_3$ (Zhu and Hor, 1995), and the Ruddlesden–Popper manganites $Ca_{3-x}Th_xMn_2O_7$ (Lobanov *et al.*, 2003).

3.7.4 Halides

(a) Binary halides

The halides of thorium had been treated comprehensively in 1968 by Brown (1968), and the fluorides in particular have been reviewed by Penneman *et al.* (1973) and Taylor (1976). In addition, a later volume of the *Gmelin Handbook* has discussed thorium halides (Gmelin, 1993a).

The tetrahalides of thorium are known for the whole halogen series (Table 3.7). Thorium fluoride, ThF_4, can be obtained by various procedures (Moissan and Martinsen, 1905; Duboin, 1908a; Chauvenet, 1911; Lipkind and Newton, 1952). Precipitation from aqueous Th^{4+}-containing solutions leads to hydrates of ThF_4 that are, however, not easily dehydrated due to the formation of hydroxide or oxide fluorides (Briggs and Cavendish, 1971). Under careful conditions, for example under streaming HF or F_2 gas, dehydration to pure ThF_4 is possible (Pastor and Arita, 1974). Alternative routes avoiding aqueous media are the reaction of thorium metal or thorium carbide with fluorine (Moissan and Étard, 1896, 1897), or the action of hydrogen fluoride on other thorium halides, thorium oxide or hydroxide, and thorium oxalate or oxide carbonate (Newton *et al.*, 1952a). As mentioned in the Section 3.7.1, the reaction of thorium hydrides with fluorine provides a route to ThF_4 (Lipkind and Newton, 1952). An elegant way to obtain pure ThF_4 is the reaction of ThO_2

Table 3.7 *Crystallographic data of binary thorium halides.*

with NH_4HF_2. Ammonium hydrogen fluoride serves as the fluorinating agent and is much easier to handle than hydrogen fluoride itself. The reaction yields the ternary fluoride NH_4ThF_5 that decomposes above 300°C to the tetrafluoride (Asprey and Haire, 1973). The disadvantage of the method compared to the direct hydrofluorination is that an eight-fold excess of NH_4HF_2 is needed.

The monoclinic crystal structure of ThF_4 is isotypic with those of zirconium and hafnium fluoride and contains Th^{4+} ions in slightly distorted square antiprismatic coordination of fluoride ions (Zachariasen, 1949a; Asprey and Haire, 1973; Benner and Müller, 1990). Each of the fluorine atoms is attached to another thorium ion, leading to a three-dimensional structure according to ${}^{3}_{\infty}[ThF_{8/4}]$. Surprisingly, the thorium fluoride hydrate that can be precipitated from aqueous solution (Berzelius, 1829; Chydenius, 1863) has not been structurally characterized up to now. It is believed to be an octahydrate, which decomposes to a tetrahydrate on further drying and then finally to a dihydrate on heating (Chauvenet, 1911). The only hydrate of ThF_4 that is structurally known is $Th_6F_{24}\cdot H_2O$ ($=ThF_4\cdot 1/6H_2O$) (Cousson *et al.*, 1978). Similarly to the anhydrous fluoride it consists of three-dimensionally connected square antiprisms $[ThF_8]$. Six of these aniprisms are arranged in a way that empty voids are formed in which the water molecule resides having contact to two of the six Th^{4+} ions (Fig. 3.7). It is assumed that this compound can be obtained by

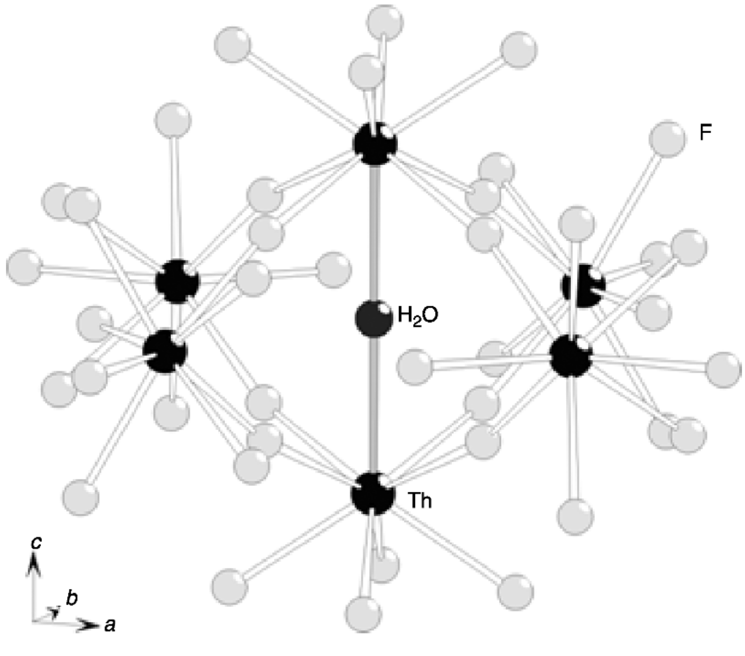

Fig. 3.7 *Detail of the crystal structure of $Th_6F_{24}\cdot H_2O$; the H_2O molecule resides in a void formed by six square antiprismatic $[ThF_8]$ polyhedra.*

careful dehydration of higher hydrates but usually hydrolysis is observed yielding $Th(OH)F_3 \cdot H_2O$ and then finally $ThOF_2$ (Marden and Rentschler, 1927; Zachariasen, 1949a; D'Eye, 1958). The structure of neither of the latter two compounds is known without some question. For $ThOF_2$, however, an orthorhombic unit cell has been determined, which has a close relationship to the hexagonal one of LaF_3. Probably the structure can be seen as an ordering variant of the LaF_3-type of structure. The treatment of $ThOF_2$ with steam at 900°C will yield thoria (Chydenius, 1863; Cline *et al.*, 1944).

Thorium tetrachloride, $ThCl_4$, can be crystallized from aqueous solution as an octahydrate, which is easily transformed to basic chlorides upon heating above 100°C (Chauvenet, 1911; Dergunov and Bergman, 1948; Knacke *et al.*, 1972a,b). Dehydration has also been done by refluxing the hydrates with thionyl chloride but the product was hard to get free of $SOCl_2$. Other routes have been employed to produce pure $ThCl_4$ (Chydenius, 1863) including the reaction of ThH_4 with HCl and the action of chlorine on thorium metal (Krüss and Nilson, 1887a; Lipkind and Newton, 1952), ThH_4, or thorium carbide (Nilson, 1876, 1882a,b, 1883; Moissan and Étard, 1896, 1897; von Wartenberg, 1909). Furthermore mixtures of chlorine and carbon or S_2Cl_2 were used for the chlorination of ThO_2 (Matignon and Bourion, 1904; Meyer and Gumperz, 1905; Bourion, 1909; von Wartenberg, 1909; Yen *et al.*, 1963), and also carbon tetrachloride (Matignon and Delepine, 1901; von Bolton, 1908; Knacke *et al.*, 1972a), phosgene (Baskerville, 1901; Karabasch, 1958), and phosphorus pentachloride (Smith and Harris, 1895; Matignon, 1908) were applied as chlorinating agents and mixtures of chlorine and CO or CO_2 for the chlorination of thorium oxalate and nitrate, respectively (Dean and Chandler, 1957). A facile synthesis of $ThCl_4$ is provided in the reaction of thorium metal with NH_4Cl in sealed tubes (Schleid *et al.*, 1987). Purification of $ThCl_4$ can be achieved by sublimation. $ThCl_4$ melts at 770°C (Moissan and Martinsen, 1905; Fischer *et al.*, 1939) and boils at 921°C. The results of vapor pressure measurements as a function of the temperature have been compiled (Fuger *et al.*, 1983).

$ThCl_4$ is dimorphic and exhibits a phase transition at 405°C (Mooney, 1949; Mucker *et al.*, 1969; Mason *et al.*, 1974a). The phase transition can only be observed under special conditions and in very pure samples. Usually the high-temperature phase β-$ThCl_4$ remains even at temperatures below 405°C as a metastable compound. Both the low-temperature phase α-$ThCl_4$ and the high-temperature phase β-$ThCl_4$ are tetragonal and show eight-fold coordinated Th^{4+} ions. The coordination polyhedra are slightly distorted dodecahedra that are connected via four edges to a three-dimensional structure. Thus, each of the chloride ligands are connected to two Th^{4+} ions. The difference in the two polymorphs results from small differences in the orientation of the $[ThCl_8]$ polyhedra with respect to each other (Fig. 3.8). The symmetry decreases from $I4_1/amd$ for β-$ThCl_4$ to $I4_1/a$ for α-$ThCl_4$. The two modifications of $ThCl_4$ are related in much the same way as are zicon ($ZrSiO_4$) and scheelite ($CaWO_4$).

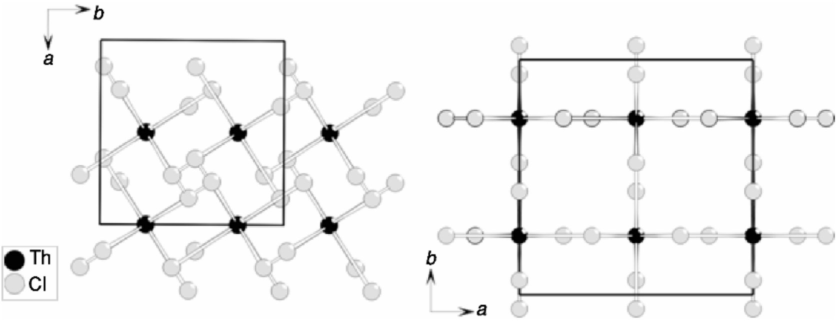

Fig. 3.8 *Projections of the crystal structures of* α*-ThCl*$_4$ (*right*) *and* β*-ThCl*$_4$ (*left*) *onto* (001).

In fact the structures of $ThCl_4$ result if the atoms in the tetrahedral centers (Si and W, respectively) are removed in the oxo-compounds. More recent investigations gave some evidence that there is a third modification of $ThCl_4$ below 70 K that has a complicated incommensurate structure related to that of α-$ThCl_4$ (Khan Malek *et al.*, 1982; Bernard *et al.*, 1983; Krupa *et al.*, 1987).

Structural data of $ThCl_4$ hydrates are not known up to now but the enthalpies of formation of the di-, tetra-, hepta- and octahydrates have been evaluated (Fuger *et al.*, 1983) from enthalpy of solution measurements (Chauvenet, 1911). Also the basic chlorides that are frequently observed as the products of the thermal treatment of the hydrates are poorly investigated (Bagnall *et al.*, 1968). It is only for the oxychloride $ThOCl_2$ that lattice parameters have been calculated from powder diffraction data based on the data given for $PaOCl_2$ (Bagnall *et al.*, 1968). The heat of formation of $ThOCl_2$ has been reported several times (Yen *et al.*, 1963; Korshunov and Drobot, 1971; Knacke *et al.*, 1972b; Fuger *et al.*, 1983) and will be discussed in proper context in Chapter 19. Chlorides of lower-valent thorium have been reported to form by electrochemical reduction of a $ThCl_4$/KCl melt (Chiotti and Dock, 1975) but these observations are still in need of confirmation.

Analogous to the tetrachloride, $ThBr_4$ can be obtained from aqueous solution, for example, by adding $Th(OH)_4$ to aqueous HBr. Depending on the drying conditions various hydrates may form. The main disadvantage of the wet route for preparing $ThBr_4$ is the contamination of the product with hydrolysis products like $ThOBr_2$. Dry routes to $ThBr_4$ include the action of bromine on thorium metal, ThH_4, ThC, or on mixtures of ThO_2 and C (Nilson, 1876; Troost and Ouvrard, 1889; Moissan and Étard, 1896, 1897; Matthews, 1898; Moissan and Martinsen, 1905; Fischer *et al.*, 1939; Young and Fletcher, 1939; Lipkind and Newton, 1952). Moreover, the reaction of gaseous HBr with ThH_4 (Lipkind and Newton, 1952) and of a mixture of S_2Cl_2 and gaseous HBr with ThO_2 have been employed (Bourion, 1907). Sublimation above 600°C in vacuum should be applied for purification. The temperature dependence of the vapor pressure has been investigated (Fischer *et al.*, 1939) and melting (679°C) and boiling (857°C) points have been reported (Fischer *et al.*, 1939; Mason *et al.*, 1974b).

As found for the tetrachloride, $ThBr_4$ is also dimorphic (D'Eye, 1950; Brown *et al.*, 1973; Fuger and Brown, 1973; Mason *et al.*, 1974b; Guillaumont, 1983). Both modifications, β-$ThBr_4$ and α-$ThBr_4$, are isotypic to the respective chlorides. The transition temperature is slightly higher compared to $ThCl_4$ and is determined to be 426°C. Again, the β-phase is found to remain metastable even below 426°C. The phase transition has been investigated in detail by means of nuclear quadrupolar resonance (NQR) on the ^{79}Br isotope (Kravchenko *et al.*, 1975). According to these experiments, the time to achieve complete conversion is strongly dependent on the previous treatment of the sample and is reduced after one conversion cycle has passed. Analogous to $ThCl_4$ another phase transition is found at lower temperature. According to NQR and electron paramagnetic resonance (EPR) measurements as well as neutron and X-ray diffractions, the transition is second order and occurs at 92 K (Kravchenko *et al.*, 1975). It is only observed in β-$ThBr_4$ and can be described as a continuous modulation of the bromide ions along the *c*-axis, leading to a complicated incommensurate structure (Madariaga *et al.*, 1993). The incommensurate low-temperature modifications of $ThBr_4$ and $ThCl_4$ have also been investigated spectroscopically on U^{4+}-doped samples (Krupa *et al.*, 1995).

There are two reports on the low-valent thorium bromides, $ThBr_3$ and $ThBr_2$ (Hayek and Rehner, 1949; Shchukarev *et al.*, 1956). They have been prepared from the elements in the desired molar ratio or, in the case of $ThBr_3$, by reduction of $ThBr_4$ with hydrogen. These bromides are highly reactive and show disproportionation at higher temperatures. Unfortunately no structural data are known. More recently the molecular species, $ThBr_3$, $ThBr_2$ and ThBr, have been identified by mass spectrometry in the bromination of thorium between 1500 and 2000 K (Hildenbrand and Lau, 1990).

None of the various hydrates of $ThBr_4$ that have been reported to contain 12, 10, 8, and 7 molecules of water, respectively (Lesinsky and Gundlich, 1897; Rosenheim and Schilling, 1900; Rosenheim *et al.*, 1903; Moissan and Martinsen, 1905; Chauvenet, 1911), are well characterized to date. The heat of solution has been determined in some cases and the thermal decomposition of the hydrates is known to lead to $Th(OH)Br_3$ and finally to $ThOBr_2$ (Chauvenet, 1911). The powder diffraction pattern of the oxybromide shows that this compound is not isotypic with $ThOCl_2$ but seems to have a lower symmetry (Bagnall *et al.*, 1968). $ThBr_4$ is also known to form solvates with amines (Rosenheim and Schilling, 1900; Rosenheim *et al.*, 1903), acetonitrile (Young, 1935), and trimethylphosphine (Al-Kazzaz and Louis, 1978).

Thorium tetraiodide (ThI_4) is most conveniently prepared by the reaction of the elements in sealed silica ampoules (Nilson, 1876; Moissan and Étard, 1896, 1897; Zalkin *et al.*, 1964). It is very important to exclude any traces of water or oxygen during the reaction to avoid contamination of the product with $ThOI_2$ or even ThO_2. Alternative procedures involve the reactions between ThH_4 and HI, and between thorium metal and a H_2/I_2 mixture (Lipkind and Newton, 1952). If only small amounts of ThI_4 are needed, the action of AlI_3 on ThO_2 might also be appropriate (Chaigneau, 1957). In the temperature range from 500 to 550°C, ThI_4 can be sublimed for purification under dynamic vacuum yielding yellow crystals. Knudsen cell effusion studies of ThI_4 have suggested dissociation through ThI_3, ThI_2, and ThI to thorium metal (Knacke *et al.*, 1978). On heating, ThI_4 reacts with ThO_2 to form the basic iodide $ThOI_2$ (Scaife *et al.*, 1965; Corbett *et al.*, 1969).

ThI_4 is not isotypic with the other tetrahalides. It has monoclinic symmetry and contains eight-fold coordinated Th^{4+} ions (Zalkin *et al.*, 1964). The coordination polyhedron can be seen as a distorted square antiprism. The polyhedra are linked in chains via two triangular faces leading to Th–Th distances of 4.48 Å. The chains are further connected via the two remaining iodine ligands into layers. The connectivity may be formulated as $^{2}_{\infty}[ThI^{f}_{6/2}I^{e}_{2/2}]$ (f = face; e = edge). These layers are held together only by van der Waals interactions (Fig. 3.9).

Two lower-valent thorium iodides, ThI_3 and ThI_2, are known. Both can be obtained by reduction reactions of ThI_4 with appropriate amounts of thorium metal in sealed tantalum tubes (Anderson and D'Eye, 1949; Hayek and Rehner, 1949; Hayek *et al.*, 1951; Clark and Corbett, 1963; Scaife and Wylie, 1964; Guggenberger and Jacobson, 1968). If hydrogen is used as the reducing reagent, the formation of iodide hydrides is observed (Struss and Corbett, 1978).

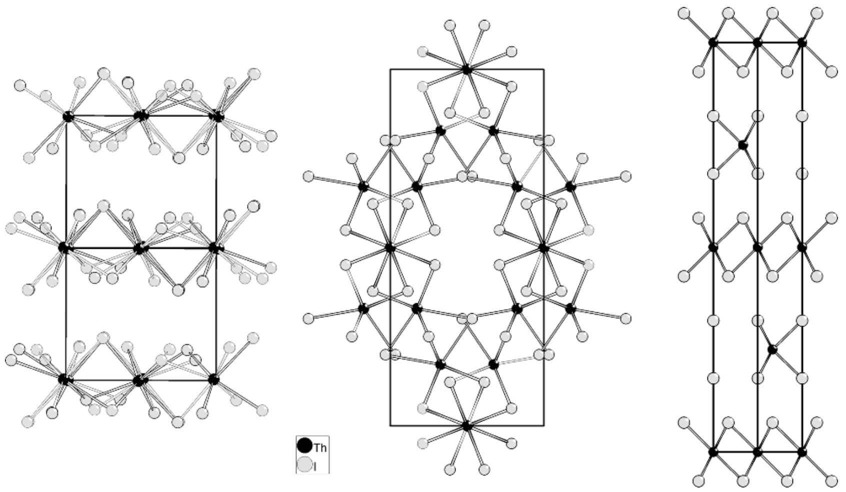

Fig. 3.9 *Crystal structures of the thorium iodides ThI_4 (left, as a projection onto the* (101) *plane),* β-*ThI_3 (middle, as a projection onto the* (001) *plane), and* β-*ThI_2 (right, as a projection onto the* (110) *plane).*

For the preparation of ThI_2, another route has been developed. The electrolysis of thorium metal in a solution of iodine and tetraethyl ammonium perchlorate in acetonitrile affords $ThI_2{\cdot}2CH_3CN$ that can be decomposed into ThI_2 *in vacuuo* (Kumar and Tuck, 1983).

Depending on the time, the reaction of ThI_4 and Th leads to two modifications of ThI_3 (Beck and Strobel, 1982). After a short period of 2–3 days, thin shiny rods of α-ThI_3 were obtained while long heating times led to compact crystals of β-ThI_3 that show a slight green to brass-colored luster. For α-ThI_3 only the lattice constants are known while a complete structure determination has been performed for β-ThI_3 (Beck and Strobel, 1982). It shows three crystallographically different thorium atoms in the unit cell, each of them in an eightfold coordination of iodide ions. Two of the $[ThI_8]$ polyhedra are square antiprismatic, the third one is a slightly elongated cube. The $[ThI_8]$ cubes are connected via four rectangular faces to $[ThI_8]$ square antiprisms (Fig. 3.9). One half of the square antiprisms is further connected to other cubes and, the second half to other square antiprisms, leading to a three-dimensional network. The Th–I bond distances suggest that thorium is in the tetravalent state in ThI_3 and has to be formulated according to $Th^{4+}(I^-)_3(e^-)$ with the electrons delocalized or involved in metal–metal bonds. The latter assumption is supported by the relatively short Th–Th distances of 3.46 to 3.80 Å.

ThI_2 is also found to adopt two different crystal structures (Clark and Corbett, 1963; Scaife and Wylie, 1964). Lustrous gold crystals of β-ThI_2 are obtained at 700 to 850°C while α-ThI_2 forms at 600°C. Both compounds are hexagonal but a structure determination has been performed only for β-ThI_2 (Guggenberger and Jacobson, 1968). The structure can be seen as a stacking variant of the CdI_2 structure (Fig. 3.9). It has a remarkable long *c*-axis (31 Å) and the stacking sequence of the iodide ions is ...ABCCBA... with the thorium atoms in octahedral and trigonal prismatic sites (Fig. 3.9). Judging from the Th–I bond distances, Th^{4+} is present in the structure and the free electrons, according to $Th^{4+}(I^-)_2(e^-)_2$, should be responsible for the electrical conductivity of the compound. The metal–metal distances, however, are remarkably longer than those found in ThI_3. Both subiodides, ThI_3 and ThI_2, exhibit peritectic decomposition above 850°C caused by disproportionations to ThI_4 and ThI_2 or ThI_4 and Th, respectively (Scaife and Wylie, 1964).

The formation of pseudo-halides of thorium (such as thiocyanate or selenocyanate) in organic solvents has been reported, but up to now, no binary compound is known (Golub and Kalibabchuk, 1967; Laubscher and Fouché, 1971; Golub *et al.*, 1974).

(b) Polynary halides

The systems AF/ThF_4, where A is an alkali or another monovalent metal ion, have been widely investigated (Brunton *et al.*, 1965). Phase diagrams of the

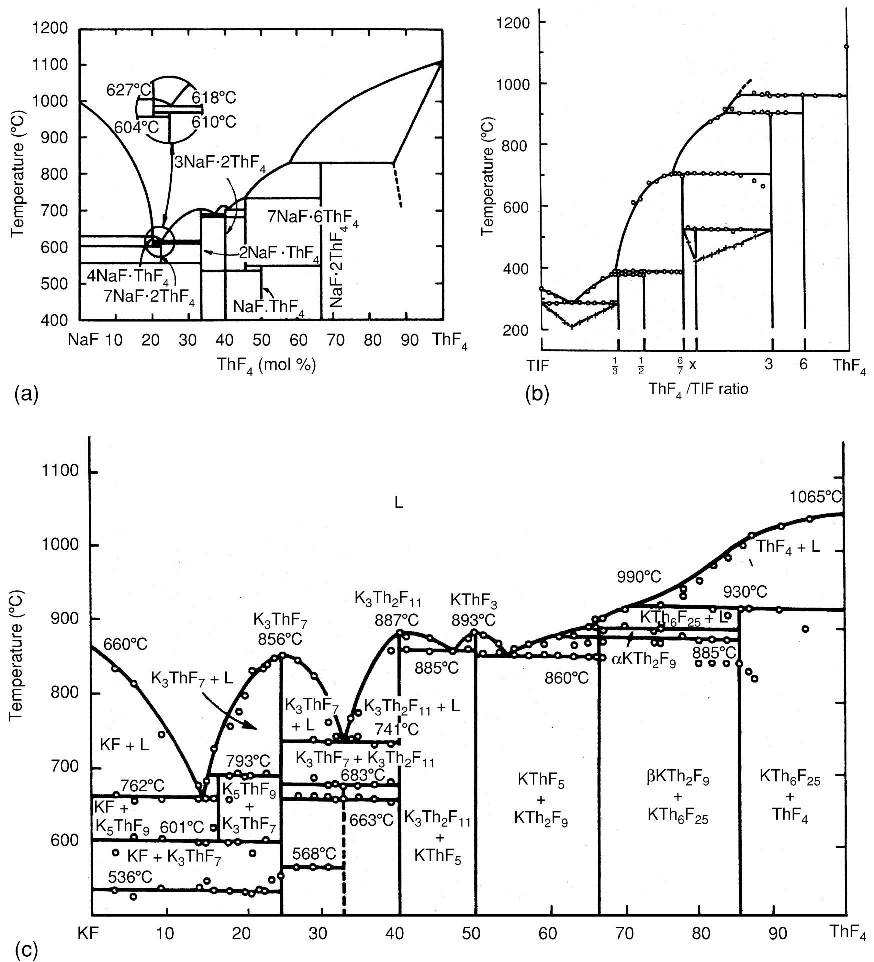

Fig. 3.10 *Phase diagrams of three AF/ThF$_4$ systems.* (*a*) *NaF/ThF$_4$* (*Thoma,* 1972). (*b*) *TlF/ThF$_4$* (*Avignant and Cousseins,* 1970). (*c*) *KF/ThF$_4$* (*Kaplan,* 1956).

systems NaF/ThF$_4$ (Thoma, 1972), KF/ThF$_4$ (Kaplan, 1956), and TlF/ThF$_4$ (Avignant and Cousseins, 1970) are given as examples in Fig. 3.10. Furthermore, the binary and also some ternary phase diagrams of ThF$_4$ with several other fluorides were determined. Table 3.8 surveys the phases that are reported to exist along with those found in the other halide systems. Unfortunately, only very few of these phases have been carefully characterized. In some cases lattice parameters of the compounds were determined by powder diffraction; moreover,

careful structure determinations remain scarce. Known crystallographic data are summarized in Table 3.9.

In the system LiF/ThF_4 four compounds are known to exist (Brown, 1968; Cousson *et al.*, 1977; Penneman *et al.*, 1973; Taylor, 1976), namely Li_3ThF_7, $LiThF_5$, $LiTh_2F_9$, and $LiTh_4F_{17}$. A complete structure analysis has been done for only one of these phases, namely Li_3ThF_7 (Cousson *et al.*, 1978;

[a] rhombohedral setting.

Laligant *et al.*, 1989; Pulcinelli and de Almeida Santos, 1989). It is dimorphic but the linkage of the monocapped square antiprisms [ThF_9] is the same in the two modifications. They are connected via two common edges to layers according to the formulation ${}^{2}_{\infty}[\mathrm{ThF}^{e}_{4/2}\mathrm{F}^{t}_{5/1}]$ (e = edge, t = terminal). The layers are stacked along the *c*-axis. The different symmetry of the two modifications arises from the different positions of the Li^+ ions in the interlayer spacings, and their positions are temperature-dependent, making the compound a good ionic conductor (Laligant *et al.*, 1992). According to powder diffraction measurements, $LiThF_5$ is isotypic with $LiUF_5$ and contains a three-dimensional network of vertex-connected monocapped square antiprisms [ThF_9] that incorporate the Li^+ in a six-fold coordination (Keenan, 1966). The lattice parameter of the other two fluorides have been obtained by powder XRD (Harris *et al.*, 1959; Cousson *et al.*, 1978).

The system NaF/ThF_4 shows the formation of seven compounds (Table 3.8) (Rosenheim *et al.*, 1903; Dergunov and Bergman, 1948; Brunton *et al.*, 1965; Kaplan, 1956; Ryan and Penneman, 1971; Thoma, 1972). Na_2ThF_6 may either be cubic (α-Na_2ThF_6) or trigonal (β_2-Na_2ThF_6) (Table 3.9). The cubic modification is a variant of the CaF_2-type of structure with Na^+ and Th^{4+} occupying Ca^{2+} sites in a disordered fashion (Zachariasen, 1949b). The trigonal structure of Na_2ThF_6 is very similar to the structure of LaF_3 and contains both the Na^+ and the Th^{4+} ions in tricapped trigonal prismatic coordination of fluoride anions (Zachariasen, 1948b). The polyhedra are connected via triangular faces in the [001] direction and via common edges in the (001) plane. A third modification, δ-Na_2ThF_6, has been reported to be also trigonal but has not been proved yet (Zachariasen, 1948c; Penneman *et al.*, 1973). In $NaTh_2F_9$ the Th^{4+} are nine-fold coordinated by F^- ions. The polyhedra are connected via vertices according to ${}^{3}_{\infty}[\mathrm{ThF}_{9/2}]^{-0.5}$ to a three-dimensional network with the Na^+ ions incorporated for charge compensation (Zachariasen, 1948b, 1949a). In the complex structure of $Na_7Th_6F_{31}$ nine- and ten-fold coordinated Th^{4+} ions are present (Keenan, 1966; Penneman *et al.*, 1973).

An X-ray structure analysis is available for all of the six compounds that exist in the KF/ThF_4 system (Kaplan, 1956), except for $KThF_5$ (Table 3.9). α_1-K_2ThF_6 is isotypic with the respective sodium compound, while a slight difference is found between β_1-K_2ThF_6 and β_1-Na_2ThF_6 (Zachariasen, 1948c; Ryan and Penneman, 1971). The Th/F sublattice is the same in the two compounds, however, in the former the K^+ ions are located in tricapped trigonal prismatic voids, in the latter, Na^+ occupies octahedral sites. The complex fluoride $K_7Th_6F_{31}$ (Zachariasen, 1948c; Brunton, 1971a) shows isotypism to the sodium compound. K_5ThF_9, which has also been prepared from aqueous media (Wells and Willis, 1901), consists of monomeric distorted square antiprismatic $[ThF_8]^{4-}$ anions that are connected via K^+ ions (Ryan and Penneman, 1971). Furthermore there are isolated F^- ions in the structure that are not bonded to Th^{4+}. The structure of KTh_6F_{25} is a polymorph of the CsU_6F_{25}-type with the Th^{4+} ions in nine-fold coordination by fluoride ions (Brunton, 1972).

The tricapped trigonal prismatic polyhedra are linked via shared edges and vertices. The resulting three-dimensional network incorporates the K^+ ions in voids. Finally, a mixed sodium potassium fluoride is known: $NaKThF_6$ (Brunton, 1970).

Among the compounds found in the RbF/ThF_4 system (Dergunov and Bergman, 1948; Thoma and Carlton, 1961), Rb_2ThF_6, $Rb_7Th_6F_{31}$ and $RbTh_6F_{25}$ are isotypic to their respective potassium fluorides (Harris, 1960; Penneman *et al.*, 1973). Rb_3ThF_7 has the same cubic structure as K_3UF_7 and shows a highly disordered fluoride sublattice (Dergunov and Bergman, 1948).

The same is true for Cs_3ThF_7, which is one of the seven phases that are known to exist in the CsF/ThF_4 system (Thoma and Carlton, 1961; Penneman *et al.*, 1973). Unfortunately, lattice parameters are only available for one additional compound, $CsTh_6F_{25}$. It is isotypic to CsU_6F_{25} and can be seen as a polymorph of the KTh_6F_{25}-type wherein the Th^{4+} ions are in nine-fold and the Cs^+ ions in 12-fold coordination by fluoride ions (Brunton, 1971b; Penneman *et al.*, 1973).

Although the size of the ammonium ion is comparable to the radii of K^+ and Rb^+, the NH_4F/ThF_4 system contains only a few phases, namely $(NH_4)_2ThF_6$, $(NH_4)_3ThF_7$, and $(NH_4)_4ThF_8$ (Ryan *et al.*, 1969; Penneman *et al.*, 1971). The latter two have been structurally characterized. $(NH_4)_3ThF_7$ is not isotypic with the respective potassium or cesium compounds but crystallizes with orthorhombic symmetry (Penneman *et al.*, 1971). It contains chains of edge-sharing $[ThF_9]$ polyhedra with the formulation $^1_\infty[ThF_{4/2}F_{5/1}]$ that are separated by the NH_4^+ ions. Similar chains are found in the unique crystal structure of $(NH_4)_4ThF_8$. This latter compound contains, however, an additional fluoride ion that is not coordinated to any Th^{4+} so that it should be formulated as $(NH_4)_4[ThF_7]F$ (Ryan *et al.*, 1969).

As far as structural data are known, the compounds found in the TlF/ThF_4 system show a close relationship to the respective fluorides of the larger alkali metal ions (Avignant and Cousseins, 1970). Slight deviations may be observed as can be seen from the structure of Tl_3ThF_7 and are usually attributed to the stereochemical activity of the lone electron pair on Tl^+ (Gaumet *et al.*, 1995).

Several other systems with ThF_4 have been investigated with unusual components like N_2H_5F or even NH_3OH (Table 3.8) (Sahoo and Patnaik, 1961; Satpathy and Sahoo, 1968; Glavic *et al.*, 1973; Rai and Sahoo, 1974). Single crystal structures are not known in these cases. In addition, compounds with higher valent ions have been investigated. With divalent cations, a number of compounds are known that have essentially the LaF_3 structure type, wherein the La^{3+} positions are filled by Th^{4+} and the divalent cation, respectively (Zachariasen, 1949a; Keller and Salzer, 1967; Brunton, 1973). Anion-rich fluorides can be obtained when a small amount of Th^{4+} is doped in the CaF_2 lattice and complicated phases with severe disorder in the cation and anion lattice are described for lanthanide-containing compounds like $SmTh_2F_{11}$ (Abaouz *et al.*, 1997). Finally, the zirconium thorium fluoride $ThZr_2F_{12}$ is completely ordered and contains layers of vertex-shared $[ZrF_8]$ polyhedra that alternate with layers of Th^{4+} ions in nine-fold coordination by F^- ions (Taoudi *et al.*, 1996).

A few hydrates of ternary thorium fluorides are known. Probably the most remarkable hydrate has the composition $(NH_4)_7Th_2F_{15} \cdot H_2O$ (Penneman *et al.*, 1968, 1976) and contains the dimeric anion $[Th_2F_{15}(H_2O)]^{7-}$ in which the Th^{4+} ions are linked via three fluoride ions. Furthermore the lanthanide-containing phases $LaTh_4F_{19} \cdot H_2O$ and $ThEr_2F_{10} \cdot H_2O$ have been reported in which the lanthanide and the Th^{4+} ions occupy the same sites (Guery *et al.*, 1994; Le Berre *et al.*, 2000). Finally, the fluoride hydroxide $Li_3Th_5F_{22}OH$ should be mentioned, which incorporates the Li^+ ions in a three-dimensional network of $[ThF_9]$ and $[ThF_8OH]$ polyhedra (Cousson *et al.*, 1979a).

Polynary thorium fluorides with more than one additional cation have been rarely characterized (Table 3.9). Structural data are available for $Na_3Li_4Th_6F_{31}$ (Brunton and Sears, 1969), $KNaThF_6$ (Brunton, 1970), Li_2CaThF_8 (Vedrine *et al.*, 1973), $Na_3BeTh_{10}F_{45}$ (Brunton, 1973), and $Na_3ZnTh_6F_{29}$ (Cousson *et al.*, 1979b). $Na_3Li_4Th_6F_{31}$ has the same structure as $Na_7Th_6F_{31}$, with some of the Na^+ ions being substituted by Li^+. Similarly, the structure of $KNaThF_6$ is closely related to the structure of the potassium-only compound. Li_2CaThF_8 adopts the structure of $CaWO_4$, even if the symmetry is slightly different. The Li^+ ions occupy the tetrahedral positions of the tungsten atoms, while both Ca^{2+} and Th^{4+} are found on the calcium sites of $CaWO_4$. $Na_3BeTh_{10}F_{45}$ and $Na_3ZnTh_6F_{29}$ (Fig. 3.11) have crystal structures wherein the Th^{4+} ions are found mainly in an eight-fold coordination of fluoride ions (Brunton, 1973). The thorium polyhedra are linked in complicated three-dimensional networks

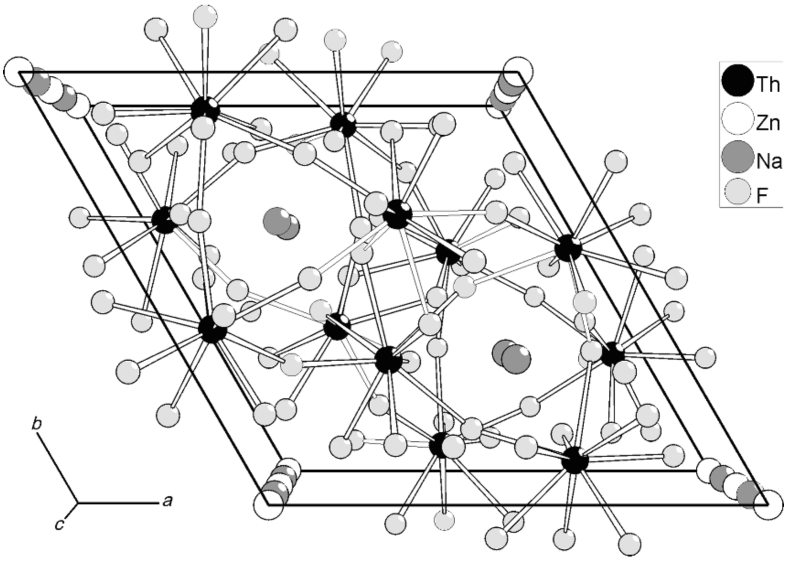

Fig. 3.11 *Crystal structure of the polynary $Na_3ZnTh_6F_{29}$.*

that incorporate the Na^+, Be^{2+}, and Zn^{2+} ions, respectively. The coordination number of the sodium ions range from six to eight. Be^{2+} is tetrahedrally coordinated, and Zn^{2+} is in the center of an octahedron.

Mixed chloride–fluorides, namely $LiThClF_4$, $CsTh_2ClF_8$, $SrThCl_2F_4$, and $BaThCl_2F_8$, have been reported but these compounds are in need of further characterization (Gudaitis *et al.*, 1972; Desyatnik *et al.*, 1974a,b).

Compared to the respective fluorides the number of well-characterized polynary thorium chlorides, bromides, or iodides is quite limited. According to phase diagram investigations containing $ThCl_4$, the compounds included in Table 3.8 are known to exist (Vdovenko *et al.*, 1974; Gershanovich and Suglobova, 1980). However, additional chlorides, which were not found in their respective phase diagrams, have been prepared by several authors (Rosenheim and Schilling, 1900; Rosenheim *et al.*, 1903; Chauvenet, 1911; Siegel, 1956; Ferraro, 1957; Adams *et al.*, 1963; Brown, 1966; Vokhmyakov *et al.*, 1973; Gorbunov *et al.*, 1974; Desyatnik and Emel'yanov, 1975). Unfortunately, the structure of only a few chlorides is known, all of them being exclusively hexachlorothorates containing the octahedral $[ThCl_6]^{2-}$ anion. Alkaline metal ions, Tl^+ and Cu^+, as well as divalent ions, for example Ba^{2+} or Pb^{2+}, may serve as counter-ions (Binnewies and Schäfer, 1973, 1974; Gorbunov *et al.*, 1974; Westland and Tarafder, 1983). Furthermore, alkyl ammonium ions can be used to crystallize the hexachlorothorate (Brown, 1966; Woodward and Ware, 1968). Occasionally, complex $[ThCl_5]^-$ and $[ThCl_7]^{3-}$ ions have been mentioned in the literature (Oyamada and Yoshida, 1975; Yoshida *et al.*, 1978). The enthalpies of formation of several thorium–alkali metal ternary chlorides have been reported. Experimental data on these chlorides, together with those on other actinide ternary halides are assembled and briefly discussed in Chapter 19.

Chloro compounds of thorium in which one or more chloride ions in $ThCl_4$ are replaced by other ligands have been prepared. These ligands can be trimethysilylamide, benzaldehyde, and methylsalicylate, for example (Bradley *et al.*, 1974).

The phase diagrams of $ThBr_4$ and the alkali metal bromides NaBr–CsBr show one compound to exist in each case (Ribas Bernat and Ramos Alonso, 1976; Ribas Bernat *et al.*, 1977; Gershanovich and Suglobova, 1981). For sodium, $NaThBr_5$ melts incongruently, and for the remaining alkali metals, the bromides A_2ThBr_6 ($A = K - Cs$) melt congruently. The structure of the equivalent sodium compound is not known, but for the compounds with heavier alkali metals, the lattice parameters have been derived from powder diffraction data. Although the data are not in entire agreement, it seems very likely that these compounds are (nearly) isotypic with the respective iodides and thus contain the octahedral $[ThBr_6]^{2-}$ anion. The same anion also occurs in the family of bromides, $AThBr_6$, with A being a divalent cation (cf. Table 3.9) (Beck and Kühn, 1995). An interesting exception is the unique crystal structure of In_2ThBr_6. It contains square antiprismatic $[ThBr_8]$ polyhedra that are linked in

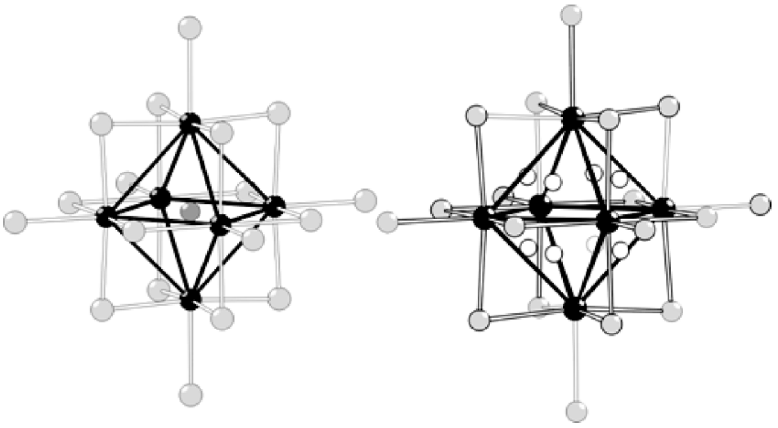

Fig. 3.12 *Octahedral* $[Th_6]$ *cluster in the crystal structures of* $Th_6Br_{15}Co$ *and* $Th_6Br_{14}H_7$*, respectively. The cobalt atom as well as the hydrogen atoms are stabilizing the cluster, which are surrounded by* 18 Br^- ions. *The hydrogen position are only occupied to* 7/8.

chains along [001] according to the formula $^1_\infty[ThBrF_{4/2}Br_{4/1}]$ via shared edges. The chains are held together by nine-fold coordinated In^+ ions (Dronskowski, 1995).

A series of reduced thorium bromides containing octahedral $[Th_6]$ clusters has been described recently. They have been prepared from $ThBr_4$ and thorium metal in the presence of either hydrogen, carbon, or a transition metal, leading to the compounds: MTh_6Br_{15} (M = Mn, Fe, Co, Ni), $Th_6Br_{14}C$, and $Th_6Br_{15}H_7$ (Böttcher *et al.*, 1991a,b). The transition metal and the carbon atom act as a stabilizing interstitial atom within the octahedron whereas the hydrogen atoms are located above the triangular faces of the empty octahedra. In each case, the $[Th_6]$ core is surrounded by 12 Br^- ions that are bridging the edges of the octahedron, and six additional anions attached to the vertices. The linkage of the $[(Th_6Br_{12})Br_6]$ units is different in $Th_6Br_{14}C$ compared to the metal-centered cubic phases, causing the slightly higher Th/Br ratio (Fig. 3.12). Another unique cluster compound is $KTh_{12}N_6Br_{29}$. It shows a core of six $[NTh_4]$ tetrahedra that are connected by sharing edges (Fig. 3.13) (Braun *et al.*, 1995).

Ternary iodides containing the octahedral $[ThI_6]^{2-}$ anion have been prepared with a number of different counter-cations, for example alkali metal ions, tetraalkyl ammonium ions, or $[As(C_6H_5)_4]^+$ (Bagnall *et al.*, 1965; Brown *et al.*, 1970a, 1976; Brendel *et al.*, 1985). The ThI_4/AI_2 systems with A being Ca, Sr, Sn, or Pb, have been investigated and for selected examples crystal structures have even been determined (Beck *et al.*, 1993). Ternary iodides have also been synthesized by the fusion of the binary iodides at elevated temperature with other divalent cations (Beck *et al.*, 1993). Finally, the mercury iodides $Hg_2ThI_8{\cdot}12H_2O$ and $Hg_5ThI_{14}{\cdot}18H_2O$ have been reported (Duboin, 1909a).

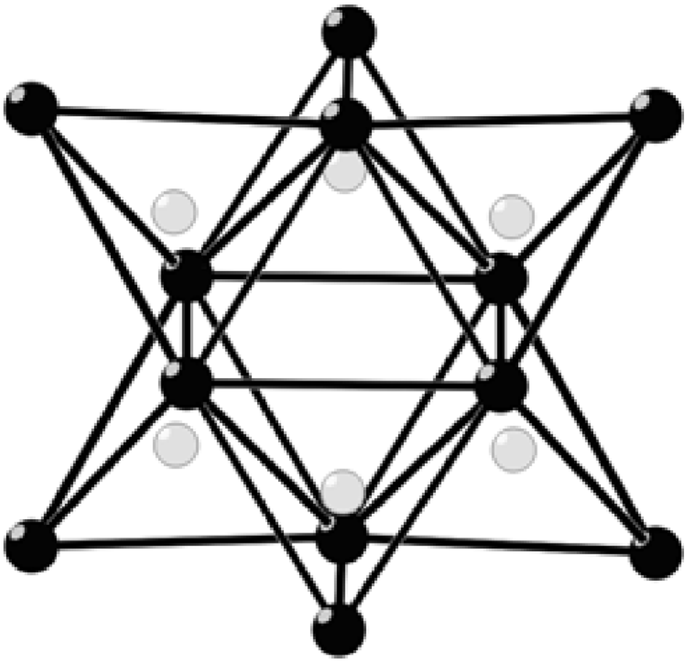

Fig. 3.13 [$Th_{12}N_6$] *core in the crystal structure of* $KTh_{12}N_6Br_{29}$. The unit consists of six linked [NTh_4] *tetrahedra. It might also be seen as an* [Th_6] *octahedron whith four of the six triangular faces capped by an additional thorium atom.*

3.7.5 Chalcogenides

The heavier analogs of oxides, the chalcogenides S, Se, and Te, all form compounds with thorium (Table 3.6). While some are based on simple crystal structures such as fluorite or NaCl, the richness of the electronic structures of sulfur, selenium, and tellurium lend themselves to forming more complex structures than the oxides. Binary thorium sulfur compounds can be prepared by the action of H_2S on the metal (Berzelius, 1829; Nilson, 1876; Moissan and Étard, 1896, 1897), the metal halide (Krüss and Volck, 1894; Duboin, 1908b), the metal hydride (Eastman *et al.*, 1950; Lipkind and Newton, 1952), or on thoria itself in the presence of carbon (Eastman *et al.*, 1950). Sulfur will react at elevated temperatures with the metal or thorium carbide and CS_2 with thoria will also form the binary sulfides. There are six generally recognized structurally characterized sulfides (including ThOS, which is not isostructural with ThS_2 or ThO_2) listed in Table 3.6 (Shalek, 1963). The sulfide with the lowest sulfur content (Khan and Peterson, 1976), ThS, stands out against ThO as not being like ZnS but rather forming the NaCl structure type (Zachariasen, 1949c). However, as mentioned earlier, the characterization of ThO remains a puzzle. ThS is metallic in appearance with a density of 9.56 g cm^{-3}. The compound sinters above 1950°C with no appreciable vapor pressure above its melting point (2200°C). The compound can be machined or polished and becomes superconducting near 0.5 K (Moodenbaugh *et al.*, 1978). The disulfide of thorium, ThS_2, is a purple-brown solid with the $PbCl_2$ structure and a density of 7.36 g cm^{-3}. It is reported to melt at 1905°C with considerable decomposition starting at 1500°C (Eastman *et al.*, 1950, 1951). Heating the disulfide in vacuum will yield a black phase, Th_7S_{12}, which melts around 1770°C (Zachariasen, 1949d; Eastman *et al.*, 1950, 1951). This compound has been mislabeled as Th_4S_7. The sesquisulfide is a brown-metallic phase, isotypic with stibnite, Sb_2S_3 (Zachariasen, 1949c). This phase also melts with no appreciable vapor pressure at high temperatures (2000°C), making it a useful high-temperature crucible material. An orange-brown material has been prepared via a lower-temperature reaction (400°C) between thorium metal and sulfur or between the hydride and excess H_2S. A 'polysulfide' phase was first identified as Th_3S_7 (Strotzer and Zumbusch, 1941) and later found (Graham and McTaggart, 1960) to evolve sulfur around 150°C to yield Th_2S_5, of tetragonal structure, although more recent studies found that it is correctly reported in the orthorhombic cell (Noël and Potel, 1982). ThOS, a yellow phase prepared from the action of thoria and CS_2 or thoria and sulfur (Krüss, 1894; Heindl and Loriers, 1974), forms in the PbFCl structure type, analogous with the rare earth series of compounds (Zachariasen, 1949c). ThOS hydrolyzes in acid solutions as do all the other binary sulfides of thorium (Dubrovskaya, 1971).

Selenium and tellurium form a series of compounds with thorium that are homologs of the sulfides. These compounds, listed in Table 3.6, are ThOSe, ThSe, Th_7Se_{12}, Th_2Se_3, $ThSe_2$, Th_2Se_5, and $ThSe_3$ (D'Eye *et al.*, 1952; D'Eye, 1953; Graham and McTaggart, 1960; Noël, 1980; Kohlmann and Beck, 1999). These phases have all been obtained by the reaction of selenium on thorium metal (D'Eye *et al.*, 1952) on the carbide, the halide, or the silicide of thorium (Moissan and Martinsen, 1905). Thorium selenides have also been produced by the reaction of hydrogen selenide gas on thorium bromide (Moissan and Martinsen, 1905). It has been reported that ThSe becomes superconducting at 1.6 K (Moodenbaugh, 1978), in contrast to earlier observations (Bucher and Staundenmann, 1968). A selenium analog to the polysulfide phase may be Th_7Se_{12} (D'Eye, 1953) or Th_2Se_5 (Graham and McTaggart, 1960). Another reported polyselenide is $ThSe_3$ (Noël and Potel, 1982), which is isotypic with USe_3 (Ben Salem *et al.*, 1984). Finally, the reaction of selenium with thoria yields ThOSe (D'Eye, 1953).

The tellurides of thorium exist in phases of similar stoichiometry but with slightly differing structures from those of the sulfides or selenides. For example, ThTe is found in the CsCl structure rather than the NaCl-type (D'Eye and Sellman, 1954). Several conflicting reports exist about the identity of a higher telluride, Th_3Te_8, although it has been confirmed to be $ThTe_3$, in a structure type analogous to the low-dimensional $ZrSe_3$-type (Graham and McTaggart, 1960). This same report also suggests that $ThTe_2$ is hexagonal rather than orthorhombic as in the $PbCl_2$-type found for $ThSe_2$. Recently, the missing link in the series, Th_7Te_{12}, was prepared and characterized as isostructural with the selenide (Tougait *et al.*, 1998). An early report on 'Th_3Te' has not been confirmed up to now and seems to be not very reliable (Montignie, 1947).

During the past decade, a series of interesting ternary and quaternary thorium chalcogenide phases have been prepared (Cody and Ibers, 1996; Wu *et al.*, 1997; Tougait *et al.*, 1998; Narducci and Ibers, 1998a,b, 2000; Choi *et al.*, 1998; Briggs-Piccoli *et al.*, 2000, 2001, 2002; Hess *et al.*, 2001). The series of layered tellurides and selenides of thorium, ATh_2Te_6, are based on the sesquiselenide or telluride structure type that has been, in effect, pried apart, reduced, and intercalated by an alkali metal (Cody and Ibers, 1996; Wu *et al.*, 1997; Tougait *et al.*, 1998). The review by Narducci and Ibers describes these reactions in detail (1998a). Indeed, a series of related transition metal compounds such as $KCuThSe_3$, $CuTh_2Te_6$, and $SrTh_2Se_5$ have been prepared from the action of tellurium or selenium, or their alkali metal salts, on thorium metal (Narducci and Ibers, 1998a, 2000).

Attempts were also made to prepare chalcophosphate analogs of the thorium phosphates discussed in Section 3.7.7e. The unique chemistry of thiophosphates and selenophosphates provided a rich set of compounds from homoleptic clusters of $[Th_2(PS_4)_6]^{10-}$ (Briggs-Piccoli *et al.*, 2002) to complex three-dimensional phases with a unique $(P_2Se_9)^{6-}$ anion building block in $Cs_4Th_4P_4Se_{26}$ (Briggs-Piccoli *et al.*, 2001).

3.7.6 Pnictides

The nitride of thorium, Th_3N_4, can be prepared by a variety of methods (Gmelin, 1987). One is the strong heating of the metal in the presence of N_2. At the turn of the last century, there was significant debate about the composition and color (chestnut, citron yellow, maroon, and black) of the thorium nitride that could be obtained by heating the metal in presence of N_2 (Matignon and Delepine, 1907; Düsing and Hüniger, 1931). The debate lingered into the 1960s and the variations in color have been attributed to vacancies in nitrogen and oxygen impurities. Indeed, the tan-colored Th_2N_3 is actually Th_2N_2O (Aronson and Auskern, 1966; Benz and Zachariasen, 1966). The golden yellow ThN (Chiotti, 1952; Olson and Mulford, 1965) may likely be seen as a thin layer on the surface of Th_3N_4 as it is the thermally stable product of all decomposition reactions of the other thorium nitrides (Aronson and Auskern, 1966). ThN displays metallic character when prepared as a thin film (Gouder *et al.*, 2002). The ThN phase is isotypic with all other actinide mononitrides and has the NaCl fcc structure (Auskern and Aronson, 1967; Benz *et al.*, 1967). ThN is a superconductor at low temperatures with an inverse dependence of pressure on the critical temperature (Dietrich, 1974).

The synthesis of the binary nitrides listed in Table 3.10 can be achieved most easily by the action of ammonia or nitrogen on heated thorium hydride

Table 3.10 *Crystallographic data of thorium pnictides.*

		Lattice parameters

(Katzin, 1983). Metal powder heated in nitrogen will yield the nitrides; in the presence of ammonia, a hydride intermediate can be formed (Juza and Gerke, 1968). These hydrogen-containing species might be nitride-imides, nitride-amides, or pure amides of thorium, as investigations of the system Th–N–H have shown. Thoria treated with carbon and heated in a nitrogen atmosphere will also yield nitrides where a finely divided metal powder can be seen as an intermediate.

The reaction of binary nitrides with thorium halides leads to the halide nitrides ThNX (X = F, Cl, Br, I). They have been shown to adopt the BiOCl-type of structure (Juza and Sievers, 1968; Blunck and Juza, 1974). Complex metal nitrides such as Th_2NOP can be prepared by heating binary nitrides with thoria and thorium phosphides (Benz and Zachariasen, 1969; Barker and Alexander, 1974). Heating the nitrides in oxygen generally yields thoria as the product and the nitrides are moisture-sensitive. Several complex mixtures of double salts have been prepared recently, namely $Ca_xTh_{3-x}\,N_{4-2x}O_{2x}$, $Sr_xTh_{3-x}\,N_{4-2x}O_{2x}$, and $Sr_xTh_{1-x}N_xO_{1-x}$ (Brese and DiSalvo, 1995a). Ternary nitrides are the lithium compound Li_2ThN_2 (Palisaar and Juza, 1971) as well as the very unique nitride perovskite phase, $TaThN_3$ (Brese and DiSalvo, 1995b).

This latter cubic perovskite was prepared by the action of Ta_3N_5 and Th_3N_4 at 1400°C as well as by the reaction of $Ta_2Th_2O_9$ and Ca_3N_2 at 1500°C.

The heavier pnictide analogs all form similar binary phases to the nitride that have been characterized by single crystal XRD analysis except for ThBi that is conspicuously absent (Ferro, 1957). Analogously to ThN, ThP, ThAs, and ThSb adopt the fcc NaCl structure (Ferro, 1955, 1956; Gingerich and Wilson, 1965; Javorsky and Benz, 1967; Baskin, 1969). The same structure has been reported for all of the actinide and lanthanide mononitrides and pnictides, respectively. Interestingly, the lattice constant has been shown to decrease when going from Th to U, then to increase through Cm, and finally to decrease again (Lam *et al.*, 1974; Damien and de Novion, 1981) (Fig. 3.14).

Adachi and Imoto reported that the cubic ThP could be made as ThP_{1-x} where x varied from 0 to 0.6. This behavior dramatically affected the hardness of the phase as well as its conductivity (Adachi and Imoto, 1968). Indeed, at 1200°C, the phase ranges from $ThP_{0.4}$ to $ThP_{0.6}$. The non-stoichiometric phases show a weak paramagnetism and the room temperature resistivity of the metallic ThP decreased with an increasing P/Th ratio for the ThP_{1-x} phases. ThP forms a solid solution with UP and displays an antiferromagnetic phase transition at 23 K with up to 40% ThP (Adachi *et al.*, 1973). ThP undergoes a

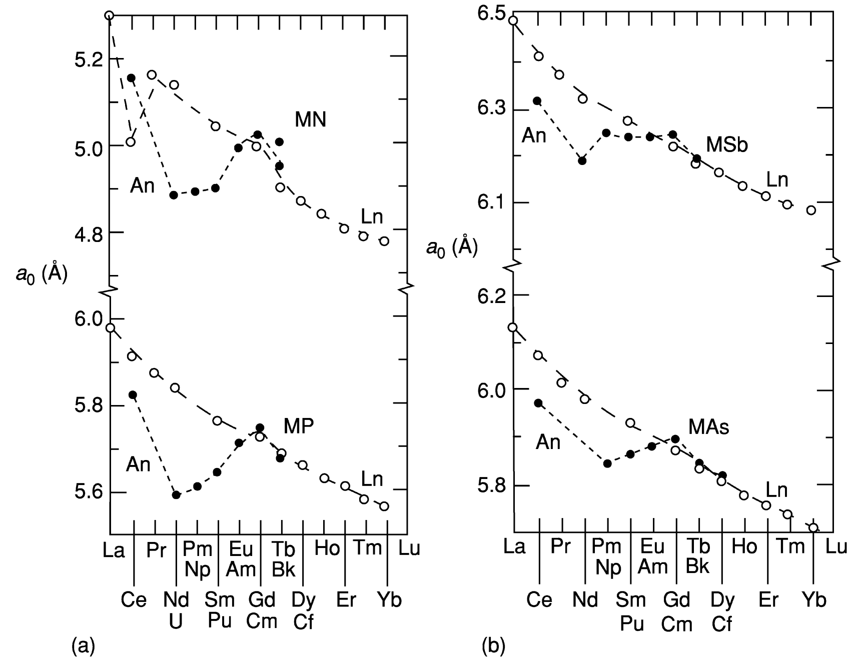

Fig. 3.14 *Lattice constants of actinide and lanthanide monopnicnitides: mononitrides and monophosphides (a); monoantimonides and monoarsenides (b) (Damien and de Novion, 1981).*

structural phase transition from the NaCl-type to the CsCl-type at 30 GPa (Staun Olsen *et al.*, 1988). The reaction between Th and Th_3P_4 at 1100°C will yield ThP (Gingerich and Wilson, 1965; Gingerich and Aronson, 1966; Javorsky and Benz, 1967). Th_3P_4 can be made by the direct combination of the elements (Gingerich and Wilson, 1965; Price and Warren, 1965), by heating $ThCl_4$ with phosphorus vapors (Moissan and Martinsen, 1905), and by the reaction of the hydride with phosphine gas (Lipkind and Newton, 1952). This phase of phosphide is a dark gray material, unlike the black ThP, and is unreactive in water. It releases phosphine upon action by acids and can be ignited to thorium phosphate by heating in air (Strotzer *et al.*, 1938; Meisel, 1939). Th_3P_4 is an n-type semiconductor with a band gap of 0.4 eV (Henkie *et al.*, 1976; Suzuki *et al.*, 1982). A very unique, phosphorus-rich Zintl phase was prepared by the action of phosphorus on thorium metal at 1040°C, yielding Th_2P_{11} (von Schnering *et al.*, 1980). This phase comprises chains of phosphorus atoms linked into two-dimensional nets comprising open and closed P_6 rings. This black, semiconducting phase (band gap of 0.3 eV) decomposes to Th_3P_4 upon heating to 1040°C in vacuum. Other complex ternary phosphides are known including $Th_5Fe_{19}P_{12}$, $ThFe_4P_2$, and $Th_2Mn_{12}P_7$ (Albering and Jeitschko, 1992; Jeitschko *et al.*, 1993). Finally, a dense, magnetoresistive skutterudite phase can be prepared from the elements to yield $ThFe_4P_{12}$ (Dordevic *et al.*, 1999).

In the thorium–arsenic system, ThAs and Th_3As_4 are black-gray compounds that are isomorphous with the associated phosphides and nitrides (Benz, 1968). Th_3As_4 is an n-type semiconductor with a band gap of 0.43 eV (Ferro, 1955; Warren and Price, 1964; Henkie and Markowski, 1978). In contrast to the Th–P system, a diarsenide, $ThAs_2$, is formed, which displays two modifications: a low-temperature phase (α), with the PbCl structure and a high-temperature phase (β) with the Fe_2As structure (Ferro, 1955; Hulliger, 1966). More complex mixtures of ThAs and ThS or ThSe have yielded compounds such as ThAsSe that display unique anomalous Kondo-like behavior (Henkie and Wawryk, 2002). Thorium antimony compounds form in the same structures as the arsenides, with ThSb, Th_3Sb_4, and $ThSb_2$ (Ferro, 1956; Hulliger, 1966, Chiotti *et al.*, 1981). Like the arsenide, ThSb undergoes a high-pressure phase transition from NaCl to the CsCl-type (Palanivel *et al.*, 1995). Kondo-like resistivity behavior was observed for solid solutions of USb and ThSb. The dilution of USb by ThSb lead to large modifications of the electrical transport properties, reflecting the change from antiferromagnetism to ferromagnetism with a concomitant decrease of the ordered magnetic moment per U atom (Frick *et al.*, 1982). In the thorium–bismuth system, three binary compounds with familiar structures are found: ThBi, $ThBi_2$, and Th_3Bi_4 (Ferro, 1957; Dahlke *et al.*, 1969). ThBi was reported as part of an alloy structure although a single crystal structure has not been determined (Borzone *et al.*, 1982). Another phase with the Mn_5Si_3-type was observed as well but was not confirmed by elemental analysis (Borzone *et al.*, 1982). Bismuth can be distilled from ThBi, yielding the thorium-rich Th_5Bi_3 hexagonal structure. During the U.S. breeder reactor program of the mid–1950s, breeder-blanket liquid Bi with a slurry of $ThBi_2$ suspended in the liquid bismuth showed promise but there was significant difficulty in suspending the inhomogeneous particles of $ThBi_2$ (Bryner and Brodsky, 1959).

3.7.7 Complex anions

Thorium compounds with complex anions play an important role in various fields, for example in separation techniques (cf. Section 3.4) and nuclear waste disposal, to name only two of them. Thus, this chemistry has been widely investigated, although often not in very detail, what is especially true with respect to structural characterizations. In the following the most important and more recent findings are summarized. For each complex anion an extra subdivision has been created and reliable crystallograhic data are presented in Table 3.11.

(a) Perchlorates

Thorium perchlorate is highly soluble in water and crystallizes, generally from acidic solution, in the form of the tetrahydrate $Th(ClO_4)_4{\cdot}4H_2O$ (Murthy and Patel, 1965). The structure of the tetrahydrate is not known, but the compound has been shown to decompose at 280°C to form $ThO(ClO_4)_2$ that finally forms ThO_2 at 335°C (Murthy and Patel, 1965). The oxide–perchlorate apparently will dissolve in water, and from XRD this is interpreted to be due to the formation of a tetrameric species (Bacon and Brown, 1969). An elegant (but somewhat dangerous) route to prepare anhydrous $Th(ClO_4)_4$ is the reaction of $ThCl_4$ with Cl_2O_6 (Koulkès-Pujo *et al.*, 1982). From X-ray powder diffraction, an orthorhombic lattice has been deduced with the space group probably being $P2_12_12$ (Ramamurthy and Patel, 1963). Due to the weak coordination tendency of the ClO_4^- ion, $Th(ClO_4)_4$ is frequently used to prepare coordination compounds of thorium in which the perchlorate anion in not included in the coordination sphere (Gmelin, 1985b, 1993a).

(b) Sulfates (VI, IV)

A detailed discussion of the older literature on thorium sulfates has been given by Mellor (1941). Thorium sulfates can be prepared by the reaction of various thorium salts, for example thorium nitrate, with concentrated sulfuric acid. Upon crystallization from aqueous solution, different hydrates can be obtained. At lower temperatures (0–45°C), $Th(SO_4)_2{\cdot}9H_2O$ has the lowest solubility (Clève, 1874; Roozeboom, 1890; Dawson and Williams, 1899). Nevertheless, the octahydrate is usually obtained even under these conditions (Clève, 1874; Krüss and Nilson, 1887b; Roozeboom, 1890; Koppel and Holtkamp, 1910). Furthermore, a hexahydrate has been mentioned and at higher temperature,

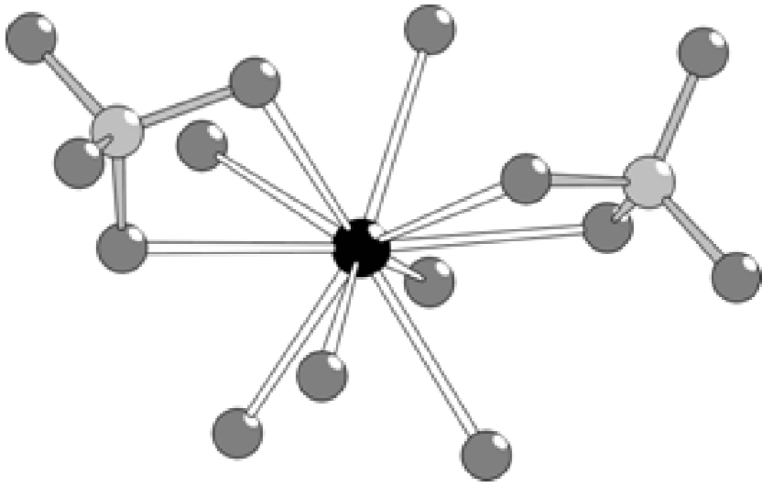

Fig. 3.15 *The* $[Th(SO_4)_2(H_2O)_6]$ *molecule in the crystal structure of* $Th(SO_4)_2{\cdot}8H_2O$.

a tetrahydrate is said to form (Roozeboom, 1890; Dawson and Williams, 1899; Wirth, 1912). A dihydrate was observed as an intermediate of the dehydration of higher hydrates (Rollefson, 1947) and $Th(SO_4)_2{\cdot}8H_2O$ has been structurally characterized (Fig. 3.15). It shows the Th^{4+} ions in a ten-fold coordination by oxygen atoms, which belong to six water molecules and two chelating sulfate ions. The coordination polyhedron is a distorted bicapped squared antiprism. The crystal structure is completed by two crystal water molecules (Habash and Smith, 1983).

The formation of basic thorium sulfates has also been frequently observed but these compounds are not well characterized (Krüss and Nilson, 1887b; Wyrouboff and Verneuil, 1898b, 1899; Meyer and Gumperz, 1905). $ThOSO_4$ has been reported to form upon dehydration of $ThOSO_4{\cdot}3H_2O$ but none of these compounds has been further investigated (Wyrouboff, 1901; Wöhler *et al.*, 1908; Hauser and Wirth, 1908; Barre, 1910, 1911; Halla, 1912). The structure is known only for $Th(OH)_2SO_4$, which has been thought to be $ThOSO_4{\cdot}H_2O$ (Lundgren, 1950). The thorium ions are connected as dimers by two OH^- ions. The coordination sphere of Th^{4+} is completed by four monodentate sulfate groups and the dimeric $[Th_2(OH)_2(SO_4)_8]$ units are linked into a three-dimensional network.

Various polynary sulfates containing alkali metals are thought to exist (Colani, 1909; Barre, 1912). The phase diagram of $Na_2SO_4/Th(SO_4)_2$ has been determined recently wherein the compound $Na_{12}Th(SO_4)_8$ is found (Fedorov and Fedorov, 2001). Solid state reactions of ThO_2 with $KHSO_4$, $K_2S_2O_8$, and $K_2S_2O_7$ afforded $K_4Th(SO_4)_4$ (Keskar *et al.*, 2000). Also the reactions of ThO_2 with $(NH_4)_2SO_4$, and mixtures of $(NH_4)_2SO_4$ with NH_4NO_3 or NH_4HF, have been studied (Singh Mudher *et al.*, 1995). Furthermore, the rubidium compound, $Rb_2Th(SO_4)_3$, has been synthesized. Despite these investigations no structural data of the anhydrous species have been reported until now. A little more information is available for the hydrated polynary sulfates (Cleve, 1874; Manuelli and Gasparinetti, 1902; Rosenheim *et al.*, 1903; Barre, 1910, 1911). According to very old data, they may contain alkali and thorium metal ions in a ratio of 1:1, 2:1, 3:1, and 4:1, but newer investigations determined the compositions as $A_2Th(SO_4)_3 \cdot xH_2O$ and $A_4Th(SO_4)_4 \cdot xH_2O$ (A = Na–Cs, NH_4) (Gmelin, 1986b), where the water content x varies from 2 to 6. Additionally, $M_6Th(SO_4)_5 \cdot 3H_2O$ (M = Cs, NH_4) and $(NH_4)_8Th(SO_4)_6 \cdot 2H_2O$ are known (Gmelin, 1986b). For several compounds, infrared spectroscopy (IR) data are available (Evstaf'eva *et al.*, 1966) and structure determinations have been done for $Na_2Th(SO_4)_3 \cdot 6H_2O$ (Habash and Smith, 1990), $Cs_2Th(SO_4)_3 \cdot 2H_2O$ (Habash and Smith, 1992), and $K_4Th(SO_4)_4 \cdot 2H_2O$ (Arutyunyan *et al.*, 1963). The sodium compound exhibits chains of ${}^{1}_{\infty}[Th(H_2O)_{3/1}(SO_4)_{6/2}]$ running along [100] in which the Th^{4+} ions are surrounded by six monodentate SO_4^{2-} ions and three H_2O molecules to form a tricapped trigonal prism. The chains are linked by the Na^+ ions and three non-coordinating water molecules are found in the unit cell. In $Cs_2Th(SO_4)_3 \cdot 2H_2O$ the $[Th(H_2O)_2(SO_4)_5]$ polyhedra are linked to layers according to ${}^{2}_{\infty}[Th(H_2O)_2(SO_4)_{4/2}(SO_4)_{1/1}]$ that are connected by the Cs^+ ions. For the Th^{4+} ions a coordination number of nine arises due to the chelating nature of two of the SO_4^{2-} groups. In $K_4Th(SO_4)_4 \cdot 2H_2O$ zigzag chains are found with the formula ${}^{1}_{\infty}[Th(H_2O)_{2/1}(SO_4)_{4/2}(SO_4)_{2/1}]$. One of the SO_4^{2-} ions acts as chelating ligand leading to a coordination number of 9 for Th^{4+}.

Thorium sulfates containing other counter-cations besides alkali metals are rarely described. They include the manganese compound $MnTh(SO_4)_3 \cdot 7H_2O$ that was obtained from an aqueous solution of the binary sulfates at 30°C, the tin compound, $Sn_2Th(SO_4)_4 \cdot 2H_2O$ (Weinland and Kühl, 1907), and the poorly characterized thallium sulfates (Fernandes, 1925). Finally, the organic guanidinium ion has been used for the precipitation of thorium sulfato complexes (Molodkin *et al.*, 1964).

With $Th(SO_3F)_4$, one fluorosulfate of thorium has been synthesized by the reaction of HSO_3F with thorium acetate. According to IR measurements the anions act as bidentate ligands. The thermal decomposition of the compound yields SO_2F_2 and $Th(SO_4)_2$ (Paul *et al.*, 1981).

Thorium sulfate (IV), $Th(SO_3)_2 \cdot xH_2O$, is said to form as a white precipitate when SO_2 is passed through a solution containing Th^{4+} ions or when an alkali metal sulfite is added (Clève, 1874; Chavastelon, 1900; Baskerville, 1901; Grossmann, 1905). Based on differential thermal analysis (DTA) investigations, the water content x is believed to be four (Golovnya *et al.*, 1967a,b). Hydrolysis of the thorium sulfites or their thermal decomposition leads to basic compounds with different compositions (Golovnya *et al.*, 1964, 1967a). Furthermore, various ternary sulfites containing alkali metal ions or the ammonium ion have been mentioned, but a more precise characterization is needed for these compounds

(Chavastelon, 1900; Golovnya *et al.*, 1967b,c). A number of organic solvates of thorium sulfites are reported, but again, further characterization is still needed (Golovnya *et al.*, 1967b).

(c) Nitrates

Nitrates of thorium may be prepared by dissolving $Th(OH)_4$ in nitric acid. Depending on the concentration of the acid, three different hydrates form upon evaporation. If the acid concentration is in the range between 1 and 54%, a pentahydrate crystallizes while a tetrahydrate is obtained at concentrations up to 75% (Ferraro *et al.*, 1954). Both hydrates have molecular structures. The tetrahydrate contains $[Th(NO_3)_4(H_2O)_4]$ molecules with all of the nitrate groups being attached in a chelating manner to the Th^{4+} ions, leading to a coordination number of 12 (Charpin *et al.*, 1987). In the non-centrosymmetric pentahydrate, $Th(NO_3)_4 \cdot 5H_2O$, there are also four chelating nitrate groups around Th^{4+} but only three additional H_2O molecules, yielding a coordination number of 11. The remaining water molecules are held via hydrogen bonds in the structure so that the compound has to be formulated according to $[Th(NO_3)_4(H_2O)_3] \cdot 2H_2O$ (Ueki *et al.*, 1966). The structure of the pentahydrate has also been determined by neutron diffraction so that exact hydrogen positions are known (Taylor *et al.*, 1966). Furthermore, thermodynamic data have been provided for the pentahydrate (Ferraro *et al.*, 1956; Cheda *et al.*, 1976; Morss and McCue, 1976).

From nearly neutral solutions, a hexahydrate was said to crystallize (Fuhse, 1897; Misciatelli, 1930a,b). Unfortunately it has not been structurally characterized and due to the well-known tendency of Th^{4+} compounds to hydrolyze, it might be possible that the hexahydrate is in fact a basic species. With $ThOH(NO_3)_3 \cdot 4H_2O$, another basic nitrate is known (Johansson, 1968a,b). As seen in Fig. 3.16, it contains the dimers $[Th_2(OH)_2(NO_3)_6(H_2O)_6]$, with the Th^{4+} ions in an 11-fold coordination by three H_2O molecules, two hydroxide ions, and three chelating nitrate groups. The dimers are arranged in the lattice with additional crystal water molecules. The thermal decomposition of thorium nitrate hydrates leads to ThO_2. According to DTA and thermogravimetry (TG) measurements, various intermediates can be observed (Tiwari and Sinha, 1980). Acidic thorium nitrates have been reported, for example $H_2Th(NO_3)_6{\cdot}3H_2O$, but unfortunately they have not been characterized (Moseley *et al.*, 1971). Also $Th(NO_3)_4{\cdot}2N_2O_5$, which is said to form in highly concentrated HNO_3, has not been investigated further (Kolb, 1913; Misciatelli, 1930a,b; Ferraro *et al.*, 1954, 1955).

Thorium nitrate is well soluble in water and various oxygen-containing organic solvents such as alcohols, ketones, ethers, and esters (Imre, 1927; Misciatelli, 1929; Templeton and Hall, 1947; Rothschild *et al.*, 1948; Yaffe, 1949; Bock and Bock, 1950). The solid solvate $Th(NO_3)_4 \cdot 3H_2O \cdot 3C_2H_5OCH_2CH_2OC_2H_5$ has been crystallized from a solution of thorium

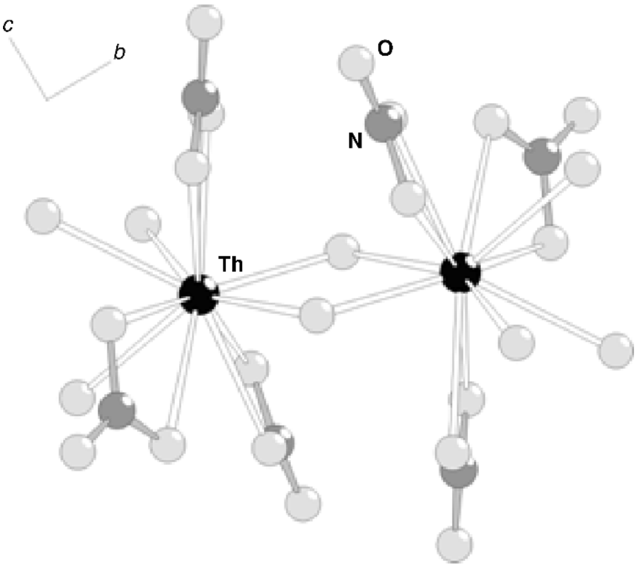

Fig. 3.16 *The dimeric unit* $[Th_2(OH)_2(NO_3)_6(H_2O)_6]$ *in the crystal structure of* $ThOH(NO_3)_3{\cdot}4H_2O$.

nitrate in the diethylether of ethyleneglycol (Katzin, 1948), and compounds with a variety of nitrogen bases in place of water are known (Kolb *et al.*, 1908; Kolb, 1913). It is possible to extract thorium nitrate from aqueous solution with an immiscible organic solvent if the aqueous phase is extremely concentrated, or if it contains high concentrations of ammonium nitrate (Templeton and Hall, 1947; Rothschild *et al.*, 1948; Hyde and Wolf, 1952; Newton *et al.*, 1952b). Since the rare earth metal ions do not extract well under the same conditions, being almost totally restricted to the aqueous phase, the procedure finds application in the preparation of pure thorium salts from ores containing rare earth elements.

A particularly useful liquid extractant is tri(*n*-butyl)phosphate (TBP) (Warf, 1949; Anderson, 1950), as well as other phosphate esters (Peppard, 1966, 1971; Shoun and McDowell, 1980). These compounds differ from ordinary nucleophilic solvents in that they interact specifically with the metal ion through the oxygen atom of the phosphoryl group to form a very strong solvation bond. In the case of thorium nitrate, this results in the formation of very stable complexes in the organic phase, with two and three molecules of phosphate per molecule of thorium nitrate (Katzin *et al.*, 1956). The TBP adduct is stable even against considerable dilution with 'inert' fluids such as benzene, CCl_4, or aliphatic hydrocarbons, which are themselves not solvents for thorium nitrate (Anderson, 1950; Katzin *et al.*, 1956). The coordination interaction of Th^{4+} in aqueous solution with phosphate esters is the basis of an important commercial process for the extraction and purification of thorium. Normally, addition of ammonia to the aqueous phase causes the formation of hydroxo complexes that reduce the efficiency of the thorium nitrate extraction. If this is coupled with addition of a neutral salting agent such as lithium nitrate, it is found that extraction is enhanced by formation of a hydroxynitrate of thorium. The polymeric complex has been formulated as $[Th_4(OH)_{10}(NO_3)_6(TBP)_4]$, thus contains one tri(*n*-butyl)phosphate molecule per thorium atom in contrast to the monomeric unhydrolyzed thorium nitrate complex (Klyuchnikov *et al.*, 1972). Thorium nitrate forms 1:1 or 1:2 complexes with crown ethers, depending on the size of the crown (Zhou *et al.*, 1981; Rozen *et al.*, 1982; Wang *et al.*, 1982). These can also be used as extractants (Wang *et al.*, 1983).

Organic donor molecules such as butylamine, dimethylamine, aromatic amine *N*-oxides, and others have been frequently used to prepare complexes with thorium nitrate (Rickard and Woolard, 1978). A compound with trimethylphosphine oxide, $Th(NO_3)_4 \cdot 3/8(Me_3PO)$, has been crystallographically characterized (Alcock *et al.*, 1978). It contains $[Th(NO_3)_3(Me_3PO)]^+$ cations and $[Th(NO_3)_6]^{2-}$ anions, a structural feature that is frequently displayed by transition metal–halide complexes (Katzin, 1966).

A number of ternary thorium nitrates with mono or divalent counter-cations are known (Jacoby, 1901; Meyer and Jacoby, 1901; Sachs, 1901). Those of the type $A_2Th(NO_3)_6$ contains the complex anion $[Th(NO_3)_6]^{2-}$ that shows the Th^{4+} ion in 12-fold coordination by oxygen atoms (Spirlet *et al.*, 1992). The latter contains six chelating nitrate groups, as it was shown from the structure determination of the ammonium compound. The same complex anion is found in the nitrates $BTh(NO_3)_6 \cdot 8H_2O$ with B = Mg, Mn, Co, Ni, Zn (Geipel, 1992). In this case, the counter-ions are octahedral $[B(H_2O)_6]^{2+}$ complexes according to the formulation $[B(H_2O)_6][Th(NO_3)_6] \cdot 2H_2O$ (Scavnicar and Prodic, 1965). Another series of ternary nitrates with monovalent cations includes members of the composition $ATh(NO_3)_5{\cdot}xH_2O$, with A = NH_4, Na, K. They have not been fully characterized, so the amount of crystal water is not known (Meyer and Jacoby, 1901; Molodkin *et al.*, 1971; Volkov *et al.*, 1974). Furthermore, the nitrates $K_3Th(NO_3)_7$ and $K_3H_3Th(NO_3)_{10}{\cdot}4H_2O$ have been reported, but again structural data are not known (Meyer and Jacoby, 1901; Molodkin *et al.*, 1971).

(d) Carbonates

Thorium hydroxide absorbs CO_2 readily (Berzelius, 1829; Chydenius, 1863; Clève, 1885; Chauvenet, 1911), where the end product is the hydrated $ThOCO_3$, and finally $Th(CO_3)_2{\cdot}0.5H_2O$ under high CO_2 pressures. The composition of this latter product has also been given as $Th(OH)_2CO_3{\cdot}2H_2O$ (Kharitonov *et al.*, 1969). Hydrates of the oxycarbonate are also produced by the action of sodium or ammonium carbonate on a solution of a thorium salt. The carbonate is somewhat soluble in excess alkali carbonate solution (Clève, 1885) because of the formation of complexes strong enough to prevent precipitation of thorium by ammonia, fluoride, or phosphate. Sodium hydroxide, however, will bring about precipitation (Sollman and Brown, 1907). The nature of the carbonato complexes (Dervin and Faucherre, 1973a,b; Shetty *et al.*, 1976) will be discussed in more detail in Section 3.8. Crystallization of these complexes is possible using various counter-cations, and compounds with Na^+, K^+, Tl^+, NH_4+, $(HGua)^+$ (guanidinium), Ca^{2+}, Ba^{2+}, and $[Co(NH_3)_6]^{3+}$ have been reported (Clève, 1874; Rosenheim *et al.*, 1903; Canneri, 1925; Rosenheim and Kelmy, 1932; Chernyaev *et al.*, 1958; Kharitonov *et al.*, 1969; Ueno and Hoshi, 1970; Dervin and Faucherre, 1973b; Dervin *et al.*, 1973; Voliotis and Rimsky, 1975, 1988). All of the salts are hydrated and the sodium compound, $Na_6Th(CO_3)_5 \cdot xH_2O$, has been reported to occur with a considerable range of hydration. In the crystal structures of $Na_6Th(CO_3)_5 \cdot 12H_2O$ and $[C(NH_2)_3]_6Th(CO_3)_5{\cdot}4H_2O$, the Th^{4+} ions are in ten-fold coordination by oxygen atoms (Voliotis *et al.*, 1977). In the mineral tuliokite, $Na_6BaTh(CO_3)_6 \cdot 6H_2O$, six chelating carbonate groups are attached to the Th^{4+} ion leading to a $[ThO_{12}]$ icosahedron (Yamnova *et al.*, 1990). Carbonates containing additional anions have been reported, for example $Na_5Th(CO_3)_4OH \cdot 9H_2O$, $Na_4Th(CO_3)_4 \cdot 7H_2O$, $(HGua)_4Th(CO_3)_4 \cdot 6H_2O$, $(HGua)_2Th(CO_3)_3 \cdot 5H_2O$, $K_3Th(CO_3)_3(OH) \cdot 5H_2O$, $(NH_4)_2Th(CO_3)_3 \cdot 6H_2O$, $Na_2Th(CO_3)_2(OH)_2 \cdot 10H_2O$, $K_2Th(CO_3)_2(OH)_2 \cdot 10H_2O$, and the fluoride carbonate $(HGua)_5Th(CO_3)_3F_3$ (Voliotis, 1979).

(e) Phosphates

Phosphates of thorium have been investigated for many years (Troost and Ouvrard, 1885; Johnson, 1889; Kauffmann, 1899; Hecht, 1928; King, 1945; Dupuis and Duval, 1949; Burdese and Borlera, 1963; Hubin, 1971; Laud, 1971). More recent studies were carried out in relation with the potential of phosphate matrices to be used as radioactive waste storage material, due to their resistance to radiation effects and their low solubilities (Baglan *et al.*, 1994; Merigou *et al.*, 1995; Genet *et al.*, 1996; Dacheux *et al.*, 1998; Volkov, 1999; Brandel *et al.*, 2001a,b). The system ThO_2/P_2O_5 has been studied in the 1960s and the phosphates $Th_3(PO_4)_4$, $(ThO_3)(PO_4)_2$, $(ThO)_2P_2O_7$, ThP_2O_7, and $ThO_2{\cdot}0.8P_2O_5$ have been reported. Recent investigations, however, show that $ThO_2{\cdot}0.8P_2O_5$ and the orthophosphate, $Th_3(PO_4)_4$, do not exist (Bénard *et al.*, 1996; Brandel *et al.*, 1998). Instead, the phosphate–diphosphate $Th_4(PO_4)_4P_2O_7$ has been obtained under similar conditions. Subsequently it has been shown that the compound can be synthesized applying dry or wet preparative routes and even single crystals have been grown. Besides ThP_2O_7 (Burdese and Borlera, 1963), the orthophosphate–disphosphate is the only structurally known binary thorium phosphate to date, although various other species, for example $ThOH(PO_4)$ and $Th_2(PO_4)_2HPO_4{\cdot}H_2O$, have been reported (d'Ans and Dawihl, 1929; Merkusheva, 1967; Molodkin *et al.*, 1968a; Brandel *et al.*, 2001a,b). In the crystal structure of the orthophosphate–diphosphate

(Bénard *et al.*, 1996), Th^{4+} is surrounded by four monodentate and one chelating PO_4^{3-} groups and one diphosphate ion. The latter suffers from a positional disorder. In ThP_2O_7, the Th^{4+} ions are octahedrally surrounded by six monodentate $P_2O_7^{4-}$ ions and the polyhedra are linked in a three-dimensional cubic network. The compound is thought to exhibit a second modification that has unfortunately not been structurally characterized.

Several ternary thorium phosphates are known, especially those with additional monovalent cations like alkali metals, silver, copper, and thallium (Wallroth, 1883; Palmer, 1895; Haber, 1897; Schmid and Mooney, 1964; Matkovic and Sljukic, 1965; Matkovic *et al.*, 1966, 1968, 1970; Molodkin *et al.*, 1970; Topic *et al.*, 1970; Popovic, 1971; Laügt, 1973; Ruzic Toros *et al.*, 1974; Kojic-Prodic *et al.*, 1982; Galesic *et al.*, 1984; Arsalane and Ziyad, 1996). Phosphates with the composition $MTh_2(PO_4)_3$ (M = Na, K) show ferroelectric properties and are thus of special interest. In the crystal structure, the Th^{4+} ions are nine-fold coordinated by oxygen atoms that belong to seven PO_4^{3-} ions. Two of the latter are chelating ligands. The linkage of the polyhedra leads to parallel layers (100) that are further linked into a three-dimensional network in [100] direction. The Na^+ or K^+ ions in $MTh_2(PO_4)_3$ can be replaced by Pb^{2+} ions, leading to the composition $Pb_{0.5}Th_2(PO_4)_3$ without structural changes (El-Yacoubi *et al.*, 1997). The structure of $CuTh_2(PO_4)_3$ is very similar, although the coordination number of Th^{4+} is lowered to eight. Another characteristic feature of the structure is the linear two-fold coordination of the Cu^+ ions (Louer *et al.*, 1995).

(f) Vanadates

The vanadates of thorium have been investigated to a much lesser extent than the respective phosphates. They seem to parallel the structural chemistry of the phosphates (Le Flem and Hagenmuller, 1964; Le Flem *et al.*, 1965; Quarton *et al.*, 1970; Baran *et al.*, 1974; Elfakir *et al.*, 1987), but high-quality structure determinations are rare. For example, such determinations have been performed for $MTh_2(VO_4)_3$ (M = K, Rb) and 'ThV_2O_7' (Quarton and Kahn, 1979; Elfakir *et al.*, 1987, 1989; Nabar and Mangaonkar, 1991; Launay *et al.*, 1992; Pai *et al.*, 2002). The latter compound is not a divanadate but a mixed *ortho*-vanadate–*catena*-vanadate with the formula $Th(VO_4)(VO_3)$ (Fig. 3.17). Other structurally characterized vanadates include $BaMTh(VO_4)_3$ (M = La, Pr) that adopt the monazite structure type (Nabar and Mhatre, 2001) and the silver compound, $AgTh_2(VO_4)_3$, in the zircon-type (Elfakir *et al.*, 1990). Monazite-, scheelite-, and zircon-type structures have also been frequently observed for other ternary or quaternary thorium *ortho*-vanadates, namely $Pb_{0.5}Th_{0.5}(VO_4)$ (Botto and Baran, 1981; Andreetti *et al.*, 1984; Calestani and Andreetti, 1984), $MLaTh(VO_4)_3$ (M = Sr, Pb) (Nabar and Mhatre, 1982), and $CdMTh(VO_4)_3$ (M = La, Yb) (Nabar *et al.*, 1981). Furthermore, a hydrogenvanadate, Th $(HVO_4)_2{\cdot}5H_2O$, is said to precipitate, when VO_4^{3-} is added to solution of a thorium salt (Clève, 1874; Volck, 1894; Neish, 1904).

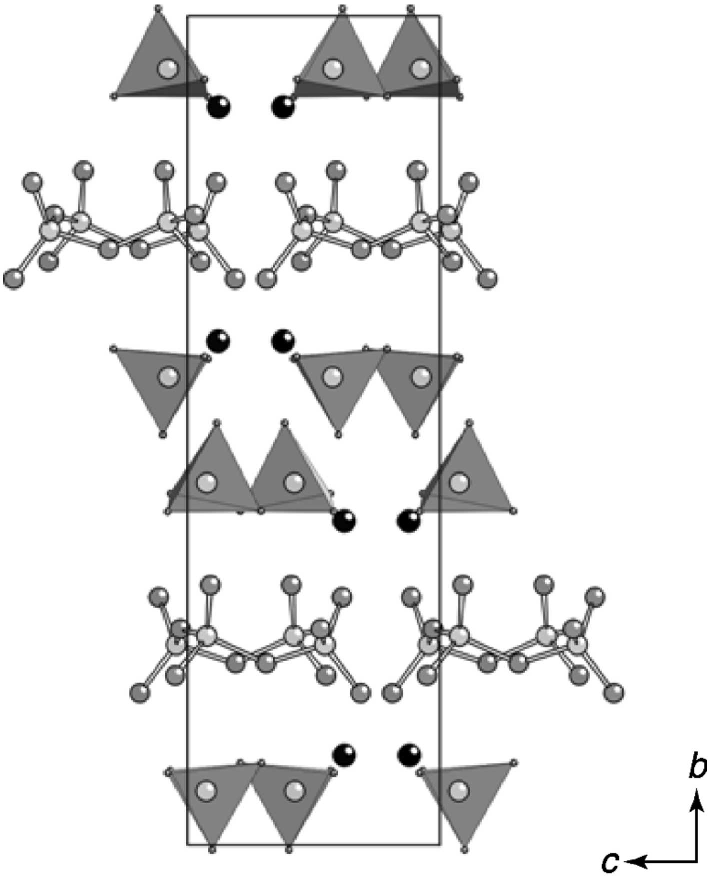

Fig. 3.17 *Crystal structure of Th(VO_4)(VO_3) (or ThV_2O_7). The structure contains isolated* ortho-*vanadate ions (drawn as tetrahedra) and* catena-*vanadate strands.*

(g) Molybdates

One compound, Th(MoO_4)$_2$, is found in the system ThO_2/MoO_3 (Zambonini, 1923; Thoret *et al.*, 1970; Pagès and Freundlich, 1971; Thoret, 1971, 1974). It can be obtained by fusion of the binary oxides or as a hydrate by adding ammonium or alkali metal molybdate to Th^{4+} solutions (Metzger and Zons, 1912; Banks and Diehl, 1947; Trunov and Kovba, 1963; Trunov *et al.*, 1966; Thoret *et al.*, 1968). Th(MoO_4)$_2$ is dimorphic. The orthorhombic low-temperature form shows the Th^{4+} ion in an eight-fold coordination by eight monodentate MoO_4^{2-} groups (Thoret *et al.*, 1970; Thoret, 1974). The molybdate tetrahedra are coordinated to four Th^{4+} ions, leading to a three-dimensional network. In the high-temperature trigonal modification, one set of thorium ions are coordinated by six oxygen atoms while the other set has tricapped trigonal-prismatic coordination polyhedra (Cremers *et al.*, 1983; Larson *et al.*, 1989).

With alkali metal molybdates, M_2MoO_4, $Th(MoO_4)_2$ forms a great variety of compounds (Barbieri, 1913; Thoret, 1971, 1974; Bushuev and Trunov, 1974). The compositions $M_2Th_4(MoO_4)_9$, $M_2Th_2(MoO_4)_5$, $M_2Th(MoO_4)_3$, $M_4Th(MoO_4)_4$, $M_6Th(MoO_4)_5$, and $M_8Th(MoO_4)_6$ have been reported, but only very few of them are properly characterized. In $K_2Th(MoO_4)_3$ the Th^{4+} ions are coordinated by eight oxygen atoms that belong to one chelating and six monodentate MoO_4^{2-} ions (Huyghe *et al.*, 1991a). The $[Th(MoO_4)_7]$ polyhedra are linked to chains along [001] that are held together by K^+ ions. $K_4Th(MoO_4)_4$ consists of a three-dimensional network with the formula $^3_\infty[Th(MoO_4)_{8/2}]$, where the potassium ions are found in holes in the structure (Huyghe *et al.*, 1991b). All of the MoO_4^{2-} groups are monodentate, leading to a coordination number of eight for Th^{4+}. The potassium-rich molybdate $K_8Th(MoO_4)_6$ contains isolated $[Th(MoO_4)_6]^{8-}$ ions in which Th^{4+} attains a coordination number of eight due to the chelating nature of two of the six molybdate groups (Huyghe *et al.*, 1993). The cadmium compound $CdTh(MoO_4)_3$ shows the Th^{4+} ions in tricapped trigonal-prismatic coordination of nine monodentate MoO_4^{2-} groups (Launay and Rimsky, 1980). The prisms are connected to columns along the *c*-axis that are stacked in a hexagonal fashion. In this way channels are formed in which the Cd^{2+} ions reside in an octahedral coordination. $Cu_2Th_4(MoO_4)_9$ has a complicated three-dimensional structure with nine-fold coordinated thorium ions (Launay *et al.*, 1998).

(h) Chromates

Upon addition of dichromate to a solution containing Th^{4+}, the thorium chromate $Th(CrO_4)_2 \cdot 3H_2O$ precipitates at room temperature (Palmer, 1895; Haber, 1897; Britton, 1923). At higher temperatures, a monohydrate precipitates (Palmer, 1895). Both hydrates have been investigated by optical microscopy and seem to be hexagonal or rhombic (Vasilega *et al.*, 1980). According to thermal investigations $Th(CrO_4)_2 \cdot 3H_2O$ dehydrates by a three-step mechanism (Vasilega *et al.*, 1980). Above 280°C, the anhydrous chromate is obtained that remains stable up to 620°C where it decomposes to ThO_2 and Cr_2O_3. Under acidic conditions, for example in concentrated chromic acid, $Th(CrO_4)_2 \cdot CrO_3 \cdot 3H_2O$ is found as the equilibrium solid in the system $ThO_2/CrO_3/H_2O$ (Palmer, 1895; Britton, 1923). None of these compounds is structurally characterized, but the basic chromate, $Th(OH)_2CrO_4 \cdot H_2O$ (Palmer, 1895; Britton, 1923), has been investigated by means of XRD (Lundgren and Sillen, 1949). Its crystal structure contains zigzag-chains of hydroxo-bridged Th^{4+} ions along [010]. Further linkage of the thorium ions is achieved through bonding to CrO_4^{2-} ions.

(i) Miscellaneous oxometallates

A limited number of thorium compounds with oxo-anions other than those discussed above have been mentioned in the literature. The arsenates of thorium are obviously related to the phosphates (Le Flem, 1967; Hubin, 1971; Chernorukov *et al.*, 1974a,b), while the tungstates resemble the molybdates (de Maayer *et al.*, 1972; Thoret, 1974). Thorium *ortho*-germanate, $ThGeO_4$, has been shown to be dimorphic (Bertaut and Durif, 1954; Perezy Jorba *et al.*, 1961; Harris and Finch, 1972) and adopts either the zircon or the scheelite structure type (Ennaciri *et al.*, 1986). This compound has been used as a host lattice for trivalent lanthanides (Gutowska *et al.*, 1981). Besides the most important silicate minerals thorite, huttonite, and thorogummite already mentioned in Section 3.3, a number of complex silicate minerals is known, which are, however, often not characterized completely. Structural data are, for example, available for ekanite, $Ca_2ThSi_8O_{20}$ (Szymanski *et al.*, 1982), and $Ca_6Th_4(SiO_4)_6O_2$, which has the apatite type of structure (Engel, 1978). Furthermore the structure of the mineral thornasite, $Na_{12}Th_3(Si_8O_{19})_4 \cdot 18H_2O$, has been reported recently (Li *et al.*, 2000). One borate, $Th(B_2O_5)$, has been structurally investigated. It contains $B_2O_5^{4-}$ ions and eight-fold coordinated Th^{4+} ions (Baskin *et al.*, 1961; Cousson and Gasperin, 1991).

Additional thorium compounds with transition metal oxo-anions such as the perrhenates should be mentioned. $Th(ReO_4)_4 \cdot 4H_2O$ was obtained from $Th(OH)_4$ and $HReO_4$ (Silvestre *et al.*, 1971; Zaitseva *et al.*, 1984). Its structure is not known but is has been shown to dehydrate in four steps yielding $Th(ReO_4)_4$, which finally decomposes to $Th_2O(ReO_4)_6$ (Zaitseva *et al.*, 1984). $Th(ReO_4)_4$ forms ternary compounds with alkali perrhenates and mixed anionic species with WO_4^{2-} and MoO_4^{2-} (Silvestre, 1978).

Other oxo-metallates reported are the titanate $ThTi_2O_6$ (brannerite structure) (Perezy Jorba *et al.*, 1961; Radzewitz, 1966; Ruh and Wadsley, 1966; Loye *et al.*, 1968; Kahn-Harari, 1971; Zunic *et al.*, 1984; Mitchell and Chakhmouradian, 1999), the niobate $ThNb_4O_{12}$ (Keller, 1965; Trunov and Kovba, 1966; Alario-Franco *et al.*, 1982), and the tantalates $ThTa_2O_7$, $Th_2Ta_2O_9$ (Keller, 1965; Schmidt and Gruehn, 1989, 1990), $Th_2Ta_6O_{19}$ (Busch *et al.*, 1996), and $Th_4Ta_{18}O_{53}$ (Busch and Gruehn, 1996) have been reported. Structurally, however, they are preferably described as double oxides rather than oxo-metallates. Values for the enthalpies of formation of thorite, huttonite (Mazeina *et al.*, 2005) and thorium brannerite (Helean *et al.*, 2003) are given in Chapter 19.

(j) Carboxylates and related organic salts

Carboxylate complexes of thorium have been frequently investigated with respect to the role they may play in solvent extraction processes. Carboxylates and related salts have also been employed in gravimetric analyses for thorium, either by direct weighing if the compound is stoichiometric, or after ignition to thorium dioxide. Thus, there are a large number of papers describing these compounds. Most of them have been mentioned in the *Gmelin Handbook* (Gmelin, 1988a), so only selected examples will be presented here.

The most investigated groups among the carboxylates are formates and acetates. Formates and formato complexes can be obtained by the reaction of formic acid with $ThCl_4$ or other salts of Th^{4+}. In acid solution, $Th(OOCH)_4$, is formed, which has been shown to be polymorphic (Mentzen, 1969, 1971a,b; Greis *et al.*, 1977) and may contain different amounts of crystal water (Claudel and Mentzen, 1966; Thakur *et al.*, 1980). If the pH of the solution increases above 6, basic formates start to form. They may have different compositions like $ThOH(OOCH)_3$, $Th(OH)_2(OOCH)_2$, and $Th(OH)_3(OOCH)$ (Gmelin, 1988a) but they have not been structurally characterized. Various metal ions have been used to crystallize formato complexes, such as $MTh(OOCH)_5$ (M = K, Rb, Cs, NH_4) and $MTh(OOCH)_6$ (M = Sr, Ba). All these complexes have been characterized by thermal analysis and vibrational spectroscopy (Molodkin *et al.*, 1968b; Gmelin, 1988a).

The structural knowlegde of thorium acetates and acetato complexes is also quite limited, although quite a number of compounds have been described. The tetraacetate, $Th(CH_3COO)_4$, is said to be isotypic with the respective uranium acetate (Eliseev *et al.*, 1967; Bressat *et al.*, 1968; Gmelin, 1988a), and similar to the formates, various hydrates and basic salts are known. Derivatives of acetic acid such as CF_3COOH, CCl_3COOH, $CHCl_2COOH$, $CH_2ClCOOH$, $C_6H_5CH_2COOH$, $C_6H_5CH(OH)COOH$, naphtyl acetic acid, and others, have been used to prepare the respective salts (Katzin and Gulyas, 1960; Gmelin, 1988a). Even bromo- and iodoacetates are known. Among the chloroacetates, one compound has been investigated crystallographically. It has the composition $[Th_6(CHCl_2\ COO)_{12}(OH)_{12}(H_2O)_2]$ and shows an octahedral $[Th_6]$ core surrounded by the ligands.

With increasing complexity of the carboxylic acids, less is known structurally about their thorium compounds. The compounds prepared include glycolates, propionates, butyrates, and their derivatives. Furthermore, compounds with unsaturated mono carboxylic acids have been reported, for example crotonates and cinnamates.

The largest group of thorium salts of dicarboxylic acids are the oxalates and oxalato complexes, for which some crystallographic data are available (Gmelin, 1988a). More complex dicarboxylic acids have been employed, and even the thorium salts of long-chain acids like sebacic acid, $HOOC(CH_2)_8COOH$, are known. The latter has been used, along with *m*-nitrobenzoic acid (Neish, 1904), picrolonic acid (Hecht and Ehrmann, 1935; Dupuis and Duval, 1949), or 'ferron' (7-iodo-8-hydroxyquinoline-5-sulfonic acid), for analytical purposes (Dupuis and Duval, 1949).

3.7.8 Coordination compounds

Coordination compounds of thorium are of special interest because the knowledge of their behavior and their properties is fundamental for the understanding of separation processes (for example, the thorium extraction [THOREX] process that involves tri(*n*-butyl)phosphate complexes) (Peppard and Mason, 1963), see Chapter 24, the development of decontamination methods, and the treatment of radioactive waste. Thus, the number of compounds reported in literature is very large. The *Gmelin Handbook* provides a comprehensive overview of the compounds investigated until 1983 (literature closing date) (Gmelin, 1985b). A more recent review (Agarwal *et al.*, 2000) covers thorium compounds with neutral oxygen donor ligands. These ligands can be divided with respect to the atom to which the oxygen donor is bonded: ligands containing a C–O group may, for example, be alcohols, phenols, ketones, esters, ethers, formamide, acetamide, those containing a N–O group are typically pyridine and quinoline *N*-oxides or even nitrosyl chloride and P=O, As=O, and S=O groups are known for the respective phosphine, arsine, and sulfoxides. The group of neutral oxygen donor ligands is probably the most investigated, but also a great number of complexes with neutral nitrogen donor ligands are known (Vigato *et al.*, 1977). Besides NH_3 (Matthews, 1898; von Bolton, 1908; Clark, 1924), the ligands are higher amines, hydrazine and its derivatives, and pyridine and its derivatives (Matthews, 1898;Adi and Murty, 1978; Al-Daher and Bagnall, 1984). Coordination compounds with charged ligands besides the above-mentioned carboxylates have been also frequently investigated. Among these ligands are the diketonates and related ligands, tropolone and its derivatives, and a great number of Schiff base ligands (Biradar and Kulkarni, 1972).

One of the most important thorium coordination compounds is thorium tetrakis(acetylacetonate), $Th(acac)_4$, which can be sublimed at temperatures below its melting point of 171°C (Urbain, 1896). This is also true for most of the substituted acetylacetonates, for example the trifluoromethylacetylacetonate, whose structure has been determined and that shows the thorium atoms in square antiprismatic coordination of oxygen atoms (Wessels *et al.*, 1972). These compounds are generally efficiently extracted into water-immiscible solvents, a property that has been used, for example, with thenoyltrifluoroacetone, to measure complexation of thorium with various anions (Calvin, 1944; Day and Stoughton, 1950). Another ligand that has been studied in more detail is 8-hydroxyquinoline ('oxine') and its derivatives (Frazer and Rimmer, 1968; Abraham and Corsini, 1970; Corsini and Abraham, 1970; Singer *et al.*, 1970; White and Ohnesorge, 1970). Also heteroleptic species involving oxine and another ligand, for example dimethylsulfoxide, are known (Singer *et al.*, 1970; Andruchow and Karraker, 1973). As a thorium complex with eight-fold thorium coordination with sulfur atoms, thorium(IV) tetrakis(*N*,*N*-diethyldithiocarbamate) should be mentioned (Brown *et al.*, 1970b). A path to related compounds is through intermediates such as $Th(NEt_2)_4$ (Bradley and Gitlitz, 1969; Watt and Gadd, 1973), which, when treated with CXY (X,Y = O, S, Se etc.), gives carbamates, thiocarbamates, mixed compounds like $Th[OSCN(CH_3)_2]_4$, and even $Th(Se_2CNEt_2)_4$ (Bagnall and Yanir, 1974). It is very surprising that despite the large number of complexes that have been prepared, the number of structure determinations is very limited.

3.7.9 Organothorium compounds

As Chapters 25 and 26 are devoted to the synthesis, the characterization and the properties of the organoactinide compounds, only selected examples shall be mentioned briefly here.

Thorocene, $Th(COT)_2$ (COT = cyclo-octatetraene), has been prepared by treating $ThCl_4$ in tetrahydrofuran (THF) with $K_2(COT)$ at dry-ice temperature (Streitwieser and Yoshida, 1969). The yellow crystals of $Th(COT)_2$ sublime at 0.01 mmHg pressure and 160°C. Thorocene, isomorphous with $U(COT)_2$ (uranocene) (Avdeef *et al.*, 1972), is unstable in air, decomposes in water, and undergoes thermal decomposition without melting above 190°C. Gas-phase photoelectron spectra have been used to elucidate the bonding in thoracene (Fragala *et al.*, 1976; Clark and Green, 1977). This compound has also been prepared by treating ThF_4 with Mg(COT) (Starks *et al.*, 1974). In addition, a number of half-sandwich Th(IV) complexes with COT have been reported (LeVanda *et al.*, 1980; Zalkin *et al.*, 1980).

Numerous complexes with the cyclopentadienyl (Cp^-) anion have been reported. $Th(Cp)_4$ was first prepared by the reaction of $ThCl_4$ with KCp (Fischer and Treiber, 1962). This compound sublimes between 250 and 290°C at 10^{-3} to 10^{-4} mmHg. Tris(cyclopentadienyl) halides and alkoxides of thorium have been synthesized (Ter Haar and Dubeck, 1964; Marks *et al.*, 1976), and, in general, these air-sensitive compounds sublime below 200°C and 10^{-3} to 10^{-4} mmHg pressure. Related tris(indenyl)thorium halides and alkoxides have been prepared (Laubereau *et al.*, 1971; Goffart *et al.*, 1975, 1977). The only bis (cyclopentadienyl)thorium dihalide reported is $ThI_2(Cp)_2$, prepared from ThI_4 and $Mg(Cp)_2$ (Reid and Wailes, 1966), whereas it is believed that the chloride analog would be unstable, similar to the uranium compound (Ernst *et al.*, 1979). In contrast, the permethylated Cp derivative $C_5(CH_3)_5^-$ (=Cp*) has been used to prepare stable dichlorides, $(Cp^*)_2ThCl_2$ (Manriquez *et al.*, 1978; Blake *et al.*, 1998). The CpTh trihalides have been described to exist as adducts with ethers, $CpThX_3 \cdot 2L$ (L = tetrahydrofurane or 1/2 dimethoxyethane [DME]) (Bagnall *et al.*, 1978). Analogous indenyl (Goffart *et al.*, 1980) and Cp* compounds have also been reported (Mintz *et al.*, 1982).

Tetrabenzylthorium, $Th(CH_2C_6H_5)_4$, is the best-characterized thorium homoalkyl compound reported to date (Köhler *et al.*, 1974). The light-yellow, air-sensitive, crystalline compound decomposes slowly at room temperature. A second tetrahydrocarbyl thorium complex has been reported, $Th(CH_3)_4(dmpe)_2$ (dmpe = bis(dimethylphosphino)ethane), prepared by the reaction of $ThCl_4(dmpe)_2$ with CH_3Li (Edwards *et al.*, 1981). It is stable up to –20°C in the absence of air and moisture. These two thorium phosphine complexes, along with $Th(OC_6H_5)_4(dmpe)_2$ and $Th(CH_2C_6H_5)_4(dmpe)_2$, were the first isolated and characterized species of their kind (Edwards *et al.*, 1984). Tetraallylthorium, $Th(C_3H_5)_4$, has been reported and decomposes slowly above 0°C (Wilke *et al.*, 1966).

The reaction of the Cp– (Marks and Wachter, 1976), indenyl– (Goffart *et al.*, 1977), and Cp*–thorium chlorides (Fagan *et al.*, 1981; Fendrick, 1984) with alkylating or arylating reagents has yielded the corresponding π-ligand thorium hydrocarbyls. In a thermodynamic study on the series $(Cp^*)_2ThR_2$, it was observed that the bond disruption enthalpies of the thorium–ligand σ-bonds were about 250–335 kJ mol^{-1}, significantly greater than similar transition metal bond enthalpies (Bruno *et al.*, 1983).

More recent investigations on organothorium chemistry were intended to introduce new ligands in that field and to synthesize low-valent thorium compounds. For example, the bicyclic pentalene dianion $C_8H_6^{2-}$ has been used to prepare a new type of thorium sandwich complex. The crystal structure, as well as the photoelectron spectra, of $[Th\{C_6H_4(Si^iPr_3\text{–}1{,}5)_2\}_2]$ was reported (Cloke and Hitchcock, 1997; Cloke *et al.*, 1999). Another very interesting ligand, the dicarbollide anion $C_2B_9H_{11}^{2-}$, should be mentioned: it is found in the complexes $[Li(THF)_4]_2[Th(\eta^5\text{-}C_2B_9H_{11})_2X_2]$ (X = Cl, Br, I) (Rabinovich *et al.*, 1997).

The number of potentially low-valent organothorium complexes is still very limited. Two forms of $Th(C_5H_5)_3$ have been reported. Purple $Th(C_5H_5)_3$ was prepared by sodium naphtalide reduction of $Th(C_5H_5)_3Cl$ in THF. The latter was removed under vacuum (Kanellakopulos *et al.*, 1974). According to X-ray powder diffraction measurements, the compound is isotypic with the analogs of heavier 5f elements and has an effective magnetic moment of $0.331\mu_B$. The green form of $Th(C_5H_5)_3$ was formed via photolysis of $Th(C_5H_5)_3[(CH(CH_3)_2]$ in benzene solution and has a magnetic moment of $0.404\mu_B$ (Kalina *et al.*, 1977). A recent example is $[Th\{COT(TBS)_2\}_2][K(DME)_2]$ – with $COT(TBS)_2$ = $\eta\text{-}C_8H_6(t\mathrm{Bu}Me_2Si)_2\text{–}1{,}4$ – that has been prepared by the reaction of a suspension of $[Th\{COT(TBS)_2\}_2]$ in DME with elemental potassium (Parry *et al.*, 1999). Furthermore, the first organometallic compounds of divalent thorium have been reported recently. They contain the complex Et_8-calix[4]tetrapyrrole ligand and are potentially divalent synthons (Korobkov *et al.*, 2003).

3.8 SOLUTION CHEMISTRY

3.8.1 Redox properties

Thorium is known to have only one stable oxidation state in aqueous solution, the tetravalent state, $Th^{4+}(aq)$ (Gmelin, 1988c).

Th(III) has been recently claimed by Klapötke and Schulz (1997) to be formed by reaction of $ThCl_4$ with HN_3 in slightly acidic solution and to be stable for at least 1 h. Reportedly, the reaction involved:

$$Th^{4+} + HN_3 \rightarrow Th^{3+} + 1.5N_2 + H^+$$

Yet, the reaction has been shown to be thermodynamically impossible by Ionova *et al.* (1998). First, the stabilization of d-electrons by the crystal field effect is not sufficient to assign, as suggested by Bratsch and Lagowski (1986), a value of –3.0 V to the redox potential of the couple M^{4+}/M^{3+}. Besides, a value between –3.35 and –3.82 V, in the same range as the previously published one, –3.7 V (Nugent *et al.*, 1973), is much more probable. Secondly, the reducing ability of HN_3 has been overestimated and the authors concluded that the spectra published by Klapötke and Schulz (1997), as a proof of the existence of Th^{3+}(aq) (broad absorption signal centered around 460 nm and intense peaks at 392, 190 and below 185 nm), correspond, in fact, to azido–chloro complexes of Th(IV).

3.8.2 Structure of the aqueous Th^{4+} ion

The LIII-edge extended X-ray fine structure (EXAFS) experiments on 0.03–0.05 M Th(IV) in 1.5 M $HClO_4$ solutions have clearly defined the structure of the Th(IV) aqua ion (Moll *et al.*, 1999). A least-squares refinement of the data leads to a Th–O distance of (2.45 ± 0.01) Å and a coordination number of (10.8 ± 0.5) which is larger than the older values estimated by Johansson *et al.* (1991) from low-angle X-ray scattering (LAXS) results (8.0 ± 0.5 water molecules at 2.485 Å) or by Fratiello *et al.* (1970) from ^1H NMR data at low temperatures and higher concentrations (nine water molecules in the first hydration sphere).

The results of Moll *et al.* are consistent with the structural parameters obtained in the same study for U^{4+}(aq) (CN = 10 ± 1; $R = 2.42 \pm 0.01$ Å) and previously by Allen *et al.* (1997) for Np^{4+}(aq) (CN = 11.2 ± 0.4; $R = 2.40 \pm 0.01$ Å). A correlation between the hydration number (higher than 6) of highly charged metal ions and the bond distance shows also that a M–O distance of 2.45 Å is in favor of a hydration number closer to 10 (Sandström *et al.*, 2001). More precise systematics and correlation between the space around the cation and its charge have been proposed by David and Vokhmin (2003). They give consistent coordination numbers of Th^{4+}, U^{4+}, Np^{4+}, and Pu^{4+}: 11.0, 10.65, 10.2, and 10.0, respectively. The same authors have evaluated the corresponding ionic radii, 1.178 Å for Th^{4+}, and a size of the coordinated water molecule of 1.335 Å, by assuming a pure electrostatic bond. It would result in a larger cation–oxygen distance of 2.51 Å. The observed difference with experimental data (0.06 Å) has been interpreted by a covalent effect and the effective charge of the Th^{4+} aquo ion has been evaluated to be 3.82 (David and Vokhmin, 2003). Finally, the same authors have determined the number of water molecules in a second hydration sphere as 13.4.

3.8.3 Thermodynamics of the Th^{4+}(aq) ion

The data on the standard enthalpy of formation, entropy, and corresponding Gibbs energy, adopted in this review and shown in Table 3.12, are those given in the compilation of Martinot and Fuger (1985), except for a small difference in the standard Gibbs energy of formation, due to the use of a more recent value for the entropy of Th(cr) (see Chapter 19).

Table 3.12 *Main thermodynamic properties of the thorium aqueous ion at* 25°C (*see text for references*).

$E°(Th^{4+}/Th)$	$\Delta_f H°$(kJ mol^{-1})	$\Delta_f G°$(kJ mol^{-1})	$S°$ (J K^{-1} mol^{-1})
−(1.828 ± 0.015) V/NHE	−(769.0 ± 2.5)	−(705.5 ± 5.6)	−(422.6 ± 16.7)

Thermodynamic models have been proposed recently by David and Vokhmin (2001) to evaluate the Gibbs hydration energy and the entropy of the aquo ions. Corresponding values are $\Delta_{hyd}G°(Th^{4+}) = -6100$ kJ mol^{-1} and $S°(Th^{4+},aq) = -438$ J mol^{-1} K^{-1} (David and Vokhmin, 2003). The entropy value is consistent with the experimental value, –(422.6 ± 16.7) J K^{-1} mol^{-1} (Martinot and Fuger, 1985).

The standard state partial molar heat capacities and volumes of Th^{4+}(aq) have been recently determined from 10 to 55°C under conditions minimizing complications due to hydrolysis and ion-pairing equilibria or ion–ligand complexation (measurements on aqueous solutions containing $Th(ClO_4)_4$ in dilute $HClO_4$ (Hovey, 1997)). The values obtained at 25°C, $C_p°(Th^{4+},aq) = -(224 \pm 3)$ J $K^{-1}mol^{-1}$ and $V°(Th^{4+},aq) = -(60.6 \pm 0.5)$ cm^3 mol^{-1}, appear as more negative than those of any monoatomic aqueous ion. These results are also quite different from the previous estimations: $C_p°(Th^{4+},aq) = -(1 \pm 11)$ J K^{-1} mol^{-1} (Morss and McCue, 1976) recalculated as −(60 ± 11) J K^{-1} mol^{-1} using a newer $C_p°(NO_3^-$,aq) value, –72 J K^{-1} mol^{-1} (Hovey, 1997) and $V°(Th^{4+},aq)$ = –53.5 and –54.6 cm^3 mol^{-1} from the values given in the International Critical Tables (1928) for the standard state partial molar volumes of $ThCl_4$(aq) and $Th(NO_3)_4$(aq), respectively.

3.8.4 Hydrolysis behavior

Being the largest actinide tetravalent ion, Th^{4+}(aq) is also the least hydrolyzable of them (Onosov, 1971). Because of its size, it is less hydrolyzable than many other multi-charged ions such as iron(III); tetravalent thorium may therefore be studied over a larger range of concentrations, at pH values up to 4. However, its tendency to undergo polynucleation reactions and colloid formation, as well as the low solubility of its hydroxide or hydrous oxide, limit the possibilities of investigation. For these reasons, the oxide/hydroxide solubility products and hydrolysis constants published in the literature show great discrepancies.

Very recently, Neck and Kim (2001) have proposed a critical review and a comprehensive set of thermodynamic constants at zero ionic strength and 25°C. In the first part of their work, they compared the frequently accepted constants of Baes *et al.* (1965), Baes and Mesmer (1976), Brown *et al.* (1983), Grenthe and Lagerman (1991), and Ekberg and Albisson (2000). All these data, which are reported in Table 3.13, are based on potentiometric titrations at 15, 25, or 35°C with relatively low thorium concentrations (2×10^{-4} to 10^{-5} M).

Ekberg and Albinsson have performed, in addition, solvent extraction experiments with a total concentration of Th(IV) in the range 10^{-5} to 10^{-7} M. It should be outlined that, under the conditions usually applied in potentiometric and solvent extraction studies ($[\mathrm{Th}]_{\mathrm{tot}} = 2 \times 10^{-4}$ to 2×10^{-2} M; pH = 2.5–4; Kraus and Holmberg, 1954; Hietanen and Sillen, 1964; Baes *et al.*, 1965; Nakashima and Zimmer, 1984), polynuclear species are of major importance and laser-induced breakdown detection (LIBD) has shown that a considerable amount of colloids were present at $\log[\mathrm{H}^+] \leq -(1.90 \pm 0.02)$ for $\log[\mathrm{Th}]_{\mathrm{tot}} = -(2.04 \pm 0.02)$ and at $\log\,[\mathrm{H}^+] \leq -(2.40 \pm 0.03)$ for $\log[\mathrm{Th}]_{\mathrm{tot}} = -(4.05 \pm 0.02)$ (Bundschuh *et al.*, 2000). We can also cite the work of Moulin *et al.* (2001) who recently applied electrospray ionization–mass spectrometry to determine the hydrolysis of Th(IV) in dilute solution, but the equilibrium constants so-determined $\log K^\circ_{11} = -(2.0 \pm 0.2), \log K^\circ_{12} = -(4.5 \pm 0.5), \text{and} \log K^\circ_{13} = -(7.5 \pm 1.0)$ are so large, compared to those obtained from the above-cited well-established methods, that it is difficult to consider them as reliable.

As we can see from Table 3.13, the first mononuclear hydrolysis constants found by Brown *et al.* (1983) and Ekberg and Albinsson (2000) are about one order of magnitude higher than the constants derived by Baes and Mesmer (1976) and Grenthe and Lagerman (1991). Moreover, the hydrolysis constants reported for $\mathrm{Th(OH)}_2^{2+}$, $\mathrm{Th(OH)}_3^{+}$, and $\mathrm{Th(OH)_4(aq)}$ differ between authors by several orders of magnitude. In order to select the best available data, Neck and Kim (2000) estimated the 'unknown' formation constants of $\mathrm{Th(OH)}_n^{(4-n)+}$ by two methods.The first one, method A, is based on the empirical intercorrelation between hydrolysis constants of actinide ions at different oxidation states. The second method, B, developed by the authors consists of applying a semiempirical approach, in which the decrease of the stepwise complexation constants for a given metal–ligand system is related to the increasing electrostatic repulsion between the ligands. From their results collected in Table 3.13, Neck and Kim concluded that the higher $\log \beta^\circ_{11}$ values, in the range 11.7–11.9, and the lower $\log \beta^\circ_{13}$ and $\log \beta^\circ_{14}$ values (Ekberg and Albinsson, 2000) should be preferred. Consequently, their selected values are $\log \beta^\circ_{1n} = (11.8 \pm 0.2), (22.0 \pm 0.6), (31.0 \pm 1.0)$, and (39.0 ± 0.5) for $n = 1, 2, 3$, and 4, respectively (Neck and Kim, 2000). These data have been used to plot the speciation diagrams given in Fig. 3.18.

Following a similar approach, Moriyama *et al.* (1999) analyzed the mononuclear hydrolysis constants of actinide ions by using a simple hard sphere model. Systematic trends were thus obtained, from which the values given in Table 3.13 have been deduced ($\log \beta^\circ_{1n} = 12.56$, 23.84, 32.76, and 40.40 for $n = 1, 2, 3$, and 4, respectively). These values are intermediate between the two series calculated by Neck and Kim (2000) and are in rather good agreement with the averages of literature data ($\log \beta^\circ_{1n} = 11.27$, 22.43, 33.41, and 40.94 for $n = 1, 2, 3$, and 4, respectively) given by Moriyama *et al.* (1999).

Table 3.13 *Experimental and estimated hydrolysis constants proposed for Th(IV) at 25°C and defined as follows ([i] and γ_i denoting the concentration and the activity coefficient of the species i):*

$$K_{1-n} = [Th(OH)_n^{(4-n)+}][H^+]^n/[Th^{4+}]$$

$$\beta^\circ_{1-n} = [Th(OH)_n^{(4-n)+}](\gamma_{Th(OH)n})/[Th^{4+}](\gamma_{Th})[OH^-]^n(\gamma_{OH})^n$$

The values at $I = 0$ (log β°_{1n}) have been calculated by Neck and Kim (2001) by applying the specific interaction theory (SIT) following the NEA Thermochemical Data Base project (Grenthe et al., 1992).

3.8.5 Solubility

(a) In non-complexing media

In perchlorate media, an average hydroxyl number, *n* (OH^- groups bound per thorium), of about 2.5 can be reached without delayed precipitation. All hydrolyzed solutions contain polymeric species and the weight-average degree of polymerization increases with the degree of hydrolysis (Danesi *et al.*, 1968; Hietanen and Sillen, 1964). The presence of the $Th_2(OH)_2^{6+}$ polymer is well recognized in most of the studies (Hietanen and Sillen, 1964; Baes *et al.*, 1965; Milic, 1971, 1981; Milic and Suranji, 1982; Moon, 1989), but other polymers such as $Th_2(OH)_3^{5+}$ (Milic, 1981, Moon, 1989), $Th_2(OH)_4^{5+}$ (Moon, 1989), $Th_4(OH)_8^{8+}$ (Baes *et al.*, 1965; Ekberg and Albinsson, 2000), $Th_4(OH)_{12}^{4+}$ (Brown *et al.*, 1983), $Th_5(OH)_{12}^{8+}$ (Lefèbvre, 1957), $Th_6(OH)_{14}^{10+}$ (Milic, 1981), $Th_6(OH)_{15}^{9+}$ (Baes *et al.*, 1965; Brown *et al.*, 1983; Ekberg and Albinsson, 2000) have been found as well. The corresponding conditional constants collected in Table 3.14 show a rather reasonable agreement between the different studies for the species commonly detected. The experimental conditions, especially the total thorium concentration involved in the measurements, may explain why different sets of polynuclear species are discussed in the different studies (some species can have a too low concentration to be detected and/or can precipitate). However, it is interesting to note that $Th_6(OH)_{15}^{9+}$ is the only polynuclear species expected to predominate in the simple Th(IV)/H_2O system, when the total Th(IV) concentration exceeds $\sim 10^{-3}$ M (and up to at least 1 M) and for a pH range centered around 4.5–5 (see Fig. 3.18(b)).

The structure of highly hydrolyzed thorium salt solutions has been studied by electronic microscopy (Dobry *et al.*, 1953; Dzimitrowickz *et al.*, 1985) and light or X-ray scattering techniques (Dobry *et al.*, 1953; Hentz and Johnson, 1966; Magini *et al.*, 1976). The details of this structure are dependent on sample history. At room temperature, the hydrolysis complexes contain a small number of Th(IV) atoms probably situated at the corners of slightly distorted face-sharing tetrahedral. At higher temperatures, small crystallites (~40 Å) are formed, which have the ThO_2 structure. These crystallites tend to join to other crystallites, in random orientation, to form particles of up to 170 Å in diameter (Magini *et al.*, 1976). Finally, the small fragments of fluorite can be connected (e.g. cross-linking by oxide bridges) in a random manner into larger, porous agglomerates irregular in shape and size up to 800–15000 Å (Dzimitrowickz *et al.*, 1985). In dilute colloidal solutions ($[Th]_{tot} < 10^{-2}$ mol L^{-1}), filamentous particles with a statistic average length of 700 Å are observed; they are wound into compact balls in more concentrated solutions (Dobry *et al.*, 1953).

The solubility products reported for the thorium oxide and hydroxide species show considerable discrepancies (Table 3.15). The reasons can be found in: (1) the characteristics of the solid phase (degree of crystallization, morphology, etc.), which depend on the history of its preparation (hydrolysis reaction, pretreatment, aging); (2) the composition of the solution (pH range, ionic strength); (3) the method of evaluating the total concentration of thorium in solution (cutting size for the phase separation); (4) the generally too simplified chemical model used to derive the solubility product; and (5) the set of hydrolysis constants used in the data treatment.

Concerning the first point, it is important to distinguish between the amorphous fresh hydroxide precipitate, just washed prior to experiments,

the hydrous oxide or microcrystalline $ThO_2 \cdot nH_2O$ showing very broad X-ray powder diffraction peaks, and the well-crystallized thorine, obtained after appropriate heating steps. The four other points have to be taken into account to select and interpret the various solubility curves published in the literature. This task has been recently accomplished by Neck and Kim (2001). First, they analyzed the solubility data obtained for amorphous Th(IV) precipitates (not treated at higher temperature but only washed with water) at $I \leq 1$ M by using a chemical model that includes all mononuclear species $Th(OH)_n^{(4-n)+}$ up to $n = 4$ and two polynuclear species, $Th_4(OH)_{12}^{4+}$ and $Th_6(OH)_{15}^{9+}$. For this purpose, they chose the hydrolysis constants, $\log K_{4-12}$ and $\log K_{6-15}$, given in Table 3.14 and derived by Brown *et al.* (1983) from potentiometric titrations at pH = 3–4, in combination with their selected data for the mononuclear hydrolysis species (see Table 3.13).

By monitoring the initial colloid generation (with size of 16–23 nm) as a function of pH and Th(IV) concentration with the use of LIBD, Bundschuh *et al.* (2000) determined a value of $\log K^{\circ}_{sp}$ equal to $-(52.8 \pm 0.3)$ (also calculated with the specific interaction theory (SIT) coefficients of Nuclear Energy Agency Thermochemical Database Project [NEA-TDB] data), which corresponds both to the solubility products of crystalline ThO_2 (values of Moon (1989) revisited by Neck and Kim (2001) [see Table 3.15]) and to the value calculated from thermochemical data for ThO_2, $\log K^{\circ}_{sp} = -(54.2 \pm 1.3)$ (Rai *et al.*, 1987). The difference is ascribed to a particle size effect and it is concluded that the colloids formed in the coulometric pH titration experiments consist of crystalline thorium dioxide. This conclusion is also supported by the work of Dzimitrowickz *et al.* (1985).

Moreover, it is evident from Fig. 3.19 that the degree of crystallization of ThO_2 influences its solubility behavior essentially in acidic media. At pH < 2.5, the experimental solubility curve of ThO_2(cr) seems to indicate an equilibrium between the solid phase and Th^{4+}(aq) (slope of −4 for the microcrystalline precipitates only). However, such an equilibrium has never been observed when the dissolution process is studied from under-saturation (Hubert *et al.*, 2001; Neck, 2002). With increasing pH, the solubility data deviate more and more from the expected curve. The hydrolysis of the Th^{4+} ions leads to increased Th(IV) concentrations, which are not in equilibrium with ThO_2(cr), but with an amorphous surface layer of $Th(OH)_4$ covering the crystalline solid, as judiciously explained by Neck and Kim (2001). In fact, kinetic effects play an important role in the overall process, as outlined by Hubert *et al.* (2001).

(b) In complexing media

The precipitation of thorium by various inorganic and organic ligands and the characterization of the resulting solids were treated at some length in Section 3.7.7. Therefore the discussion here will be limited to the role of the carbonate

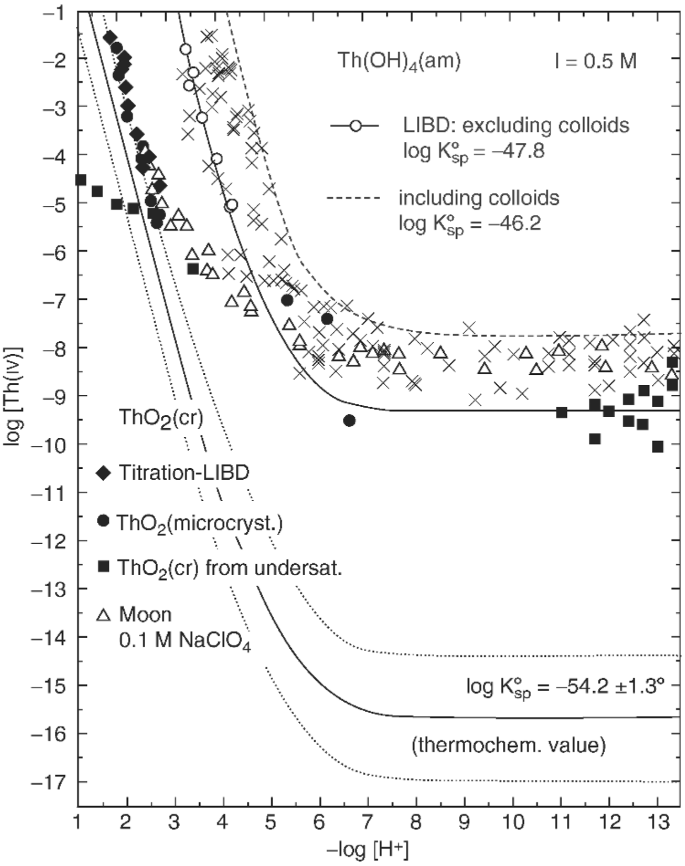

Fig. 3.19 *Experimental and calculated solubility of ThO_2(cr) in comparison with that of Th(IV) hydroxide or hydrous oxide at* $I = 0.5$ M *and* 25°C (*Neck,* 2002). *The experimental data for ThO_2(cr) are those determined by Neck* (2002) *by titration–LIBD and from under- and oversaturation* (*filled symbols*) *and by Moon* (1989) *in* 0.1 M $NaClO_4$ *at* 18°C (*open triangles*). *The solubility data for amorphous precipitates* (*crosses*) *are taken from Moon* (1989), *Felmy et al.* (1997), *Östhols et al.* (1994), *Rai et al.* (1997), *Neck and Kim* (2000), *all data being at* $I = 0.5$–0.6 M *and* 18–25°C. *The curves calculated for the two kinds of solids and for* $I = 0.5$ M *are based on the hydrolysis constants selected by Neck and Kim* (2001) *and on the solubility products* $\log K^{\circ}_{sp}(ThO_2, cr) = -(54.2 \pm 1.3)$ (*Rai et al.,* 1987) *and* $\log K^{\circ}_{sp}(Th(OH)_4, am) = -(47.0 \pm 0.8)$ (*Neck and Kim,* 2001).

and the phosphate ions on the solubility of thorium and, consequently, on its behavior in natural waters.

The presence of carbonates in solution greatly increases the solubility of thorium dioxide. An increase by one order of magnitude of the carbonate concentration (in the range 0.1–2.0 M Na_2CO_3) leads to an increase by about five orders of magnitude of the solubility of hydrous ThO_2(am) (Rai *et al.*, 1995). Moreover, for a fixed carbonate concentration [1 M Na_2CO_3 (Rai *et al.*, 1995) or $pCO_2 = 0.1$ atm (Östhols *et al.*, 1994)], a large pH dependency is observed. The fitting of their solubility data has lead Östhols *et al.* (1994) to propose the following equilibrium constants:

$$ThO_2 + H^+ + H_2O + CO_3^{2-} \leftrightarrow Th(OH)_3CO_3^-;\ \log K_{131} = 6.11 \pm 0.19,\ \log K^\circ_{131} = 6.78 \pm 0.30$$

$$ThO_2 + 4H^+ + 5CO_3^{2-} \leftrightarrow Th(CO_3)_5^{6-};\ \log K_{105} = 42.12 \pm 0.32,\ \log K^\circ_{105} = 39.64 \pm 0.40$$

that were calculated by using the hydrolysis constants determined in 3 M $NaClO_4$ by Grenthe and Lagerman (1991) and were corrected to 0.5 M $NaClO_4$ (Grenthe *et al.*, 1992) .

The ion interaction model of Pitzer has been developed, extending to high concentration, and applied satisfactorily by Felmy *et al.* (1997) to describe, on the basis of the above equilibria, the solubility data obtained by both Rai *et al.* (1995) and Östhols *et al.* (1994) in the aqueous Na^+–HCO_3^- – CO_3^{2-}–OH^-–ClO_4^- –H_2O system. They have estimated $\log K^\circ_{105}$ to be 37.6 and log K°_{131} to be 6.78; these values are identical or close to those previously determined by Östhols *et al.* (1994). However, a considerable uncertainty in the determination of the value for $\log K^\circ_{105}$, due to the introduction of large mixing terms with the bulk anionic species, has been outlined by the authors.

The effect of phosphate on the solubility of microcrystalline ThO_2 has been observed to be very limited (Östhols, 1995). The only data for which there is a significant deviation from the solubility of ThO_2(am) as predicted in the absence of phosphates, are those obtained in 0.1 M phosphate solutions in the pH range 10.5–13. Here, a small increase in solubility has been found. However, an analysis of the solid phase has shown a small but significant phosphate content. This suggests the formation of a sparingly soluble thorium phosphate in the experiments, meaning that there will eventually be a decrease of the thorium solubility in the presence of excess amounts of phosphate.

It has been concluded from other solubility measurements (Fourest *et al.*, 1999) carried out on a synthesized thorium phosphate–diphosphate, $Th_4(PO_4)_4P_2O_7$ (incorrectly named 'Th orthophosphate' in a previous study (Baglan *et al.*, 1994)) that the total concentration of Th(IV) in solution ($-3 < \log [Th] < -7$ for $0 < pH < 5$) is mainly controlled by the precipitation of two compounds: $Th(HPO_4)_2$ in acidic media ($pH < 4.5$) and $Th(OH)_4$ in basic and near-neutral media. However, more recently, Thomas *et al.* (2000) and Brandel *et al.* (2001b) have characterized by electron probe microanalysis (EPMA), XRD, IR, TGA, and DTA, the crystallized phase formed during the dissolution of $Th_4(PO_4)_4P_2O_7$, when the saturation of the leachate is reached. They have shown that the thorium concentration in phosphate-containing solutions is controlled by the precipitation of the thorium phosphate–hydrogenphosphate hydrate, $Th_2(PO_4)_2(HPO_4) \cdot H_2O$, which has a very low solubility product: $\log K^\circ_{sp} = -(66.6 \pm 1.2)$ (Thomas *et al.*, 2001).

3.8.6 Complexation

(a) Inorganic ligands

To our knowledge, the formation of Th(IV) complexes with most of the common inorganic ligands, such as F^-, Cl^-, SO_4^{2-}, andNO_3^{2-}, has not been re-investigated recently (Hogfeld, 1982). The stability constants of the corresponding equilibria, collected in Table 3.16, are those previously reported by Langmuir and Herman (1980) in their review paper. From these values, it can be concluded that weak 1:1 complexes are formed with chloride and nitrate anions and that higher order complexes, even if they have been pointed out in the literature (Langmuir and Herman, 1980; Fuger *et al.*, 1992), are unimportant. Colin-Blumenfeld (1987) has thus shown, through thermodynamic calculations, that $Th(NO_3)_2^2+$ can only exist in acidic solutions (pH < 3.2) containing high concentrations of nitrates (>0.1 M). Similarly, $Th(Cl)_2^{2+}$ is expected to be found only at pH < 4 and for $[Cl^-]_{tot} > 0.5$ M (Colin-Blumenfeld, 1987).

On the contrary, strong complexes of Th(IV) are formed with F^- and SO_4^{2-} and particularly with carbonate and phosphate ligands which are known to appreciably affect the speciation of Th(IV) in natural waters. A very strong complexation of Th(IV) by the HPO_4^{2-} species is indicated by the stability constants published by Moskvin *et al.* (1967) (see Table 3.16). These data are found in many databases used for geochemical modeling, but they were derived from solubility of an ill-defined solid thorium phosphate in acidic phosphate media (hydrogen concentration of 0.35 M). They cannot explain the ThO_2 solubility results obtained by Östhols (1995). Moreover, extraction experiments by acetylacetone in the two-phase system 1 M $Na(H)ClO_4$/toluene carried out by Engkvist and Albinsson (1994) at pH 8 and 9 (HPO_4^{2-} being thus the dominant species) give cumulative stability constants of Th^{4+}/HPO_4^{2-} much lower than the values published earlier; these new β values suffer, however, from large uncertainties.

The stability constants known for $Th^{4+}/H_2PO_4^-$ and Th^{4+}/H_3PO_4, and reported in Table 3.16, are those collected by Langmuir and Herman (1980). They have not been checked by subsequent studies, but their role is of minimal importance in the speciation of thorium in neutral and basic media. No data have been published on the complexation of Th^{4+} by the PO_4^{3-} ions, except the following equilibrium proposed by Östhols (1995):

$$Th^{4+} + 4H_2O + PO_4^{3-} \leftrightarrow Th(OH)_4PO_4^{3-} + 4H^+ \quad \log K = -(14.90 \pm 0.36)(0.35\ \text{M})$$

Finally, mention can be made of the study of Fourest *et al.* (1994). The solubility curves obtained by equilibrating solid thorium phosphate-diphosphate and highly concentrated phosphate solutions have led to the determination of $ThO(HPO_4)_3(H_2PO_4)^{5-}$ and $ThO(HPO_4)_3(H_2PO_4)_2^{6-}$ as the presumed complex forms of Th(IV) at pH 6–7 and for $0.3 < [PO_4]_{tot} < 0.8$ and $0.8 < [PO_4]_{tot} < 1.5$ M, respectively.

[b] Derived by using the K°_{sp} value of Ryan and Rai (1987) given in Table 3.15.

Despite the studies mentioned above, the thermodynamic database for tetravalent actinides remains rather poor for the complexation with inorganic anions, such as carbonate, phosphate, sulfate, fluoride, and chloride, which are dominant in natural aquatic systems. Consequently, a new semiempirical approach (based on an energy term describing the interligand electrostatic repulsion) has been developed by Neck and Kim (2000) with a first application for the mononuclear complexes with a high number of carbonate ligands. For such a ligand, this model predicts a slight decrease from $\log\beta_4^{\circ}$ to $\log\beta_5^{\circ}$ and a strong decrease from $\log\beta_5^{\circ}$ to $\log\beta_6^{\circ}$. Hence the pentacarbonate complex is expected to be the limiting Th(IV)–carbonate complex at high carbonate concentration. Moreover, the existence of $Th(CO_3)_5^{6-}$ has been confirmed by several experiments using various methods: cryoscopy, conductometry, and ionic exchange (Dervin and Faucherre, 1973a), solvent extraction followed by neutron activation (Joao *et al.*, 1987, 1995), solubility of amorphous or microcrystalline ThO_2 (Rai *et al.*, 1995; Felmy *et al.*, 1997; Östhols *et al.*, 1994) and X-ray absorption (Felmy *et al.*, 1997). The pentacarbonate complex structure is also well established in solid phase investigations (Voliotis and Rimsky, 1975). The stability constant values published in the frame of these works for the corresponding reaction:

$$Th^{4+} + 5CO_3^{2-} \leftrightarrow Th(CO_3)_5^{6-}$$

are collected in Table 3.16. The value obtained by Joao *et al.* (1987) recalculated by taking into account the complex really formed between Th(IV) and ethylenediaminetetraacetic acid (EDTA) at high pH (Th(OH)Y and not ThY) (Östhols *et al.*, 1994) is in general agreement with the value estimated by these authors. The estimation of Faucherre and Dervin (1962) from measurements of freezing point depressions is open to criticism, because only the dominant reaction is postulated and Th(IV) hydrolysis is neglected in the data treatment. The remaining values (Östhols *et al.*, 1994; Rai *et al.*, 1995; Felmy *et al.*, 1997) depend on the hydrolysis constants applied for their evaluation.

X-ray absorption spectroscopy (XAS) data (Felmy *et al.*, 1997) have clearly shown a change in speciation at low bicarbonate concentrations (0.01 M solution), but the total thorium concentration was too low to allow a definitive identification of the species. Solubility data of amorphous or microcrystalline ThO_2 have been most satisfactorily explained by the introduction of a mixed $Th(OH)_3CO_3$ (Östhols *et al.*, 1994; Felmy *et al.*, 1997) with $\log K^\circ_{131} = 41.5$ (see Table 3.16).

(b) Organic ligands

The organic species, such as oxalate ($C_2O_4^{2-}$), citrate ($C_6H_5O_7^{3-}$), and EDTA ($C_{10}H_{12}O_8N_2^{4-}$), form strong complexes with thorium and ‘organic’ complexation can predominate in natural waters over ‘inorganic’ by orders of magnitude, even when the concentrations of organic ligands are low as compared with inorganic ones (Langmuir and Herman, 1980).

The interaction of Th(IV) with citrate has been investigated both by potentiometry in 0.1 M chloride solution (Raymond *et al.*, 1987) and solvent extraction (thenoyltrifluoro-acetone [TTA] or dibenzoylmethane [DBM] in toluene) in perchlorate (0.1–14 M $NaClO_4$; pH: 1.8–4.0) and chloride (0.1–5.0 M NaCl; pH: 3) solutions (Choppin *et al.*, 1996). The former study covers a wider pH range (pH: 1–6) and a larger set of stability constants has been derived from the results than in the latter one. However, attention should be paid to the choice of hydrolysis constants used to fit the results. Moreover, the contribution of mixed hydroxy species, not yet identified, can be expected to be more important in basic media. Nevertheless, a relatively good agreement is observed for the two $Th(Cit)^+$ formation constants (see Table 3.17).

The Th(IV)/oxalate constants determined by using solvent extraction techniques (TTA and bis(2-ethylhexyl)phosphoric acid [HDEHP] in toluene; pH: 1.3–4.0; $I = 1, 3, 5, 7$, and 9 M) (Erten *et al.*, 1994) appear somewhat different from the values previously obtained from solubility measurements, but the approach of Moskvin and Essen (1967) has already been subjected to some criticism in the case of the phosphate ligands (Östhols, 1995).

Other anions of organic acids, such as formate, acetate, chloroacetate, tartrate, malate, salicylate, sulfosalicylate, and so on, form complexes with Th(IV). They are too numerous to be listed in Table 3.16, but the corresponding stability constants can be found in various compilations: Sillen and Martell (1964, 1971), Perrin (1982), or the most recent database issued by the National Institute of Standards and Technology (NIST, 2002).

Humic and fulvic acids have been identified as efficient complexing agents for ions such as Th^{4+}. Their influence on thorium mobilization in natural waters have been discussed in several publications (Choppin and Allard, 1985; Cacheris and Choppin, 1987; Miekeley and Küchler, 1987). The Th(IV)–humate complex has been recently analyzed by X-ray photoelectron spectroscopy (XPS)

(Schild and Marquardt, 2000). The XPS study corroborates EXAFS results (Denecke *et al.*, 1999) according to which Th(IV) is predominantly bound to carboxylic groups of humic acids.

3.8.7 Analytical chemistry

As Chapter 30 is devoted to trace analysis of actinides in geological, environmental, and biological matrices, only summarized considerations will be given here, centered on the determination of thorium in natural waters. Extensive information on the techniques used in analytical chemistry of thorium, including the 'classical' gravimetric, titrimetric, and photometric methods, is also given in the *Gmelin Handbook* (1990b).

Because of its low solubility and its ability to be sorbed as hydroxo complexes, the concentration of thorium in natural waters is, in general, below 0.1 μg L^{-1} and its quantitative determination is difficult. The most important analytical methods for the determination of Th(IV) in the range of low concentrations have been compiled and discussed by Hill and Lieser (1992). In most cases, a preconcentration step – coprecipitation, solvent extraction, and/or ion exchange separation – is performed prior to the measurement.

Inductively coupled plasma mass spectrometry (ICP-MS) is the most sensitive method with usual limits of detection around 0.01 μg kg^{-1} (Gray, 1985) and a reported limit value as low as 0.2 ng kg^{-1} (Chiappini *et al.*, 1996), but this method needs costly pieces of equipment. Two other methods exhibit low detection limits (0.1 μg kg^{-1}) and are well suited for routine analysis (Hill and Lieser, 1992):

- Spectrophotometry, with the procedure described by Keil (1981) coupling preliminary extraction and Th(IV) complexation with arsenazo;
- Voltammetry, with the procedure reported by Wang and Zadeii (1986) using a chelating reagent (with a concentration to be optimized).

However, in practical applications, drawbacks are encountered with both methods due to the presence of uranium and aluminium, respectively. To avoid these drawbacks, a selective preconcentration of Th(IV) is thus necessary (Hill and Lieser, 1992).

Gamma- and alpha-spectrometries, with sensitivity around 1 μg kg^{-1} (Singh *et al.*, 1979; Kovalchuk *et al.*, 1982; Jiang and Kuroda, 1987), are essentially used for isotopic determinations. However, these standard radiochemical techniques require preconcentration and long counting times. ^{228}Th can be determined from two successive gamma-measurements of the ^{224}Ra daughters, but a delay of 20 days is necessary to obtain reliable results for ^{228}Th (Surbeck, 1995). The chemical separation techniques for the classical alpha-spectrometry have been reviewed by De Regge and Boden (1984). These techniques often need optimization because around 50% of the initial activity can be lost at the chemical separation stage (Vera Tomé *et al.*, 1994). Liquid scintillation spectrometers, which allow discrimination between alpha and beta decays, and are commercially available, offer, in combination with selective extractive scintillators, a more advantageous solution to the problem of the isotopic determination of ^{232}Th, ^{230}Th, and ^{228}Th, in spite of a low-energy resolution compared to alpha-spectrometry (Dacheux and Aupiais, 1997). With the PERALS (name registered to Ordela, Inc.) system, a limit of detection as low as 0.2 μg kg^{-1} can be reached for ^{232}Th [value obtained for 250 mL and 3 days of counting (Dacheux and Aupiais, 1997)]. Moreover, PERALS spectrometry can be associated to six short liquid–liquid extraction steps to isolate Th from other actinides (U, Pu, Am, and Cm) prior to its detection at very low levels (the use of spikes during the chemical procedure is necessary for complex matrices).

CHAPTER FOUR

PROTACTINIUM

Boris F. Myasoedov, H. W. Kirby, and Ivan G. Tananaev

4.1 INTRODUCTION

Protactinium, element 91, is one of the most rare of the naturally occurring elements and may well be the most difficult of all to extract from natural sources. Protactinium is, formally, the third element of the actinide series and the first having a 5f electron. The superconducting properties of protactinium metal provide clear evidence that Pa is a true actinide element (Smith *et al.*, 1979). Its chemical behavior in aqueous solution, however, would seem to place it in group VB of the Mendeleev's table, below Ta and Nb.

The predominant oxidation state is 5+. Pa(v) forms no simple cations in aqueous solution and, like Ta, it exhibits an extraordinarily high tendency to undergo hydrolysis, to form polymers, and to be adsorbed on almost any available surface. These tendencies undoubtedly account for the many reports of erratic and irreproducible behavior of protactinium as well as for its frustrating habit of disappearing in the hands of inexperienced or unwary investigators. A useful review of the chemical properties of Pa important in an analytical context has been made by Pal'shin *et al.* (1970) and Myasoedov *et al.* (1978).

The most important natural isotope is ^{231}Pa, but the industrial importance of Pa stems chiefly from the role of its artificial isotope, ^{233}Pa, as an intermediate in the production of fissile ^{233}U in thorium breeder reactors. It was, in fact, the need for a relatively stable isotope that could be used for macroscopic chemical studies, which was responsible for the revival of interest in the recovery of ^{231}Pa from natural sources (Katzin, 1952). The result has been a rapid growth in our understanding of Pa chemistry, as summarized in numerous critical review articles (Gmelin, 1942, 1977; Elson, 1954; Katz and Seaborg, 1957; Haïssinsky and Bouissières, 1958; Kirby, 1959; Salutsky, 1962; Brown and Maddock, 1963; Sedlet, 1964; Guillaumont and deMiranda, 1966; Keller, 1966a; Brown and Maddock, 1967; Guillaumont *et al.*, 1968; Brown, 1969; Muxart *et al.*, 1969; Muxart and Guillaumont, 1974; Morgan and Beetham, 1990), books (Cotton *et al.*, 1999) and presentations (Weigel 1978; Jung *et al.*, 1993; Greenwood and Earnshaw 1997; Sime, 1997).

4.1.1 Discovery of protactinium

During the preparation of the periodic table Mendeleev (1872) placed in the vacant space in group V between Th(IV) and U(VI) an unknown hypothetical element No. 91 named 'eka-tantalum' with atomic mass of about 235, and chemical properties similar to Nb and Ta. Forty years later, Russell (1913), Fajans (1913a,b), and Soddy (1913a,b) independently proposed the radioactive displacement principles, i.e. two simple rules for reconciling the chemical and radioactive properties of the 33 radioelements known at that time: (1) if a radioelement emits an α particle, its position in the Mendeleev's table is shifted two places to the left, or (2) if it emits a β^--particle, its position is shifted one place to the right. When the rules were applied systematically, there was one obvious discrepancy: the only known link between ^{238}U and ^{234}U, both in group VI, was element UX, a β^--emitter whose chemistry was identical with that of thorium, in group IV. It was necessary to postulate the existence of an unknown β^--emitter, in the space in the periodic table reserved by Mendeleev (1872).

Before the end of 1913, Fajans and his student, Göhring, had shown that element UX was actually a mixture of two distinct radioelements: UX_1 (^{234}Th) and UX_2 (^{234m}Pa), which gave off hard β^--rays, had a half-life of 1.15 min, and was chemically similar to Ta (Göhring, 1914a,b). They named the new element, '*brevium*' (Bv) (*brĕvis* (Latin): short, brief), because of its short half-life (Göhring, 1914b).

An analogous problem existed with respect to the origin of actinium (Göhring, 1914a). It was clear that Ac could not be a 'primary' radioelement, because its half-life was only about 30 years (Curie, 1911). On the other hand, although there was a constant ratio of Ac to U in nature (Boltwood, 1906, 1908), Ac could not be part of the main U–Ra series, because the ratio was far too low. According to the displacement laws, Ac, in group III, could only be the product either of a β^--emitter in group II or of an α-emitter in group V. The first possibility was eliminated when Soddy (1913b) proved that Ra, the only group II element in the U–Ra series, was not the parent of Ac. The only remaining alternative was an α-emitting isotope of UX_2.

In 1913, Soddy had reported the growth of Ac in two lots of UX, separated from 50 kg of uranium 4 years earlier (Soddy, 1913a). This suggested that Ac was being produced from UX 'through an intermediate substance'. Five years later Soddy and Cranston (1918) [see also Sackett (1960)] had confirmed the growth beyond doubt and had separated the parent of Ac by sublimation from pitchblende in a current of air containing CCl_4 at incipient red heat. This method was later applied by Malm and Fried (1950, 1959) to the separation of ^{233}Pa from neutron-irradiated ^{232}Th.

Almost simultaneously, Hahn and Meitner (1918) reported their independent discovery of the parent of Ac in the siliceous residue resulting from the treatment of pulverized pitchblende with hot concentrated HNO_3. They proposed the name, *protactinium*. Preliminary estimates indicated that the half-life of the new isotope was between 1200 and 180 000 years. Since the name, *brevium*, was obviously inappropriate for such a long-lived radioelement, Fajans and Morris (1913) proposed that the name of element-91 be changed to *protactinium* (linguistic purists at first insisted on calling it *protoactinium*, because '*proto* is better Greek' (Grosse, 1975), but the name *protactinium* (Pa) was restored officially in 1949 (Anonymous, 1949)).

There was still no direct evidence as to the origin of protactinium. In 1911, Antonoff (1911) had separated uranium Y – UY (^{231}Th) from a purified U solution. UY was chemically similar to Th and Antonoff (1913) suggested that this might be the point at which the Ac series branched off from the U series. In 1917, Piccard (1917) suggested that, in addition to the two known isotopes of uranium, uranium I and II (UI and UII), there might also exist a third long-lived isotope, actinouranium (AcU). AcU would decay by α-emission to yield UY, which, in turn, would decay by β^--emission to give an isotope of *brevium*. Piccard's hypothesis was confirmed experimentally in 1935, when Dempster (1935) discovered AcU (^{235}U) by mass spectrography.

4.1.2 Isolation of protactinium

The new element was isolated for the first time in 1927, when Grosse (1927, 1928) reported that he had prepared about 2 mg of essentially pure Pa_2O_5. By the end of 1934, Grosse with Agruss had developed a process for the large-scale recovery and purification of Pa (Grosse, 1934a; Grosse and Agruss, 1934, 1935a). They had isolated more than 0.15 g of Pa_2O_5, reduced it to the metal, and determined its atomic weight to be 230.6 ± 0.5 (Grosse, 1934b). In the same year, Graue and Kading (1934a,b) recovered 0.5 g of pure Pa (as K_2PaF_7) from 5.5 tons of pitchblende residues, an achievement that would not be equaled, let alone surpassed, for the next quarter of a century.

The development of atomic energy led to the processing of most of the world's known reserves of high-grade uranium ores and to the accumulation of vast stockpiles of process wastes. Among these, at the Springfields refinery of the United Kingdom Atomic Energy Authority (UKAEA) was the '*ethereal sludge*', a siliceous precipitate that had separated during the ether extraction of U from dilute HNO_3 solution. This material, amounting to some 60 tons, contained about 4 ppm of Pa, or more than ten times its equilibrium concentration in unprocessed pitchblende. Since the sludge also contained about 12 tons of U, it was economically attractive to recover both elements, with most of the development and production cost being borne by the U recovery. The process that was finally adopted yielded 127 g of 99.9% pure ^{231}Pa (Goble *et al.*, 1958; Nairn *et al.*, 1958; Jackson *et al.*, 1960a,b; Collins *et al.*, 1962; Hillary and Morgan, 1964) at a cost of about US$500 000 (CRC Handbook, 1997).

The UKAEA has generously made its stockpile of Pa available to the rest of the world at nominal cost, thereby touching off intensive investigation of Pa chemistry at many laboratories. Thanks to this concentrated effort, the new era in Pa research that started in the mid-1950s has now reached maturity. Three international conferences were convened, devoted entirely to the chemical, physical, and nuclear properties of Pa (Oak Ridge National Laboratory, 1964; Bouissières and Muxart, 1966; Born, 1971).

4.2 NUCLEAR PROPERTIES

At present, there are 29 known isotopes of Pa (Table 4.1), but only three are of particular significance to chemists. They are the naturally occurring isotopes, ^{231}Pa and ^{234}Pa, and reactor-produced ^{233}Pa. The characteristics of α-decay of Pa isotopes with mass numbers (A) till 224 were presented by Andreev *et al.* (1996b). Hyde (1961, undated) and Hyde *et al.* (1964) had exhaustively reviewed the nuclear properties of all the isotopes with A ranging from 225 to 237.

A new nuclide ^{239}Pa produced recently by multi-nucleon transfer reactions ^{238}U(p,2n)^{239}Pa (Yuan *et al.*, 1996). Protactinium was chemically separated from the uranium target and other produced elements. From the ^{239}Pa β^--decay a half-life of (106 ± 30) min was observed.

For details concerning the more recently discovered isotopes, the reader should consult the original references (Meitner *et al.*, 1938; Ghiorso *et al.*, 1948; Gofman and Seaborg, 1949; Hyde *et al.*, 1949; Meinke *et al.*, 1949, 1951, 1952, 1956; Harvey and Parsons, 1950; Barendregt and Tom, 1951; Keys, 1951; Browne *et al.*, 1954; Crane and Iddings, 1954; Zijp *et al.*, 1954; Wright *et al.*, 1957; Hill, 1958; Arbman *et al.*, 1960; Takahashi and Morinaga, 1960; Albridge *et al.*, 1961; Baranov *et al.*, 1962; Bjørnholm and Nielsen, 1962, 1963; Subrahmanyam, 1963; Wolzak and Morinaga, 1963; McCoy, 1964; Bastin *et al.*, 1966; Bjørnholm *et al.*, 1968; Hahn *et al.*, 1968; Trautmann *et al.*, 1968; Briand *et al.*, 1969; Borggreen *et al.*, 1970; dePinke *et al.*, 1970; Laurens *et al.*, 1970; Varnell, 1970; Holden and Walker, 1972; Sung-Ching-Yang *et al.*, 1972; Lederer and Shirley, 1978; Folger *et al.*, 1995; Yuan *et al.*, 1995, 1996; Andreev *et al.*, 1996a; Nishinaka *et al.*, 1997).

4.2.1 Protactinium-231

^{231}Pa, an α-emitter with fixed atomic weight 231.03588 ± 0.0002 (Delaeter and Heumann, 1991), is a member of the naturally occurring ^{235}U decay ($4n + 3$) chain. It is the daughter of ^{231}Th and the parent of ^{227}Ac, from which it derives

its name (Fig. 4.1). Reported half-lives have ranged from 32 000 years ± 10% (Grosse, 1932) to (34 300 ± 300) years (Van Winkle *et al.*, 1949); three recent determinations (Kirby, 1961; Brown *et al.*, 1968a; Robert *et al.*, 1969) yield a weighted average of (32 530 ± 250) years (at the 95% confidence level). Therefore ^{231}Pa is the only isotope easy to access in multi-gram quantities. The thermal-neutron cross section is (211 ± 2) barn (Simpson *et al.*, 1962; Gryntakis and Kim, 1974). The spontaneous fission half-life is 1.1×10^{16} years (Segrè, 1952), which gives the correlation of 0.3 of a fission per 1 g Pa per min.

The complex fine structure of the ^{231}Pa alpha-spectrum can be resolved with a passivated implanted planar silicon detector (Fig. 4.2). Baranov *et al.* (1962, 1968), using a double-focusing magnetic spectrometer, found at least 19 α-groups with energies ranging from 4.51 to 5.06 MeV and additional low-abundance groups have been detected by α–γ coincidence measurements (Lange and Hagee, 1968). Predictably, the γ-ray spectrum, as recorded with a high-resolution Ge detector, is even more complex (Fig. 4.3): 92 γ-rays have been reported, with energies up to 609 keV (dePinke *et al.*, 1970; Leang, 1970). A detailed level scheme is given in the critical compilation by Artna-Cohen (1971). The prominent γ photopeak at 27.35 keV is easily detectable even with a NaI(Tl) crystal; it uniquely identifies ^{231}Pa in the presence of other naturally occurring γ-emitters (Fig. 4.4).

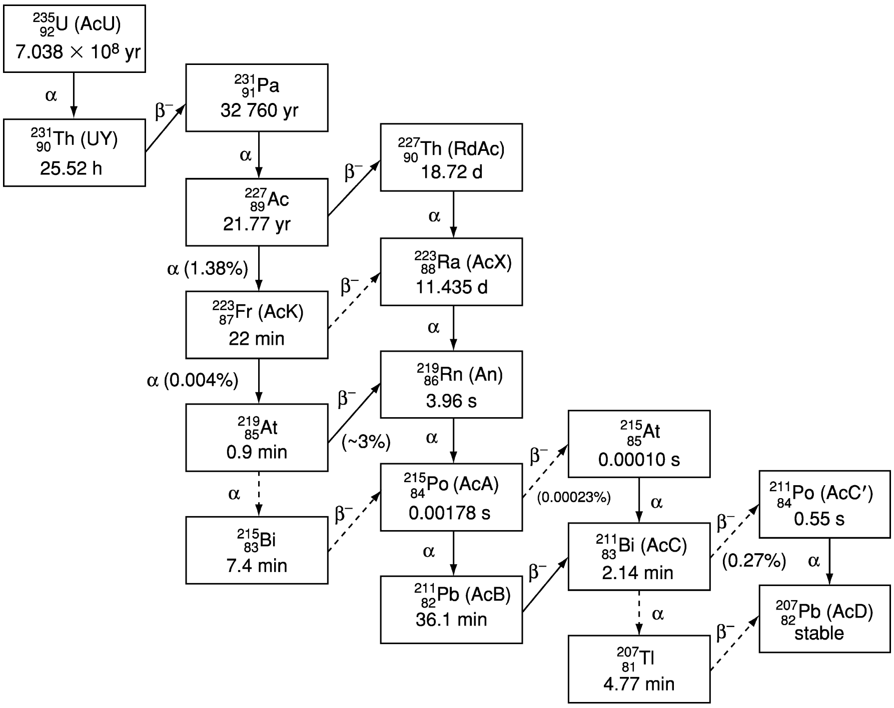

Fig. 4.1 *Uranium–actinium series* (4*n* + 3).

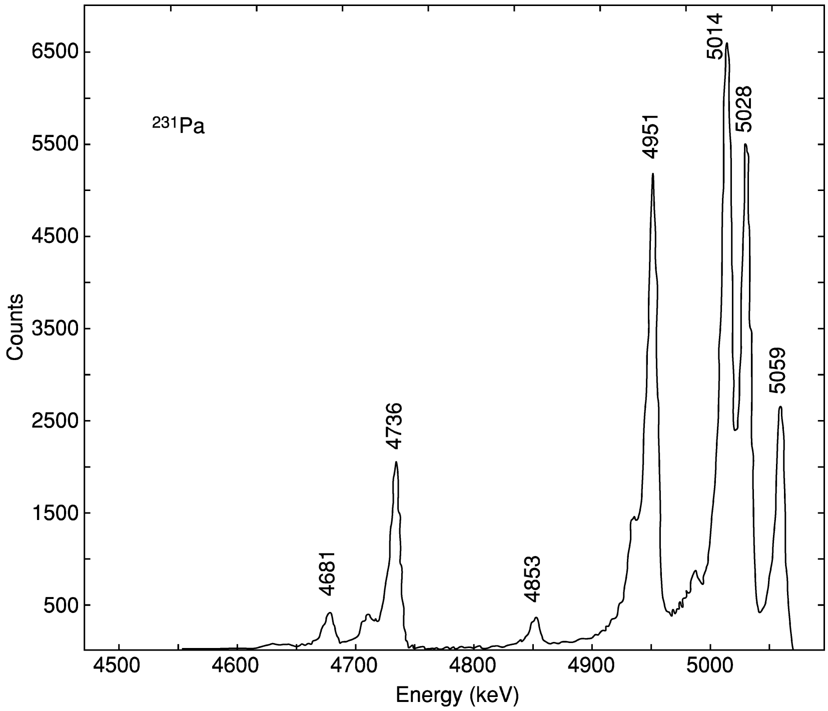

Fig. 4.2 *Alpha-spectrum of* ^{231}*Pa measured with a passivated implanted planar silicon detector* (*Ahmad,* 2004).

^{231}Pa can be separated from reprocessed U ores, or alternatively, produced by either of the two nuclear reactions: ^{232}Th(n,2n)^{231}Th (Nishina *et al.*, 1938) or ^{230}Th(n,γ)^{231}Th (Hyde, 1948). In principle, this would eliminate many of the problems attendant on the isolation of ^{231}Pa. However, neutron irradiation of ^{232}Th yields large amounts of ^{233}Pa and other undesirable contaminants, but relatively little ^{231}Pa (Table 4.2) (Schuman and Tromp, 1959; Codding *et al.*, 1964). The ^{230}Th route is only superficially more attractive, since the richest sources of ^{330}Th found thus far in U refinery waste streams and residues have always been associated with at least eight times as much ^{232}Th (Figgins and Kirby, 1966). Protactinium was not formed in the amalgam and could be also separated from thorium (David and Bouissières, 1966).

4.2.2 Protactinium-233

^{233}Pa is the only artificial isotope of Pa thus far produced in weighable amounts; the first gram was isolated in 1964 by a group at the National Reactor Testing Station in Idaho (Codding *et al.*, 1964). ^{233}Pa derives its importance from the

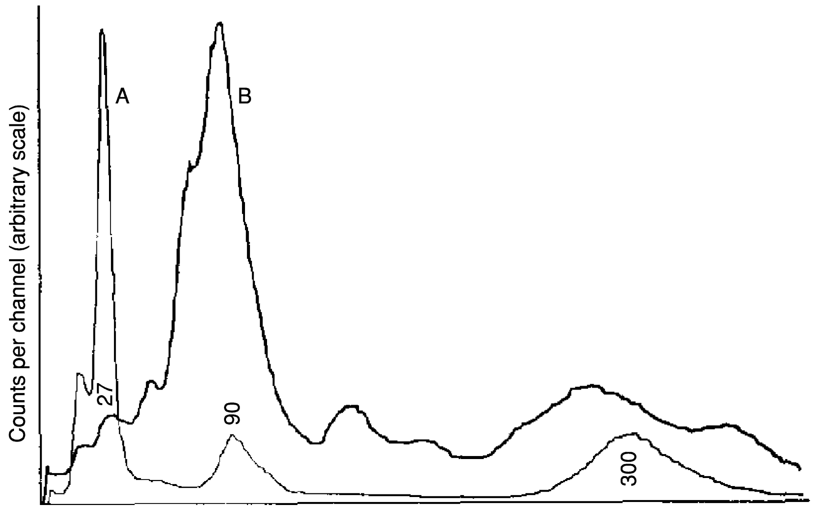

Fig. 4.4 *γ-Ray spectrum of ^{231}Pa observed with a NaI(Tl) crystal: curve A, freshly purified ^{231}Pa; curve B, raw material (~0.3 ppm ^{231}Pa).*

Table 4.2 *Calculated composition of* 100 g *of* ^{232}*Th after thermal-neutron irradiation* (*Codding* et al., 1964) (*thermal flux* = 5 × 10^{14} n $cm^{-2}s^{-1}$; *resonance flux* = (*thermal flux*)/12; *nvt* = 1.2 × 10^{21} n cm^{-2}).

Nuclide	*Amount*
^{231}Pa	98.6 g
^{232}Th	~1 mg
^{233}Pa	950 mg
^{233}U	320 mg
^{235}U	65 mg
^{235}U	5 mg
fission products	60 mg

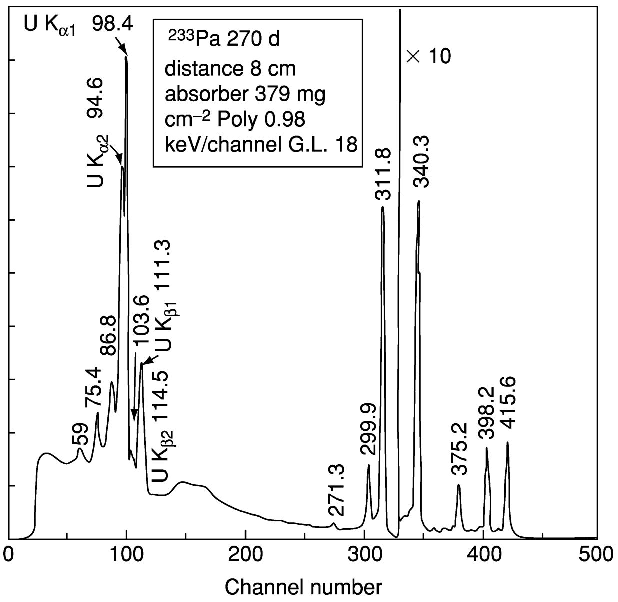

Fig. 4.5 *γ-Ray spectrum of* ^{233}*Pa observed with a Ge*(*Li*) *detector. Reproduced from Crouthamel* et al. (1970) *with permission from Pergamon Press.*

fact that it is an intermediate in the production of fissile ^{233}U. The reaction, discovered in 1938 by Meitner *et al.* (1938) (Sime, 1997) is:

$$^{232}\text{Th}\,(\text{n},\gamma)\,^{233}\text{Th}\,(\beta^-;22\ \text{min}) \rightarrow {}^{233}\text{Pa}(\beta^-;\ 27\,\text{days}) \rightarrow {}^{233}\text{U}$$

^{233}Pa has largely replaced ^{234}Pa as a tracer because of its favorable half-life (26.95 ± 0.06) days (Wright *et al.*, 1957), its relative ease of preparation (cf. Table 4.2), and its readily detectable gamma spectrum (Fig. 4.5). Using this isotope a large volume of important data on protactinium chemistry had been provided.

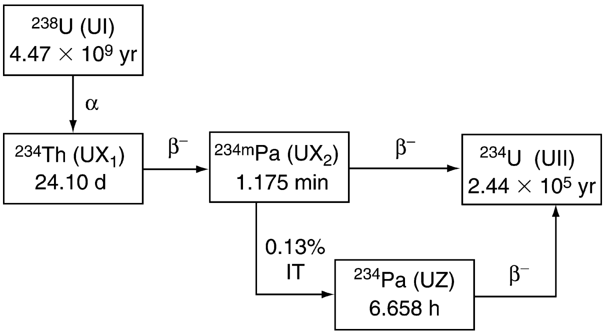

Fig. 4.6 *Genetic relationships of the* UX_1*–*UX_2*–UZ complex.*

4.2.3 Protactinium-234

The nuclide ^{234}Pa occurs naturally in two isomeric forms: ^{234m}Pa, discovered by Fajans and Göhring (1913a,b), and ^{234}Pa, discovered afterward by Hahn (1921). Their genetic relationships are indicated in Fig. 4.6. Both are β^--emitters, decaying to ^{234}U, but ^{234m}Pa is metastable and, in 0.13% of its disintegrations, it decays to its ground state by isomeric transition, yielding ^{234}Pa (Bjørnholm and Nielsen, 1963). The extraordinarily complex decay scheme of ^{234}Pa (Ellis, 1970; Ardisson and Ardisson, 1975) is difficult to study, because the intense sources needed for high-resolution spectrometry are not readily available. However, 0.8 Ci of ^{234}Th was extracted from several tons of ^{238}U, making possible the definitive study by Bjørnholm *et al.* (1967, 1968). The gamma-spectrum of ^{234}Pa (in equilibrium with ^{238}U and ^{234}Th) is shown in Fig. 4.7 (Crouthamel *et al.*, 1970).

4.3 OCCURRENCE IN NATURE

Since the half-life of ^{231}Pa is short in geological terms, its natural occurrence is closely tied to that of ^{235}U, its primordial ancestor. Uranium isotopes are widely distributed in the Earth's crust (Kirby, 1974). The average crustal abundance of U is 2.7 ppm (Taylor, 1964), of which 0.711 wt% is ^{235}U (Grundy and Hamer, 1961); therefore, the natural abundance of ^{231}Pa (calculated from its half-life and that of ^{235}U) is 0.87×10^{-6} ppm – only slightly less than that of ^{226}Ra. Assuming that the crustal mass (to a depth of 36 km) is 2.5×10^{25} g (Heydemann, 1969), the global inventory of ^{231}Pa is 2.2×10^7 metric tons.

The pronounced hydrolytic tendency of Pa is the basis of a method for dating marine sediments less than 10^6 years old (Sackett, 1960; Roshalt *et al.*, 1961, 1962; Sakanoue *et al.*, 1967; Thomson and Walton, 1971, 1972; Kirby, 1974). In an undisturbed geological formation, thematic Pa:U = 3.2×10^{-7}, but this ratio

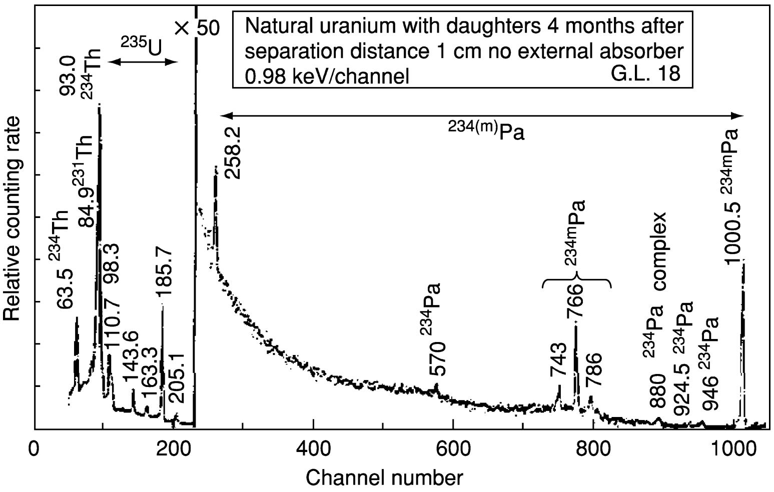

Fig. 4.7 *γ-Ray spectrum of* UX_1*–*UX_2*–UZ in equilibrium with* ^{238}U*. Reproduced from Crouthamel* et al. (1970) *with permission from Pergamon Press.*

is altered when the deposit is leached with groundwater and the U is carried to sea. At the pH of seawater, both Pa and Th hydrolyze and deposit together on the ocean floor, leaving the U in solution as UO_2^{2+}. Because ^{231}Pa and ^{230}Th decay moved at different rates, their ratio at various depths can be used to determine the rate of sedimentation.

^{231}Pa/^{235}U ages were also determined for 17 carnotites from two areas in Israel (Kaufman *et al.*, 1995). For the determination of ^{231}Pa in solids, a new method, more than ten times more precise than those determined by decay counting, based on thermal ionization mass spectroscopy (TIMS) of protactinium in carbonates was created. Carbonates between 10 and 250 000 years old can now be dated with this ^{231}Pa method. Barbados corals that have identical ^{231}Pa and ^{230}Th ages indicate that the timing of sea level change over parts of the last glacial cycle is consistent with the predictions of the Astronomical Theory (Edwards *et al.*, 1997).

^{233}Pa has not itself been detected in nature, but traces of both ^{237}Np, its parent, and ^{225}Ac, its descendant, have been identified in a U refinery waste stream (Peppard *et al.*, 1952). It may, therefore, be inferred that ^{233}Pa is being continually formed in nature by the reaction:

$$^{238}\mathrm{U}\,(\mathrm{n},2\mathrm{n})\,^{237}\mathrm{U}\,(\beta^-;\ 6.75\,\mathrm{days}) \rightarrow {}^{237}\mathrm{Np}\,(\alpha;\ 2.14\times10^6\,\mathrm{years}) \rightarrow {}^{233}\mathrm{Pa}.$$

The natural neutron output in pitchblende is about 0.05 ng^{-1} s^{-1}, attributable about equally to spontaneous fission of ^{238}U and (α,n) reactions of light elements (McKay, 1971).

4.4 PREPARATION AND PURIFICATION

No large-scale separation of ^{231}Pa has ever been made from virgin ores because the element has little commercial value. Weighable amounts of Pa have always been obtained from U refinery residues. Indeed, the economic realities are such that it is rarely possible even to optimize the segregation of Pa in a single waste stream or residue. More typically, the Pa is fractionated at every stage in the beneficiation and extraction of U from its ores.

Before the development of atomic energy, pitchblende ores were processed primarily for their Ra content. The pulverized ore, after being roasted with Na_2CO_3, was leached with aqueous solutions of H_2SO_4 or HNO_3 (or both) and the acid-insoluble material was digested with NaOH or Na_2CO_3 solutions. The residue was then leached with hydrochloric acid to recover the Ra (Curie, 1913). The final residue retained a greater or lesser fraction of the original Pa according to the relative proportions of the acids used in the digestion; a higher H_2SO_4 concentration and higher total acidity favored the dissolution of Pa (Reymond, 1931). This *Rückrückstände,* or 'residue of residues', was the raw material used by Hahn and Meitner (1918) for their discovery of ^{231}Pa, by Grosse (1927, 1928) in the isolation of the first milligram amounts, and by Graue and Kading (1934a) in the recovery of 0.5 g of the element. The analysis of one such residue is given in Table 4.3.

During and after World War II, an ether extraction process was used for the purification of U. The acid solution resulting from the ore digestion was treated with Na_2CO_3 to precipitate some of the less basic metals, while leaving the U in solution as a carbonate complex. Katzin *et al.* (1950) found that the carbonate precipitate contained 0.30–0.35 ppm of Pa and subsequent processing of this material yielded about 25 mg of pure Pa (Kraus and Van Winkle, 1952; Larson *et al.*, 1952; Thompson *et al.*, 1952). When the process was modified to eliminate the carbonate precipitation, the Pa passed through the ether extraction step into the aqueous raffinate, from which Elson *et al.* (1951) recovered 35 mg of pure material.

A later modification produced a precipitate in the aqueous waste stream, which, according to Salutsky *et al.* (1956), carried down nearly all the Pa. This material was periodically filtered off and eventually yielded a total of about 2 g of Pa (Kirby, 1959; Hertz *et al.*, 1974; Figgins *et al.*, 1975).

The aqueous raffinate from the ether extraction was treated with lime and the filtered precipitate was stored for future recovery of U and other commercially valuable metals. The accumulated material was later treated by a process of which the relevant steps were: digestion with sulfuric acid, followed by extraction with bis(2-ethylhexyl)phosphoric acid (HDEHP), and finally back-extraction with sodium carbonate solution. The waste solutions and residues were discharged to a tailings pond, where, for all practical purposes, much of the Pa and ^{230}Th were irretrievably lost. In 1972, the process was modified by

adding enough sodium hydroxide to the Na_2CO_3 strip solution to cause total precipitation of the U, thus minimizing any further loss of Pa and ^{230}Th (Haubach, 1967; Figgins and Hertz, 1972a,b, 1973). The filtered precipitate ('*Cotter concentrate*') consists of some 2000 tons (dry weight) of mixed oxides and carbonates (Table 4.3) and contains an estimated 30 tons of U_3O_8, 14 kg of ^{230}Th, and 75 g of Pa. This material has been processed at Mound Laboratory.

At the Windscale refinery of the UKAEA, after removal of a sulfate precipitate containing the Ra, the solution was buffered to pH ~2 and the U was precipitated by the addition of hydrogen peroxide. The peroxide precipitate carried down more than 80% of the Pa and, when it was redissolved in nitric acid, the low acidity encouraged the formation of a siliceous Pa-containing sludge, which deposited on the walls of the ether extraction plant and its ancillary vessels. This '*ethereal sludge*' was collected and drummed, pending future recovery of U. It proved to be the richest source of Pa ever found, ultimately yielding 127 g of the pure element (Goble *et al.*, 1958; Nairn *et al.*, 1958; Jackson *et al.*, 1960a; Collins *et al.*, 1962). The gross chemical composition of '*ethereal sludge*' is shown in Table 4.3.

4.4.1 Industrial-scale enrichment of siliceous residues

At ultra-micro concentrations with respect to other metals ions, Pa scarcely exhibits a chemistry of its own. Consequently, the procedure adopted to recover Pa from ‘natural’ sources is usually dictated less by the chemistry of Pa than by the gross chemical and physical characteristics of the source and, sometimes, by the sheer quantity of material to be processed.

The problems are magnified by the extreme complexity and variability of the sources from which ^{231}Pa is obtained, but one problem common to nearly all natural sources has been the ubiquitous presence of silica, and nearly all authors have resorted, at one stage or another, to alkaline fusion or digestion for its removal. Grosse (1934a) and Grosse and Agruss (1934, 1935a) recovered more than 100 g of pure Pa_2O_5 from 1.2 tons of *Rückrückstände,* a material composed largely of SiO_2 and Fe_2O_3 (Table 4.3). The principal steps in the enrichment process were: (1) leaching with hydrochloric acid to eliminate Fe and the more basic oxides; (2) fusing the residue with NaOH and leaching the cooled melt with water to remove soluble silicates and Pb; (3) dissolving the residue in hydrochloric acid and heating to coagulate the remaining SiO_2; (4) washing the precipitate with 20% NaOH solution and dissolving the residue in hydrochloric acid; (5) precipitating Zr (and Pa) by the addition of phosphoric acid; and (6) fusing the ZrP_2O_7 with KOH to eliminate PO_4^{3-} and the last of the SiO_2. The plant product contained more than 85% of the original Pa in a concentration of 1:5000 – an enrichment factor of about 600. Graue and Kading (1934a,b) recovered 700 mg of Pa from 5.5 tons of *Rückrückstände* by essentially the same process, except that the raw material was first fused with NaOH and then leached with hydrochloric acid. The large quantity of SiO_2 that remained in the residue was eliminated by fuming with hydrofluoric acid.

4.4.2 Enrichment of carbonate precipitates

Pa in trace amounts may fractionate unpredictably during dissolution or precipitation of a multi-component mixture. To inhibit such fractionation, many authors have introduced carriers such as Ta (Hahn and Meitner, 1918), Zr (Graue and Kading, 1934a; Grosse and Agruss, 1935a), or Ti (Zavizziano, 1935; Emmanuel-Zavizziano, 1936; Kirby, 1959), which carry Pa quantitatively when they are precipitated as phosphates or hydrated oxides.

Larson *et al.* (1952) leached a carbonate precipitate with nitric acid and digested the resultant SiO_2 gel with 10% NaOH solution to which La carrier was added to minimize losses of Pa in the alkaline solution. However, Thompson and co-workers (1952), by first digesting the carbonates with 40% NaOH, were able to remove enough SiO_2 to prevent gel formation when the metathesized residue was dissolved in 1 M HNO_3. There was no loss of Pa to the alkaline solution, probably because the residue already contained appreciable amounts of both Zr and Ti. The Pa was concentrated from the 1 M HNO_3

solution by adsorption on a MnO_2 precipitate formed *in situ* (Grosse and Agruss, 1935b; Katzin and Stoughton, 1956). Two additional cycles of MnO_2 precipitation and redissolution in HNO_3 were followed by a hydrolytic precipitation of Ti and Zr from 5 M HNO_3. The precipitate that carried down the Pa was taken up in hydrofluoric acid and evaporated to dryness in the presence of perchloric acid to eliminate SiO_2, giving a 1000-fold enrichment of the Pa with a 65% yield.

Carrying by MnO_2 is a key step in the recovery of Pa from *Cotter concentrate* (Hertz *et al.*, 1974). The solids are digested in HNO_3 solution and filtered to yield a solution that is 2–3 M in HNO_3. Essentially all the U and ^{230}Th and 50–85% of the Pa are dissolved; the undissolved residue is reserved for further digestion. The U is extracted with di-*S*-butylphenyl phosphonate (DSBPP) and the Pa and ^{230}Th are quantitatively extracted with tri-*n*-octylphosphine oxide (TOPO). ^{230}Th is stripped from the TOPO with 0.3 M H_2SO_4 and the Pa with 0.5 M $H_2C_2O_4$. Addition of potassium permanganate to the oxalic acid solution yields a precipitate of 5 g of MnO_2 containing 1–6 mg of Pa, for an enrichment factor of 500–2500.

4.4.3 Enrichment of aqueous raffinates

After the sodium carbonate precipitation step was omitted from the Mallinckrodt process, the aqueous raffinate from the diethyl ether extraction of U contained about 0.2 mg L^{-1} of Pa and 1–10 g L^{-1} for other elements (chiefly Ca, Fe, and rare earths). Elson *et al.* (1951) extracted this weakly acid solution of nitrates with 5% of its volume of tri(*n*-butyl)phosphate (TBP) and stripped the TBP with one-fourth of its volume of 0.5 M HF solution. Rare earths and Th isotopes precipitated, but the Pa remained in solution. Al^{3+} was added to complex the F^- and the solution was contacted with di-isopropylcarbinol (DIPC), which extracted 70–90% of the Pa. Back-extraction into 10% H_2O_2 gave another 20-fold volume reduction and yielded a product that contained about 4% Pa by weight, with Ca and U as the principal impurities. The overall yield was only 5–35%, however, primarily because of the poor extractability of Pa into TBP at low acidity. Peppard *et al.* (1957) later found that Pa is efficiently extracted by TBP from 5 M HCl.

In a Russian process (Shevchenko *et al.*, 1958b), the U ore is digested with nitric acid and extracted as slurry with a 10% solution of TBP in kerosene. About 75–85% of the ^{230}Th and 50–55% of the Pa pass into solution, but neither is appreciably extracted by the TBP. After phase separation and filtration, the aqueous solution is made 2 M in HNO_3 and contacted with a 15% solution of mixed mono- and di-isoamylphosphoric acids (DIAPA) in isoamylacetate. A single-stage extraction with an organic:aqueous volume ratio of 1:20 recovers 75–85% of the ^{230}Th and 82–89% of the Pa. After back-extraction with saturated aqueous $(NH_4)_2CO_3$, Fe and other heavy metals are precipitated as sulfides and the carbonate is decomposed by heating and acidification.

The ^{230}Th and Pa are precipitated with NH_4OH and calcined to yield a concentrate containing up to 1% ^{230}Th and about 0.01% Pa in a matrix of U, P, Ti, Zr, Sc, and other impurities. The Pa is separated from ^{230}Th and Sc by fluoride precipitation, which leaves Pa in the solution, from which it is coprecipitated with Zr as a phosphate in the presence of H_2O_2. The Pa:Zr ratio in the concentrate is usually 1:400 or higher.

The adsorption behavior of protactinium on zirconium phosphate cation exchanger from ammonium chloride, hydrochloric acid, and hydrochloric acid–alcohol media has been investigated (Souka *et al.*, 1975c). The distribution coefficients in solvent mixtures of hydrochloric acid and various alcohols depend on both alcohol content and acid concentration. Similar investigations have been carried out for nitric acid systems (Souka *et al.*, 1976a). Sorption of protactinium on silica gel has also attracted attention. Adsorption of ^{233}Pa on silica gel has been investigated as a possible procedure for obtaining isotopically pure uranium-233 (Chang and Ting, 1975a). Protactinium-233 sorption from oxalic acid system has been studied; a 1:1 complex of Pa and oxalate is formed in these systems and the observed adsorption is well correlated to the concentration of the oxalate complexes (Bykhovskii *et al.*, 1977). Hydrophobic silica gel has been prepared by silylation; uptake of protactinium from mixtures of hydrochloric acid and lower aliphatic alcohols increases with increasing molecular weight of the aliphatic alcohol (Caletka and Spěváčkova, 1975).

4.4.4 Enrichment of ethereal sludge

Aqueous hydrofluoric acid is the most consistently effective solvent for Pa(v), with which it forms strong anionic complexes (Guillaumont and deMiranda, 1966; Guillaumont *et al.*, 1968). It has the added advantage of dissolving the oxides of most of the elements with which Pa is normally associated in nature (Si, Fe, Ta, Zr, Ti, etc.). If Al^{3+} is added to such a solution in sufficient quantity to mask all the F^-, a precipitate forms, which carries the Pa quantitatively.

In an enrichment method reported by Goble *et al.* (1958), ethereal sludge was leached with 0.5 M HNO_3, which dissolved about 90% of the U. The residue, which retained more than 95% of the Pa, was leached with 0.5 M HF and Al sheets were suspended in the solution. After 5 days or more, the Pa separated quantitatively as a black deposit on the aluminum, from which it was loosened by treatment with 0.2 M NaOH. The precipitate was washed with dilute NaOH solution and dissolved in 8 M HCl, from which it was extracted with di-isobutylketone (DIBK). The DIBK was stripped with 8 M HCl containing a little HF. Addition of $AlCl_3$ permitted a second cycle of DIBK extraction and stripping. The crude HCl–HF product from 100 kg of sludge was 200 mg of Pa (77% yield) in 0.5 L of solution containing about 10 g of solids.

Unfortunately, this ingenious and inexpensive process failed when attempts were made to apply it on a tonnage scale, apparently because fluorides (from CaF_2 slag) had been dispersed throughout the sludge during a re-drumming operation. This resulted in unacceptable losses of Pa during the initial leaching with dilute HNO_3 solution. Furthermore, the deposition of Pa on Al plates proved too slow and cumbersome for operation on a tonnage scale.

The process that was finally adopted is outlined in Fig. 4.8 (Nairn *et al.*, 1958; Collins *et al.*, 1962). The U and Pa were dissolved by leaching the sludge with a mixture of HNO_3 and HF. After extraction of the U with TBP, Al^{3+} as chloride was added to the raffinate. A precipitate is formed, which carried down 80–95% of the Pa, with an enrichment factor of approximately 10. The precipitate was

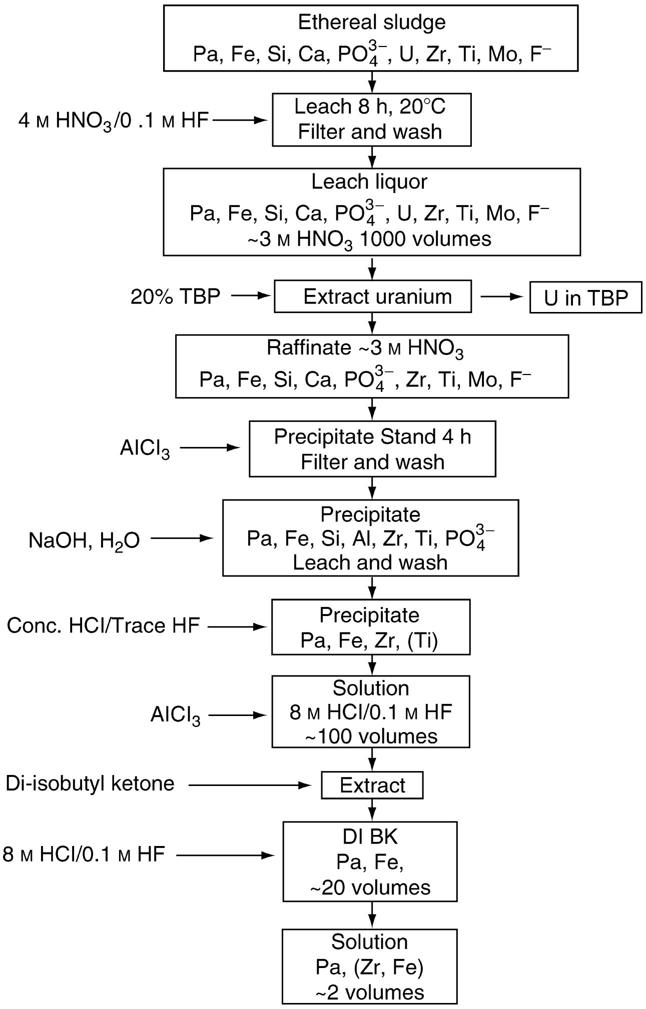

Fig. 4.8 *Recovery of protactinium and uranium from ethereal sludge* (*Nairn* et al., 1958).

digested with 10–35% NaOH to remove Si, Al, and, especially, PO_4^{3-}. The residue was dissolved in 8 M HCl and 0.1 M HF and aluminum chloride was added in a molar ratio of Al:F > 5. The solution was extracted with DIBK and stripped with 8 M HCl and 0.1 M HF. A second cycle of DIBK extraction and stripping yielded 52.4 L of an aqueous solution containing 126.75 g of Pa, 3.25 g of Zr, and 1.42 g of Fe (it was later learned that the product also contained 0.1–4% Nb) (Walter, 1963; Brown *et al.*, 1966a; Jenkins *et al.*, 1975).

Salutsky *et al.* (1956) recovered 0.5 mg of Pa from 5 kg of a material similar to ethereal sludge but only one-tenth as rich. The principal features of the method were: (1) dissolution in 1 M HCl, (2) saturation of the solution with sodium chloride, and (3) boiling to coagulate a small precipitate (chiefly Ca and Si), which quantitatively carried down the Pa. The precipitate was digested with NaOH solution to solubilize silicates and the residue was dissolved in 9 M HCl; this became the feed solution for purification of the Pa by anion exchange. However, attempts to apply this simple process to other batches of the same material failed because of the inhomogeneity of the raw material. Batchwise development and processing ultimately recovered approximately 2 g of Pa from 20 tons of residue, but only after substantial modification of the process, including (Kirby, 1959): addition of Ti as a carrier; dissolution of HCl-insoluble residues in sulfuric acid; extraction with isopropyl ether to reduce the Fe concentration to manageable proportions; and concentration of the Pa by several cycles of extraction into di-isobutylcarbinol (DIBC) and stripping with H_2O_2.

4.4.5 Purification of macroscopic amounts of ^{231}Pa

Preliminary enrichment processes such as those described above afford a high degree of decontamination from Si, Fe, U, Th, Ti, and most bivalent and trivalent elements, including the ^{231}Pa decay products (Fig. 4.1). However, Zr, Ta, and Nb are usually enriched along with the Pa and most recent work has been directed primarily at the separation of those elements, of which Nb is the most troublesome.

Methods reported for the purification of Pa after its enrichment from natural sources are so numerous that only a selected few can be mentioned here. For details of other methods, readers should consult the following reviews (Gmelin, 1942, 1977; Haïssinsky and Bouissières, 1958; Brown and Maddock, 1963, 1967; Pal'shin *et al.*, 1970) and the original publications cited therein.

(a) Precipitation and crystallization

The addition of KF to a solution of Pa(v) in hydrofluoric acid quantitatively precipitates K_2PaF_7 and separates Pa from Zr, Nb, Ti, and Ta (Grosse, 1928; Graue and Kading, 1934b; Bouissières and Haïssinsky, 1951; Cunningham, 1966).

On the other hand, during the fractional crystallization of the double ammonium fluorides, Pa crystallizes before Zr, but after Ti and Ta (Bachelet and Bouissières, 1947). Haïssinsky (Haïssinsky and Bouissières, 1951; Bouissières and Haïssinsky, 1951) separated Pa from Ta, Zr, and Ti by reducing Pa(v) to Pa(iv) with Zn amalgam in 2 M HF. The PaF_4 precipitate was redissolved in aqueous HF or H_2SO_4 in the presence of H_2O_2 or a current of air, which reoxidized the Pa.

Precipitation by H_2O_2 has been widely used to separate Pa from Nb, Ta, and Ti (Grosse, 1930; Bachelet and Bouissières, 1944, 1947; Goble *et al.*, 1958). Walter (1963) decontaminated 500 mg of Pa of about 4% Nb by adding H_2O_2 to a 40% H_2SO_4 solution of the Pa and neutralizing with ammonium hydroxide. Pal'shin *et al.* (1968a) mixed 4.1 mg of Pa with 8 mg each of Nb, Ta, and Zr in 0.25–0.5 M $H_2C_2O_4$, then precipitated the Pa by adding H_2O_2 (to 7.5%) and HCl (to 1.2 M). The precipitate, which formed during an 8–12 h period at room temperature, contained less than 1% total impurities.

The hydrolytic behavior of Pa was used by Kirby (1966) and by Kirby and Figgins (1966) to separate it from up to 13 times as much Nb. When hydrochloric acid was added to a 1 M $H_2C_2O_4$ solution containing equal amounts of the two elements, the precipitate, which developed on heating, contained 94.4% of the Pa and 2.0% of the Nb. Final purification was achieved by dissolution of the precipitate in 7 m H_2SO_4 and evaporation to fumes of SO_3, yielding Pa crystals of undetermined composition, in which the Nb content was reduced from 0.3 to 0.05% in a single stage. According to Brown and Jones (1964) and Bagnall *et al.* (1965), Pa crystallizes quantitatively as $H_3PaO(SO_4)_3$ when Pa_2O_5 is dissolved in a mixture of HF and H_2SO_4 and the solution is evaporated until all F^- has been eliminated. Two recrystallizations of a 10 g batch of Pa reduced the Nb contamination from 4 to 0.18%.

Myasoedov *et al.* (1968c) reported that Pa is quantitatively precipitated by phenylarsonic acid (PAA) from 1 to 7 N HCl, HNO_3, or H_2SO_4. In the absence of $H_2C_2O_4$, Sn(iv), Zr, Nb, Ta, and Ti are also precipitated; however, Pa is separated from Nb and Zr (but not from Ta) when PAA is added to a 2.5 M H_2SO_4 solution containing 0.1 M $H_2C_2O_4$. Both trace and major amounts of Pa have been separated from Nb, Zr, and Fe by this method.

Protactinium was isolated from liquid radioactive waste by sodium silicate, potassium silicate, and an alumina sol mixed in ratios by volume of 1:0.1 to 1. As an example, 0.94 mL of water glass containing 200 g L^{-1} of sodium silicate, and 100 mL of liquid waste containing 20 ppm of uranium was stirred, then 0.94 mL of the same water glass was added and stirred into the mixture along with 1.88 mL of an alumina sol for 10 min. Negatively charged silica particles and positively charged alumina particles absorb U and β^--decay nuclides (Pa) (Mitsubishi, 1995).

The protactinium distribution in a fluoride melt in the presence of solid oxide phases has been calculated (Alekseev *et al.*, 1988, 1989).

(b) Ion exchange

Numerous studies have demonstrated that Pa(v) at trace levels can be separated from the usual contaminants by sorption on anion-exchange resins from hydrochloric acid solutions (Kraus and Moore, 1950, 1951, 1955; Kahn and Hawkinson, 1956; Kraus *et al.*, 1956; Maddock and Pugh, 1956; Hill, 1958; Bunney *et al.*, 1959; Lebedev *et al.*, 1961; D'yachkova *et al.*, 1962; El-Dessouky, 1966; Hicks *et al.*, 1978; Kluge and Lieser, 1980; Alhassanieh *et al.*, 1999; Raje *et al.*, 2001). Typically, the feed solution is 9–10 M HCl, from which Pa(v) is strongly sorbed in anion-exchange resins such as Dowex-1, along with Fe(iii), Ta(v), Nb(v), Zr(iv), U(iv), and U(vi); Th(iv) is only weakly sorbed and appears in the feed effluent. The eluent is a mixture of HCl and HF acids, the concentration of each depending upon the separation required. For example, Zr and Pa are both eluted with 9 M HCl and 0.004 M HF, but Zr may be eluted with 6–7 M HCl, without significant desorption of Pa (Fig. 4.9).

However, attempts to apply this procedure to the purification of weighable amounts of Pa have usually been unsatisfactory, primarily because of the low capacity of the resin (5–50 μg of Pa per gram of resin) and the strong tendency of Pa to hydrolyze in HCl solutions in the absence of complexing anions (Nairn *et al.*, 1958; Kirby, 1959; Collins *et al.*, 1962). Nevertheless, several authors (Jackson *et al.*, 1960a; Stein, 1966; Suzuki and Inoue, 1966) have reported the successful purification of gram quantities of Pa by anion-exchange procedures in which a stable feed solution was prepared by first dissolving the Pa in 9 M HCl

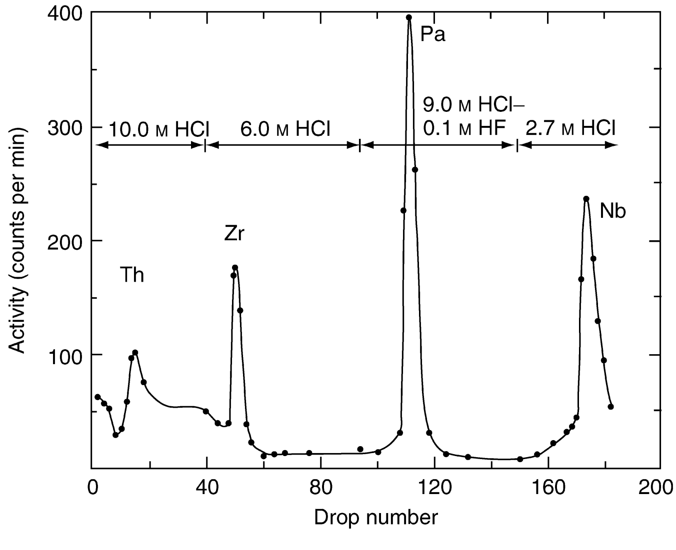

Fig. 4.9 *Separation of Th, Zr, Pa, and Nb on Dowex-*1 *anion-exchange column* (*Hill,* 1958).

containing some HF and then eliminating the F^- by complexing it with Al^{3+} or by evaporation. Sorption properties of Zr, HF, Nb, Ta, and Pa at trace levels towards a macroporous anion exchanger in HF and HCl media were investigated with two ion-exchange methods: static and dynamic. Variations of the distribution coefficients as a function of HCl and HF concentration in the range 0.02–0.8 M for both acids were presented in the form of contour plots and some of the most promising separation possibilities were pointed out (Trubert *et al.*, 1998).

Keller (1963) found that Pa(V), Nb(V), and Ta(V) are all strongly sorbed by an anion exchanger (Dowex-1) from pure hydrofluoric acid solution. However, an increase in $[H^+]$ suppresses the dissociation of HF and sharply reduces the distribution coefficient (K_d) of Pa. Chetham-Strode and Keller (1966) observed that, in >10 M HF, the K_d of Pa was more than an order of magnitude lower than that of Nb and they applied these observations to the separation of Nb and various alkali- and alkaline-earth metal ions from 1 g of Pa_2O_5. The impure Pa was loaded on Dowex-1-Ax10 in 2.5 M HF and eluted with 17 M HF; the product was contaminated only by ^{227}Th, a decay product of ^{231}Pa. Jenkins *et al.* (1975) have reported the purification of approximately 35 g of Pa by this method, with high decontamination factors for Si, Mg, Fe, Al, Cu, and Nb.

The separation of Zr, Ha, Nb, Ta, and Pa was performed on a macroporous anion-exchange resin BIO-RAD AG MP1® in HF media (Monroy-Guzman *et al.*, 1996) and a mixture of 0.01–4.0 M NH_4SCN and 0.05–3.0 M HF media to determine its analytical potential for the quantitative separation of these elements. It was found that the SCN^- concentration in mixtures NH_4SCN–HF had a strong influence on the adsorption of these ions. The K_d of these elements could be explained in terms of the formation of species: $[MF_x]^{(n-x)-}$, $[M(SCN)_y]^{(n-y)-}$, or $[MOF_x]^{(n-x-y)-}$ and $[MO(SCN)_y]^{(n-(2+y)-}$, and mixed fluorothiocyanates of the type $[M(F)_x(SCN)_y]^{(n-x-y)-}$ anionic complexes (Monroy-Guzman *et al.*, 1997).

El-Sweify *et al.* (1985) calculated the distribution of Pa, other actinides, and fission products between the chelating ion exchanger Chelex–100 and certain carboxylic acid solutions.

(c) Solvent extraction and extraction chromatography

Pal'shin *et al.* (1970) have exhaustively reviewed the analytical applications of solvent extraction and Guillaumont and deMiranda (1971) have reviewed the published data as they relate to the ionic species of Pa and the mechanism of its extraction. At tracer levels ($<10^{-4}$ M), Pa(V) is efficiently extracted from aqueous solutions by a wide variety of organic solvents (Hyde and Wolf, 1952; Elson, 1954; Sedlet, 1964); however, only a few have been found useful at macroscopic levels. Dimethyl sulfoxide (DMSO) and the related compounds, diphenyl sulfoxide, and dibenzyl sulfoxide, have received some scrutiny, but it is not clear whether these complexing agents have particular utility for protactinium separation (Reddy and Reddy, 1977; Reddy *et al.*, 1977; Chakravortty and Mohanly, 1979; Chakravortty *et al.*, 1986). As with ion exchange, the chief problems encountered in scaling up tracer-level procedures have been the low capacities of most solvents and the hydrolysis of Pa(v) in the aqueous phase, leading to the formation of 'inextractable polymers'. The most successful extractions of Pa at concentrations up to about 10 g L^{-1} have been with certain ketones, such as di-isopropylketone (DIPK) and DIBK (Goble and Maddock, 1958; Brown *et al.*, 1966a; Myasoedov *et al.*, 1966b) and long-chain alcohols, notably DIBC (Moore, 1955; Kirby, 1959; Brown and Jones, 1964; Scherff and Hermann, 1964; Brown *et al.*, 1966a; Sotobayashi *et al.*, 1977; Pathak *et al.*, 1999a,b).

DIBK was used in some studies for isolation of protactinium from raw materials (Katzin *et al.*, 1950; Katzin, 1952; Kraus and VanWinkle, 1952; Larson *et al.*, 1952; Thompson *et al.*, 1952) and from neutron-irradiated thorium (Meinke, 1946; Hyde and Wolf, 1952; Hill, 1958; Van Winkle and Kraus, 1959; Hyde *et al.*, 1951). Brown *et al.* (1966a) dealt with the problem of hydrolysis by precipitating Pa(v) from aqueous acid solutions with NH_4OH, redissolving the hydrated oxide in either 9 M H_2SO_4 and 0.5 M HF or 9 M HCI and 0.5 M HF, and then complexing the F^- with H_3BO_3. The use of sulfuric acid systems is preferred because of the greater stability of the Pa(v) complexes in that medium. In HCl and HF solutions, hydrolysis proceeds rapidly after the F^- is masked by reaction with $A1^{3+}$ or BO_3^{3-}. After adjustment of the aqueous phase to 4.5 M H_2SO_4 and 6 M HCl, the Pa(v) is extracted with DIBK, stripped with 9 M H_2SO_4 containing some H_2O_2, and re-extracted with DIBC (Fig. 4.10).

The method is said to give good decontamination from nearly all the usual impurities, including Si, Al, Fe, Nb, Zr, Ta, and ^{231}Pa decay products.

DIBC was also used for extraction studies of Pa, Nb, and element 105 – dubnium (Db) from aqueous HBr and HCl. It was shown that the extraction behavior of Db is closer to that of Nb than to Pa. The decreasing extractability from HBr (Pa $>$ Nb $>$ Db) is likely to be due to an increasing tendency of these elements to form a non-extractable polynegative complex species in concentrated HBr in the sequence Pa $<$ Nb $<$ Db (Gober *et al.*, 1992).

Milligram amounts of Pa(v) were extracted from H_2SO_4, HCl or HNO_3 acid solutions by isoamyl alcohol containing 1% PAA or 4% benzeneseleninic acid; good separation from many impurities was reported (Myasoedov *et al.*, 1966a, 1968a). Tetraphenylarsonium chloride has also been studied as a possible extractant for protactinium from hydrochloric or oxalic acid solutions (Abdel Gawad *et al.*, 1976; Souka *et al.*, 1976b). Other extraction agents have also been explored. Thus, l-phenyl-2-methyl-3-hydroxy-4-pyridone dissolved in chloroform (Tamhina *et al.*, 1976, 1978; Herak *et al.*, 1979) quantitatively extracted Pa from hydrochloric acid solution, and Pa can be separated from uranium and/or thorium by appropriate adjustment of the acidity. The antibiotic, tetracycline, was used in radiochemical analytical separations of protactinium from other actinide elements (Saiki *et al.*, 1981) and 5,7-dichloro-8-hydroxyquinoline

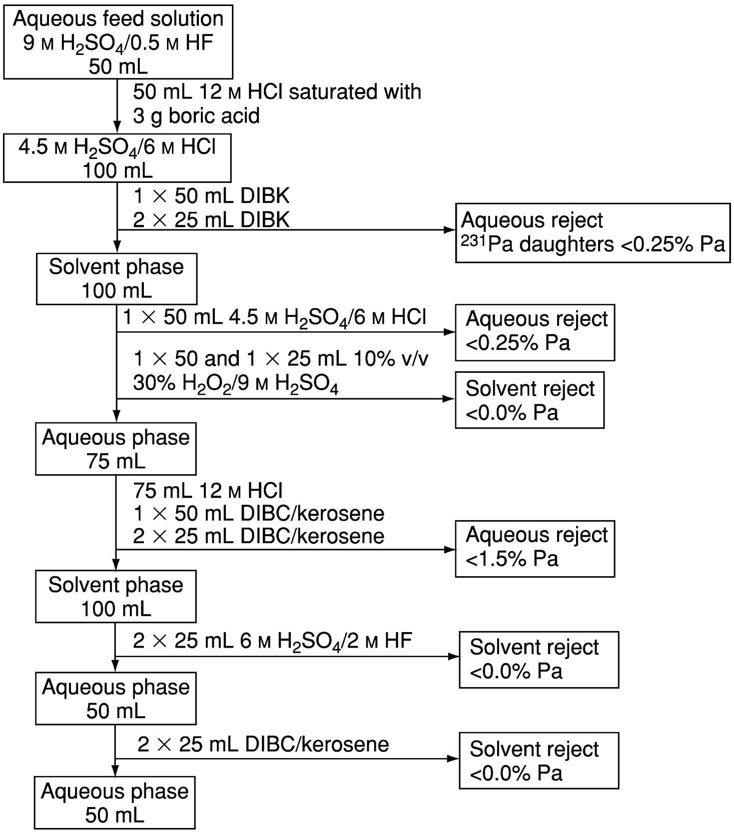

Fig. 4.10 *Purification scheme for* 555 mg *of Pa.* (*According to Brown* et al., 1966*a*.) *Reproduced with permission from Pergamon Press.*

was investigated for the separation of protactinium from niobium, tantalum, and zirconium by solvent extraction (Vaezi-Nasr *et al.*, 1979).

Myasoedov and Pal'shin (1963) and Davidov *et al.* (1966c) proposed an effective method for isolation of Pa from uranium ores and products of their reprocessing by liquid–liquid extraction with the chelating complexing reagent 3,6-bis-[(2-arsenophenyl)azo]-4,5-dihydroxy-2,7-naphthalene disulfo acid (Arsenazo-III) in isoamyl alcohol. It was shown that an effective extraction of Pa from strong acid media, even in the presence of a great amount of Al, Fe(III), Mn(II), rare earth metals, and other elements, took place. The growth of U, Zr, Th, and particularly Nb concentrations in the solutions led to a diminution of Pa isolation. This method was used for analytical control of the separation of gram amounts of Pa(V) under plant conditions.

Thenoyltrifluoroacetone (TTA) had been used for separation and purification of Pa from several elements (Meinke and Seaborg, 1950; Meinke, 1952; Bouissières *et al.*, 1953; Moore, 1955, 1956; Brown *et al.*, 1959; Moore *et al.*, 1959; Poskanzer and Foreman, 1961a,b; Myasoedov and Muxart, 1962a). TTA extraction has been applied to the extraction of Pa from 10 M HCI in which $PaOCl_6^{3-}$ appears to be a principal species (Duplessis and Guillaumont, 1979). Triphenylphosphine oxide (TPPO), triphenylarsine oxide (Maghrawy *et al.*, 1989), and mixtures of TTA and either TBP, TOPO, or TPPO have been investigated (Kandil *et al.*, 1980); a combination of TTA and TOPO has found use in the separation of protactinium and thorium by solvent extraction (Kandil and Ramadan, 1978). TBP (Peppard *et al.*, 1957; Souka *et al.*, 1975b; Svantesson *et al.*, 1979), HDEHP (Shevchenko *et al.*, 1958a; Brown and Maddock, 1963; Myasoedov and Molochnikova, 1968; Myasoedov *et al.*, 1968b; Maghrawy *et al.*, 1988), and di-2-ethyl-hexyl isobutylamide (D2EHIBA) (Pathak *et al.*, 1999a,b) have high capacities for Pa(v), but are relatively unselective.

The extraction by *N*-benzoylphenylhydroxylamine (BPHA) from HCl, and H_2SO_4 solutions was used for the separation of Pa(v) from other elements by Pal'shin *et al.* (1963) and Myasoedov *et al.* (1964). It was found that protactinium complexes with BPHA were extracted by benzene or other solvents from aqueous solutions with a wide range of acid concentrations. D'yachkova and Spitsyn (1964) studied the protactinium, zirconium, and niobium behavior by extraction with BPHA from sulfuric acid solutions. The isolation of the above elements was carried out with 0.2–0.5% solution BPHA in chloroform. The largest difference in extraction ability for these elements was observed with H_2SO_4 concentrations in the aqueous phase greater than 7 N. Rudenko *et al.* (1965) and Lapitskii *et al.* (1966) carried out the separation of protactinium from uranium and thorium by extraction with 0.1 M BPHA solution in chloroform from 4 M HCl.

The Pa(v) extraction by cupferron (CP) had been studied by Maddock and Miles (1949). It was found that Pa was easily extracted by CP in both oxygen-containing and inert solvents from inorganic acid media. Spitsyn and Golutvina (1960) used the extraction with CP for the separation of ^{233}Pa from large amounts of manganese. Rudenko *et al.* (1965) and Lapitskii *et al.* (1965) reported that the neocupferron (NCP), an analog of CP, can be also used for the separation of protactinium from uranium, thorium, and other elements. Uranium and thorium are not extracted by NCP from 2 M HCl solutions, whereas protactinium isolation by a 0.01 M solution of this reagent in chloroform is about 90%. These authors used NCP for isolation of ^{233}Pa from irradiated thorium.

The extraction of Pa by 1-phenyl-3-methyl-4-benzoylpyrazolone (PMBP) in benzene solution from H_2SO_4 media effectively isolated this element from large amounts of Fe(III), La, Nb(v), Th(IV), and U(VI) (Pal'shin *et al.*, 1970). Hence, Pa extraction and isolation by 0.1 M solution of PMBP in benzene from 5 N H_2SO_4 is greater than 98%. For the complete separation of Pa from Zr by this method, a 12% solution of H_2O_2 had been used.

The quantitative extraction of protactinium salicylate with acetone at pH 4 from saturated calcium chloride solutions was reported by Nikolaev *et al.* (1959). Under these conditions zirconium, thorium, uranium, and plutonium are extracted with protactinium. The extraction with salicylate can be used for the separation of protactinium from rare earth and other di- and tervalent elements. The quantitative extraction of protactinium oxychinolate with chloroform from solutions with pH 3–9 was described (Keller, 1966a).

Extraction by tertiary amines in early work was explored only at levels of 10^{-4} M or less, but this procedure shows promise because it permits the extraction of Pa(v) from HF-containing solutions (Moore, 1960; Muxart and Arapaki-Strapelias, 1963; Guillot, 1966; Muxart *et al.*, 1966b; Pal'shin *et al.*, 1971; Moore and Thern, 1974).

The extraction behavior of protactinium in mixtures of uranium, thorium, and neptunium with trilaurylamine from sulfonic acid solutions (Souka *et al.*, 1975c) indicates low distribution coefficients at high acid concentrations; the addition of hydrochloric acid appreciably enhances extraction. The extraction of protactinium (v) with trioctylamine (TOA) dissolved in xylene from thiocyanate solutions containing uranium and thorium have been successfully accomplished (Nekrasova *et al.*, 1975a); tracer amounts of Pa can exist in monomeric form in thiocyanate media for several months, but at Pa(v) concentrations greater than 10^{-6} M, polymers form and the efficacy of TOA as an extractant is seriously impaired (Nekrasova *et al.*, 1975b). Columns impregnated with TOA in a liquid chromatographic system were also used for the separation of ^{262,263}Db in HCl–HF media from Pa and Nb. The data obtained confirm the non-tantalum-like behavior of dubnium in 0.5 M HCl and 0.01 M HF media, and corroborate previously suggested structural differences between the halide complexes of dubnium, niobium, and protactinium, on the one hand, and those of tantalum on the other hand (Zimmerman *et al.*, 1993). Dubnium was shown to be adsorbed on the column from 12 M HCl and 0.02 M HF solutions together with its lighter homologs Nb, Ta, and the pseudohomolog Pa. In elutions with 10 M HCl and 0.025 M HF, 4 M HCl and 0.02 M HF, and 0.5 M HCl and 0.01 M HF, the extraction sequence Ta > Nb > Db > Pa was observed (Paulus *et al.*, 1998, 1999).

The formation of polymers of Pa(v) in the extractions by quaternary ammonium base Aliquat 336 from strongly alkaline solutions can be minimized by the addition of a hydroxycarboxylic acid or aminopolycarboxylic acid (Myasoedov *et al.*, 1980). While the extractability of Pa(v) can be enhanced, the separations are poor. For the systematic study of halide complexation of the group V elements, new batch extraction experiments for Nb, Ta, and Pa were performed with the Aliquat 336 in pure HF, HCl, and HBr solutions. Based on these results, new chromatographic column separations were designed to study separately the fluoride and chloride complexation of Db with Automated Rapid Chemistry Apparatus II (ARCA II). In the system Aliquat 336-HF, after feeding the activity onto the column in 0.5 M HF, dubnium did not elute in 4 M HF (Pa fraction) but showed a higher distribution coefficient close to that of

Nb (and Ta). In the system Aliquat 336-HCl, after feeding onto the column in 10 M HCl, dubnium showed a distribution coefficient in 6 M HCl close to that of Nb establishing an extraction sequence Pa $>$ Nb greater than or equal to Db $>$ Ta, which was theoretically predicted by considering the competition between hydrolysis and complex formation (Paulus *et al.*, 1998, 1999). Separation of ^{231}Pa from U and other impurities has been provided by an extraction-chromatographic method using quaternary ammonium-Kel-F materials (Zhang Xianlu *et al.*, 1993).

Extraction of protactinium(V) chloro complexes by tricaprylamine and its separation from Th(IV), U(VI), and rare earths has been described (El-Yamani and Shabana, 1985).

(d) Large-scale recovery of protactinium-231

Brown and Whittaker (1978) have described a new, ‘relatively simple’ method for the recovery and purification of protactinium-231. It has been applied with signal success to the recovery of Pa from various residues containing 1.73 g of protactinium in a state of high chemical and radiochemical purity. Efficient separation of ^{231}Pa was readily effected by dissolving the ^{231}Pa-containing residues in 5 M hydrofluoric acid. Excess ammonia is added to precipitate the hydrous oxides, which after several washes with water are redissolved in 2 M nitric acid. This precipitate is considerably enriched in ^{231}Pa. Washing the precipitated hydrous oxides with 0.5–4.0 M HNO_3 and/or 0.5 M HNO_3 and 0.3 M H_2O_2, in which protactinium(V) hydrous oxide, is essentially insoluble, removes much of the impurities carried in the initial hydrous oxide precipitation. Repetition of this cycle twice more yields Pa_2O_5 of high purity. The final traces of silicon are then removed by dissolving the hydrous oxides in 20 M HF and evaporating the solution to dryness. Recovery yields range from 92 to 96% from initial samples containing 30–75 wt% ^{231}Pa. The purity of the product is generally greater than 99%; it is also radiochemically pure.

4.4.6 Preparation of pure ^{234}Pa and ^{234m}Pa

Because of its short half-life, 1.17 min ^{234m}Pa is frequently used for classroom demonstrations of radioactive decay and growth (Booth, 1951; Carsell and Lawrence, 1959; Overman and Clark, 1960). Pure ^{234m}Pa (and its ground-state isomer, 6.7 h ^{234}Pa) can be coprecipitated directly from a 6 M HCl solution of $(NH_4)_2U_2O_7$ with BPHA (Cristallini and Flegenheimer, 1963). The procedure is rapid and gives a high degree of decontamination from both U and Th.

However, most authors prefer to make a preliminary separation of 24.1 day ^{234}Th, from which the ^{234m}Pa (and ^{234}Pa) can be repeatedly ‘milked’. The classical procedure of Crookes (1900) is still one of the most widely used for this purpose (Harvey and Parsons, 1950; Barendregt and Tom, 1951;

Bouissières *et al.*, 1953; Forrest *et al.*, 1960; Bjørnholm and Nielsen, 1963): 10–200 g of $UO_2(NO_3)_2 \cdot 6H_2O$ are dissolved in diethyl ether. The aqueous phase formed by the water of crystallization retains the ^{234}Th and some U. Repeated extraction with fresh ether removes the remaining U. Alternatively, the ^{234}Th is purified and concentrated by coprecipitation with $Fe(OH)_3$ in the presence of $(NH_4)_2CO_3$ (Hahn, 1921; Harvey and Parsons, 1950), by cation exchange from HCl solution (Zijp *et al.*, 1954; Suner *et al.*, 1974), by anion exchange from HNO_3 solution (Bunney *et al.*, 1959), or by extraction with tertiary amines (Moore and Thern, 1974; Carswell and Lawrence, 1959).

Once the ^{234}Th has been purified, the ^{234m}Pa and ^{234}Pa quickly regain equilibrium and can be isolated by any of the methods described above for the purification of ^{231}Pa, except, of course, carrier-free precipitation. Solvent extraction is the most suitable, because of its speed and selectivity, at tracer levels, Pa(v) is rapidly and quantitatively separated from Th(iv) by extraction from 6 M HCl solution with any number of organic solvents, notably DIPK, DIBK, DIPC, and DIBC (Moore, 1955; Myasoedov *et al.*, 1966a). The ^{234}Th remains in the aqueous phase. To prepare ^{234m}Pa free of ^{234}Pa, the first two or three organic extracts are discarded and, after 10–15 min, the re-grown ^{234m}Pa is extracted with fresh solvent (Bjørnholm and Nielson, 1963).

Fajans and Göhring (1913b) first separated *brevium* by selective adsorption on lead plates and by coprecipitation with Ta_2O_5. The addition of ^{232}Th keeps the mixture of ^{234}Th and ^{234m}Pa more quantitatively in solution (Guy and Russell, 1923; Jacobi, 1945). Hahn (1921) coprecipitated the mixture of ^{234}Th and ^{234m}Pa with LaF_3, leaving ^{234}Pa in the filtrate. Zijp *et al.* (1954) concentrated ^{234}Pa by MnO_2 precipitations (Maddock and Miles, 1949), alternating with extraction by TTA (Meinke, 1952).

Bjørnholm *et al.* (1967) milked 0.5–1 mCi of ^{234}Pa from 0.8 mCi of ^{234}Th by extraction into hexone (methyl isobutyl ketone, MIK) from 6 M HC1 solution. It is noteworthy, however, that many of the same problems were encountered in the initial concentration of ^{234}Th from 2 tons of U metal as in scaling up laboratory procedures for the concentration of macroscopic amounts of ^{231}Pa from natural sources.

4.4.7 Preparation of pure ^{233}Pa

Irradiation of 1 g ^{232}Th (as metal, oxide, chloride, nitrate, or basic carbonate) for 1 day in a thermal-neutron flux of 2×10^{14} n cm^{-2} s^{-1} will produce approximately 5 Ci of ^{233}Pa (Schuman and Tromp, 1959). Detailed procedures for the isolation of ^{233}Pa from Th targets are given in several review articles (Hyde and Wolf, 1952; Hyde, 1954, 1956; Haïssinsky and Bouissières, 1958; Kirby, 1959; Pal'shin *et al.*, 1970). In general, the target is dissolved in concentrated HCl or HNO_3 (usually containing 0.01–0.1 M HF as a catalyst) and the ^{233}Pa is separated from Th and other impurities by one, or a combination, of the anion-exchange and solvent extraction methods described above. Alternatively, 3 g of Th metal irradiated in a reactor with an irradiation time of 1 day in a thermal flux of 3×10^{13} n cm^{-2} s^{-1} are dissolved in nitric acid. The ^{233}Pa is adsorbed on an anion-exchange column, eluted, then is extracted by TOPO (Kuppers and Erdtmann, 1992).

A preliminary concentration by coprecipitation (Katzin and Stoughton, 1956; Fudge and Woodhead, 1957; Katzin, 1958) is often used, and was, in fact, the method adopted by Codding *et al.* (1964) to isolate 1 gram of ^{233}Pa after solvent extraction with MIK or DIPK gave unaccountably poor yields. Leaching the MnO_2 with a mixture of HNO_3 and H_2O_2 removed the Mn without loss of ^{233}Pa, which was subsequently dissolved in 6 M H_2SO_4 and re-precipitated with HNO_3. On the other hand, Schulz (1972) reported good extraction of ^{233}Pa by DIBC from 7.4 M HNO_3 solutions containing 1.4 M Th $(NO_3)_4$ and 480 Ci L^{-1} of ^{233}Pa. Macroscopic amounts of ^{233}Pa have also been recovered from HNO_3 solutions of irradiated ThO_2 by adsorption on powdered unfired Vycor glass and silica gel (Moore and Rainey, 1964; Goode and Moore, 1967); at tracer levels, ^{233}Pa has been separated from Th targets by adsorption on silica gel (Davydov *et al.*, 1965; Spitsyn *et al.*, 1969; Chang *et al.*, 1974; Chang and Ting, 1975b), on quartz sand (Sakanoue and Abe, 1967), and on activated charcoal saturated with PAA (Pal'shin *et al.*, 1966). Separations with cation and chelating resins (Kurodo and Ishida, 1965; Myasoedov *et al.*, 1969), by paper chromatography and paper electrophoresis (Vernois, 1958, 1959; Myasoedov *et al.*, 1969), and by reversed-phase partition chromatography (Fidelis *et al.*, 1963) have also been reported.

4.4.8 Toxic properties

^{231}Pa is dangerous to organisms, similar to other α-emitters with comparatively short half-lives. Once in organisms it accumulates in kidneys and bones. The maximum amount of protactinium considered not harmful after absorption by an organism is 0.03 μCi. It corresponds to 0.5 μg ^{231}Pa. Protactinium-231, contained in the air as an aerosol, is 2.5×10^{8}-fold more toxic than hydrocyanic acid at the same concentrations (Bagnall, 1966a). Therefore all operations with weighable amounts of ^{231}Pa are carried out in special isolated boxes.

4.4.9 Applications of protactinium

Pa was used for the preparation of a scintillator for detecting X-rays, comprising complex oxides of Gd, Pa, Cs, rare earth metals and other elements. This scintillator, which can significantly increase relative light emission outputs without increasing background, is used in for detecting X-rays, particularly in an X-ray computed tomography apparatus (Hitachi Metals, 1999). The coating material for a color cathode ray tube with bright green fluorescence was created by doping wih Pa (Toshiba, 1995).

Mixed oxides of Nb, Mg, Ga and Mn, doped with 0.005–0.52% Pa_2O_5, were used as high temperature dielectrics (up to 1300°C) for ceramic capacitors (Fujikawa *et al.*, 1996).

One of the important applications of Pa can be in the determination of ancient subjects using a $^{231}Pa/^{235}U$ dating method. This method was used for the dating of one of the Qafzeh human skulls, Qafzen 6, excavated in 1934 by Neuville and Stekelis and conserved at the Institut de Paléontologie Humaine in Paris, by non-destructive gamma-ray spectroscopy. A long-term measurement resulted in an age of (94 ± 10) Ka and confirmed the great antiquity of the Proto-Cro-Magnons of the Near East, contributing to the establishment of modern man's chronology (Yokoyama *et al.*, 1997). The Neanderthal hominid Tabun C1, found in Israel by Garod and Bate, was attributed to either layer B or C of their stratigraphic sequence. Gamma-ray spectroscopy of the $^{231}Pa/^{235}U$ ratios of two bones from this skeleton was used to determine their age. Calculations gave the age of the Tabun C1 mandible as 345 Ka. This suggests that Neanderthals did not necessarily coexist with the earliest modern humans in the region. The early age determined for the Tabun skeleton would suggest that Neanderthals survived as late in the Levant as they did in Europe (Schwarcz *et al.*, 1998). Uranium-series dating of bones and teeth from the Chinese Paleolithic sites has also been used (Chen and Yuan, 1988).

As a result of the development of the nuclear industry (e.g. nuclear power engineering and nuclear powered fleets), a considerable amount of radioactive wastes and spent nuclear fuel is accumulating in the world. Geological disposal of solid and solidified nuclear waste is considered as being economical, technically and ecologically the most feasible approach to completion of the nuclear fuel cycle. Thus determination of chemical behavior of actinides elements, Pa included, is an important problem of environmental science.

The sorption behavior of Pa, which is a decay product of uranium, was studied on the principal rock types from the potential areas selected for construction of a repository. The sorption distribution coefficients (K_d) of Pa were determined under ambient conditions in oxic and anoxic (N_2) atmospheres using natural fresh and brackish groundwater; and the values obtained were 0.07–2.3 and 1.7–12 $m^3\ kg^{-1}$, respectively (Kulmala *et al.*, 1998). Pickett and Murrell (1997) presented the first survey of $^{231}Pa/^{235}U$ ratios in volcanic rocks; such measurements were made possible by new mass spectrometric techniques. It was shown that the high $^{231}Pa/^{235}U$ ratios in basalts reflect a large degree of discrimination between two incompatible elements, posing challenges for modeling of melt generation and migration. Fundamental differences in $^{231}Pa/^{235}U$ ratios among different basaltic environment are likely related to differences in melting zone conditions (e.g. melting rate). Strong disequilibria in continental basalts demonstrate that Pa–U fractionation is possible in both garnet and spinel mantle stability fields.

4.5 ATOMIC PROPERTIES

Experimental measurements (Marrus *et al.*, 1961; Giaechetti, 1966; Richards *et al.*, 1968) and theoretical calculations (Judd, 1962; Wilson, 1967, 1968) agree that the ground state configuration of the neutral Pa atom is almost certainly [Rn] $5f^2 6d^1 7s^2$. However, some unpublished calculations by Maly (cited by Cauchois (1971)) indicated that the total relativistic energy of that structure was 0.9 eV higher than that of a $5f^1 6d^2 7s^2$ configuration, implying that the latter may be the more stable of the two. Giaechetti (1967) found that the ground state configuration of the first ion of Pa (Pa^{1+}) was $5f^2 7s^2$ and this was confirmed by theoretical calculations, which also yielded $5f^2 6d^1$, $5f^2$ and $5f^1$ as the ground state configurations of Pa^{2+}, Pa^{3+} and Pa^{4+}, respectively. Crystal structure stabilities and the electronic structure of Pa have been discussed by Wills and Ericsson (1992).

The emission spectrum of Pa was first recorded by Schüler and Gollnow (1934), who reported a large number of lines in the visible region, many of which showed hyperfine splitting patterns, indicating a nuclear spin of 3/2 for ^{231}Pa. Tomkins and Fred (1949) listed 263 lines in the ultraviolet region sensitive to copper spark excitation. The emission spectrum excited by a microwave discharge tube was measured by Richards and co-workers (1963, 1968), who recorded some 14 000 lines between 3 μm and 400 nm, about half of which were fitted into a level scheme of about 200 even and 300 odd levels.

Table 4.4 lists recommended X-ray atomic energy levels, based on the X-ray wavelengths re-evaluated by Bearden (1967) and by Bearden and Burr (1967).

The Mössbauer effect has been studied by Croft *et al.* (1968) with the 84.2 keV γ-ray of ^{231}Pa, following β$^-$-decay of ^{231}Th; resonance absorption was detected

Table 4.4 *Recommended values of the atomic energy levels* (eV) *of Pa* (*measured values of the X-ray absorption energies are shown in parentheses*) (*Bearden and Burr*, 1967).

with absorbers of both Pa_2O_5 and PaO_2. No isomer shift between the valence states was observed.

4.6 THE METALLIC STATE

Grosse (1934a) prepared metallic Pa by two methods: (1) Pa_2O_5 was bombarded for several hours with 35 kV electrons at a current strength of 5–10 mA and (2) the pentahalide (Cl, Br, I) was heated on a tungsten filament at a pressure of 10^{-6} to 10^{-5} torr. Later authors have prepared the metal by reduction of PaF_4 with the vapors of Ba (Sellers *et al.*, 1954; Bansal, 1966; Cunningham, 1966, 1971; Dod, 1972), Li (Fowler *et al.*, 1965; Cunningham, 1971), or Ca (Marples, 1966). A Zn–Mg reductant is said to yield an impure Pa product (Lee and Marples, 1973).

In the method used by Cunningham and his co-workers at Berkeley (Cunningham, 1971; Dod, 1972), PaF_4 is mixed with barium in a crucible fabricated from a single crystal of BaF_2 (or LiF) and supported in a tantalum foil cylinder. The assembly is evacuated to below 10^{-6} torr and heated inductively to 1250–1275°C for 4–5 min. The BaF_2 crucible is then melted by raising the temperature to 1600°C for 1.5 min and then molten Pa metal agglomerates as a small sphere at the bottom of the Ta support ring. Individual preparations are limited to about 15 mg.

Subsequently, individual preparations of Pa metal of up to 0.5 g have been successfully executed by a modified Van Arkel technique (Baybarz *et al.*, 1976; Brown *et al.*, 1977; Bohet and Muller, 1978; Brown, 1982; Spirlet, 1982). The starting material is protactinium carbide obtained by reduction of Pa_2O_5 with carbon. Heating the protactinium carbide with I_2 generates volatile PaI_5, which is then decomposed on a heated tungsten filament or, better, a sphere (Spirlet, 1979) using induction heating. Protactinium can be precipitated from diluted HF, H_2SO_4 solutions as a fine film on several metal plates (Zn, Al, Mn, and other) (Camarcat *et al.*, 1949; Haïssinsky and Bouissières, 1958; Stronski and Zelinski, 1964). The electrolytic reduction of Pa from NH_4F solutions in the presence of triethylamine at pH 5.8 and 10–20 mA cm^{-2} also has been realized (Emmanuel-Zavizziano and Haïssinsky, 1938). Preparation of a protactinium measurement source by the electroplating method also has been reported by Li Zongwei *et al.* (1998).

The availability of pure, single-crystal Pa metal has made possible the measurement of important physical parameters that cast light on the electronic structure of Pa and for the calculation of its optical properties (Gasche *et al.*, 1996). A theoretical calculation by Soderling and Eriksson (1997) predicted that protactinium metal will undergo a phase transition to the α-U orthorhombic structure below 1 Mbar (1 Mbar $\sim$100 GPa) pressure. At higher pressures, the β-phase re-enters into the phase diagram and at the highest pressures an ideal *hcp* structure becomes stable. Hence, Soderling and Eriksson expect Pa to undergo a sequence of transitions, with the first transition taking place at 0.25 Mbar and the subsequent ones above 1 Mbar. The β→α-U transition is triggered by the pressure-induced promotion of the spd-valence electrons to 5f states. In this regard Pa approaches uranium, which at ambient conditions has one more 5f electron than Pa at similar conditions. At higher compression of Pa, the 5f band broadens and electrostatic interactions in combination with Born–Mayer repulsion become increasingly important and drive Pa gradually to more close-packed structures. At ultra-high pressures, the balance between electrostatic energy, Born–Mayer repulsion, and one-electron band energy stabilizes the *hcp* (ideal packing) structure.

Recent experimental results (Haire *et al.*, 2003) confirm that the stable room temperature and pressure phase of Pa metal is the body-centered tetragonal (*bct*) phase. Under high pressure this phase is stable until 77(5) GPa (77 GPa ~0.77 Mbar) where it is converted to orthorhombic, the α-uranium phase, with a small (0.8%) volume collapse. The relative volume of the *bct* phase decreased smoothly from 1 atm down to a volume ratio of ~0.7 before the high-pressure phase transformation. Experiments continued to a pressure of 130 GPa with no further phase change but with a smooth decrease in the volume of the orthorhombic phase of ~0.62. Haire *et al.* (2003) attribute the structural phase change to an increase in 5f bonding at the higher pressures.

The superconducting properties of Pa metal have been described by Smith *et al.* (1979), who determined the superconducting transition temperature and upper critical magnetic field. Since the superconducting properties of Pa are markedly affected by its 5f electronic structure, it is now evident that Pa is a true actinide element. The heat capacity of a single Pa crystal in the temperature range 4.9–18 K has been reported (Stewart *et al.*, 1980). The unit cell volume of Pa metal first decreases and then increases on cooling from 300 to 50 K (Benedict *et al.*, 1979). The importance of the expansion coefficient in the explanation of specific-heat parameters has been discussed by Mortimer (1979). A Mössbauer resonance of ^{231}Pa at 84.2 keV in Pa metal has been reported; the electric field gradient in Pa metal is $|eq_Z| = (2.05 \pm 0.15) \times 10^{18}$ V cm^{-2} (Friedt *et al.*, 1978; Rebizant *et al.*, 1979). The vapor pressure of liquid Pa metal in the temperature range 2500–2900 K has been measured by a combination of mass spectrometry and Knudsen effusion techniques; the vapor pressure (in Pascals) is given (Bradbury, 1981) by:

$$\log[P(\mathrm{Pa(liq)})] = -[(31\,328 \pm 375)/T] + (10.83 \pm 0.13).$$

Pa metal is malleable and ductile (Zachariasen, 1952; Sellers *et al.*, 1954). Other physical properties are summarized in Table 4.5. The enthalpy of sublimation of Pa(s) at 298 K has been calculated to be 660 (Bradbury, 1981) or 570 kJ mol^{-1} (Kleinschmidt *et al.*, 1983).

Metallic Pa is attacked by 8 M HCl, 12 M HF, or 2.5 M H_2SO_4, but the initial reaction ceases quickly, possibly because of the accumulation of a protective layer resulting from the hydrolysis of Pa(V) or Pa(IV) at the metal surface.

The metal does not react with 8 M HNO_3 even in the presence of 0.01 M HF. The most effective solvent found thus far is a mixture of 8 M HCl and 1 M HF (Cunningham, 1971).

According to Dod (1972), metal samples exposed to air at room temperature show little or no tarnishing over a period of several months. A slight loss of metallic luster was observed when a sample of Pa metal was heated in air for 1 h at 100°C. Heating for 1 h at 300°C caused the sample to turn grayish white and begin to disintegrate. Pa metal exposed to O_2, H_2O, or CO_2 at 300 and 500°C yielded Pa_2O_5; reaction with NH_3 and H_2 produced PaN_2 and PaH_3, respectively. The metal reacts quantitatively with excess I_2 above 400°C to yield a sublimate of crystalline, black PaI_5 (Sellers *et al.*, 1954; Brown *et al.*, 1967b).

4.6.1 Alloys

Erdmann and Keller (Erdmann, 1971; Erdmann and Keller, 1971, 1973) have prepared Pa–noble-metal alloy phases by reduction of Pa_2O_5 with highly purified H_2 in the presence of Pt, Ir, and Rh. Preparation conditions and some properties of these intermetallic compounds are listed in Table 4.6. Reaction of Pa_2O_5 with beryllium metal has been reported by Benedict *et al.* (1975) to form $Be_{13}Pa$.

4.7 SIMPLE AND COMPLEX COMPOUNDS

4.7.1 Protactinium hydride

Perlman and Weisman (1951) and Sellers *et al.* (1954) reacted H_2 with Pa metal at about 250°C and a pressure of about 600 torr, and obtained a black flaky substance, isostructural with β-UH_3. The compound was cubic, with a unit cell constant $a = (6.648 \pm 0.005)$ Å. However, Dod (1972) reported the formation at 100, 200, and 300°C of a gray, powdered substance that is isostructural with α-UH_3. The unit cell constant of α-PaH_3 is (4.150 ± 0.002) Å for the product obtained at 100 and 200°C and (4.154 ± 0.002) Å at 300°C. Subsequently, Brown (1982) prepared α- and β-PaH_3 at 250 and 400°C, respectively.

4.7.2 Protactinium carbides

Lorenz *et al.* (1969) prepared PaC by reduction of Pa_2O_5 with graphite at reduced pressure and temperatures above 1200°C. The product obtained at 1950°C was face-centered cubic (*fcc*) (NaCl type) with $a = (5.0608 \pm 0.0002)$ Å. At 2200°C, some additional weak lines, attributable to PaC_2, were observed; this structure was body-centered tetragonal with $a = (3.61 \pm 0.01)$ Å and $c = (6.11 \pm 0.01)$ Å. According to Sellers *et al.* (1954), PaC was 'probably' prepared by the reduction of PaF_4 with Ba in a carbon crucible. The magnetic susceptibility of PaC between 4 K and room temperature was measured by Hery *et al.* (1977). The magnetic susceptibility of PaC is weak (about -50×10^6 (emu cg)·mol^{-1}) and essentially independent of temperature, which may be taken to indicate the absence of 5f electrons and the presence of Pa(v) in the compound. Theoretical calculations by Maillet (1982) suggest that in ThC 5f electron participation in the bonding is minimal, but that in PaC the 5f electron bonding contribution is important.

4.7.3 Protactinium oxides

The known binary oxides of Pa are listed in Table 4.7. White Pa_2O_5 is obtained when the hydrated oxide, $Pa_2O_5 \cdot nH_2O$, and a wide variety of protactinium compounds as well are heated in oxygen or air above 500°C (Kirby, 1961) or 650°C (Sellers *et al.*, 1954; Keller, 1977). Thermochemical studies (Kleinschmidt and Ward, 1986) and differential thermal analysis shows three endothermic peaks, with maxima at 80, 390, and 630°C, and an exothermic peak, whose maximum occurs at 610°C (Stchouzkoy *et al.*, 1968). Several crystal modifications can be prepared, depending on the temperature to which the Pa_2O_5 is heated (Stchouzkoy *et al.*, 1964, 1966b; Roberts and Walter, 1966).

Black PaO_2 is prepared by the reduction of Pa_2O_5 with H_2 at 1550°C (Sellers *et al.*, 1954). Pa dioxide did not dissolve in H_2SO_4, HNO_3, or HCl solutions but reacted with HF because of the Pa(iv) oxidation to the pentavalent state by O_2 (Pal'shin *et al.*, 1970). Four intermediate phases have been identified by reduction of the pentoxide and oxidation of the dioxide (Roberts and Walter, 1966). A monoxide has been claimed to exist as a coating on metal preparations (Sellers *et al.*, 1954).

The heat of formation of Pa_2O_5 is about 106 kJ mol^{-1} as calculated by Augoustinik (1947). Pa_2O_5 did not dissolve in concentrated HNO_3 (Jones, 1966), but dissolved in HF and in a HF + H_2SO_4 mixture (Codding *et al.*, 1964) and reacted at high temperatures with solid oxides of metals of groups I and II of the periodic table (Pal'shin *et al.*, 1970).

Ternary oxides and oxide phases of different compositions and structures have been prepared by reaction of PaO_2 and Pa_2O_5 with the oxides of other elements (Table 4.8) (Keller, 1964a,b, 1965a–c, 1966a,b, 1971; Keller and Walter, 1965; Keller *et al.*, 1965; Iyer and Smith, 1966).

[a] Could not be prepared in the pure state; always contained varying amounts of Pa(v).

The pale yellow product, which precipitates upon addition of H_2O_2 to a solution of Pa(v) in 0.25 M H_2SO_4, has been assigned the formula $Pa_2O_9 \cdot 3H_2O$ (Stchouzkoy *et al.*, 1966b). It is considered to be an unstable peroxide with a composition that varies with time over the range $Pa_2O_x \cdot 3H_2O$ with $5 < x < 9$.

4.7.4 Protactinium halides

Methods for preparing all the binary halides and many of the oxyhalides of Pa(iv) and Pa(v) are summarized schematically in Figs. 4.11, 4.12, and 4.13; those compounds which have been fully characterized are listed in Table 4.9. The preparative methods shown in Figs. 4.11 and 4.12 use an aqueous acid solution of Pa(v) as the starting material for the synthesis of binary protactinium halides. PaF_5 can be prepared by fluorination of PaC at 570 K or $PaCl_5$ at 295 K. The reaction products are isostructural with β-UF_5 (Brown *et al.*, 1982a). $PaF_5 \cdot 2H_2O$ is prepared by the evaporation of Pa solution in 30% HF

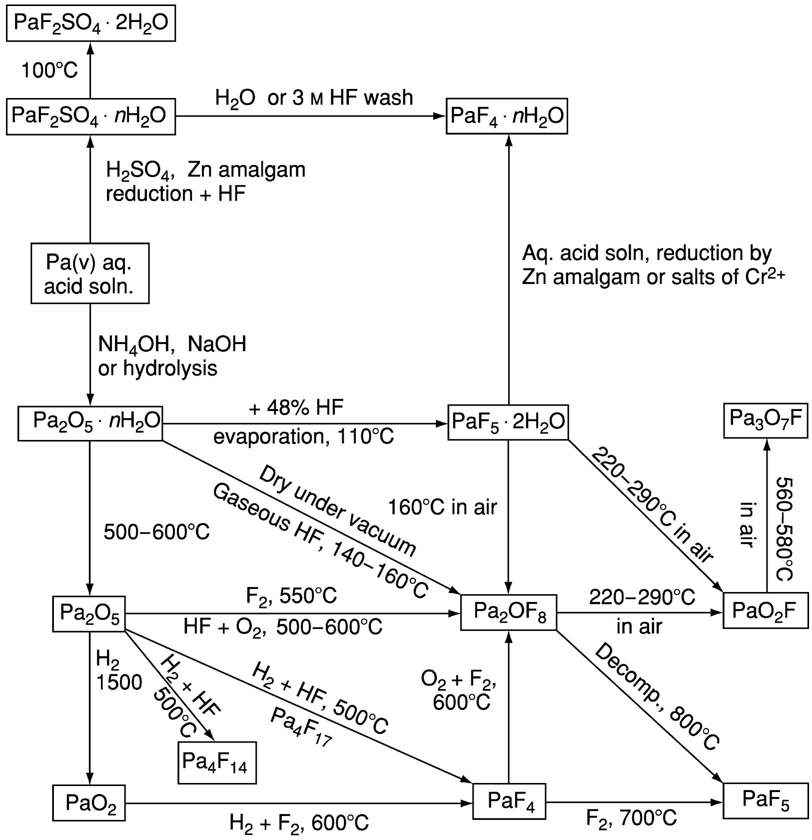

Fig. 4.11 *Preparation of some fluoride derivatives of Pa*(*IV*) *and Pa*(*V*) (*Muxart and Guillaumont*, 1974; *Pal'shin* et al., 1968a).

(Grosse, 1934c). Protactinium carbide is also useful in the preparation of other binary penta- and tetrahalides. Brown *et al.* (1976a) treated PaC with I_2 at 400°C, Br_2 at 350°C, and $SOCl_2$ at 200°C to obtain PaI_5, $PaBr_5$, and $PaCl_5$, respectively. PaI_4 was obtained by reaction of PaC with PaI_5 at 600°C or by the treatment with HgI_2 at 500°C. These compounds were also prepared by reactions of Pa_2O_5 with $Cl_2 + CCl_4$ at 300°C ($\rightarrow PaCl_5$) (Pissot *et al.*, 1966); CCl_4 at 400°C ($\rightarrow PaCl_4$) (Sellers *et al.*, 1954); $AlBr_3$ at 317°C ($\rightarrow PaBr_5$); and AlI_3 at $\leq$300°C ($\rightarrow PaI_5$) (D'Ege *et al.*, 1963) and so on.

Protactinium pentafluoride is reduced to PaF_4 by PF_3 but no reaction occurs with AsF_3. $PaCl_5$ and $PaCl_4$ are formed from PaF_5 and PaF_4 by reaction with PCl_3 and $SiCl_4$, respectively. PaF_5 reacts with CCl_4 to give $PaCl_xF_{5-x}$ (x probably 1), but no reaction is observed with PaF_4 (O'Donnell *et al.*, 1977). Whereas UF_5 is very soluble in acetonitrile, PaF_5 forms a sparingly soluble complex. An adduct $PaF_5 \cdot 2Ph_3PO$ forms on addition of TPPO to PaF_5 in acetonitrile

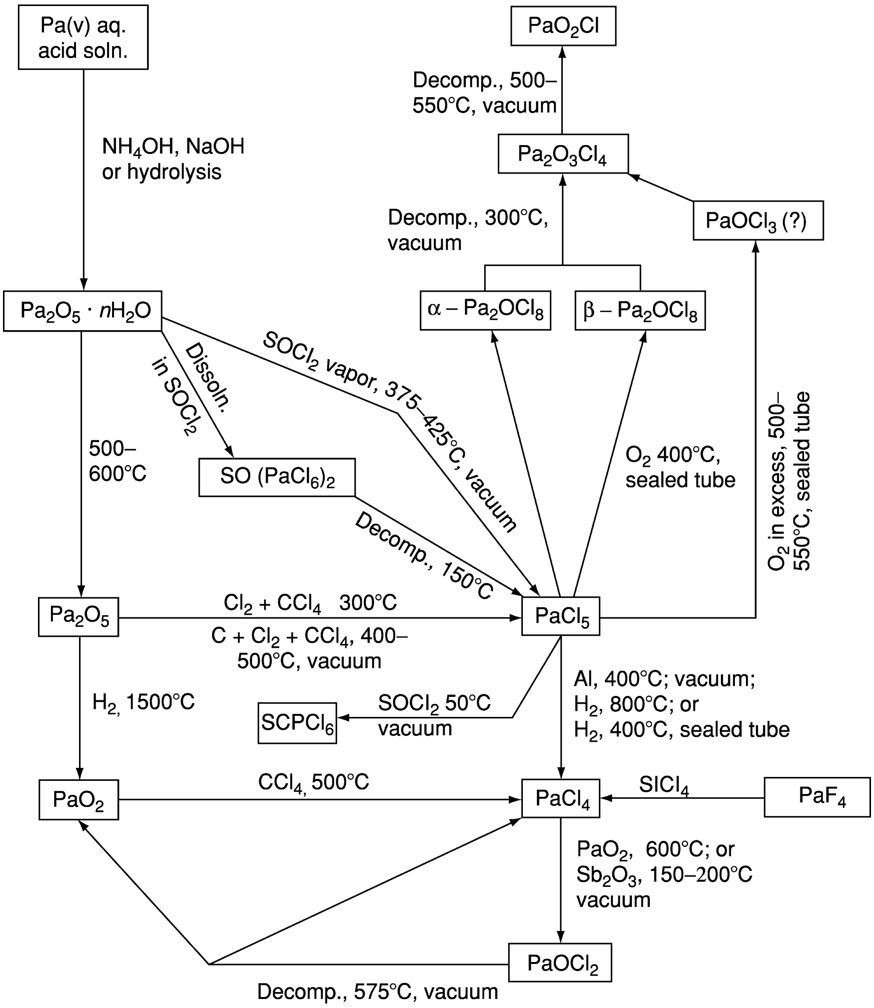

Fig. 4.12 *Preparation of some chlorides and oxychlorides of Pa*(IV) *and Pa*(V) (*Muxart and Guillaumont*, 1974; *Pal'shin* et al., 1968*a*).

(Brown *et al.*, 1982b). Brown (1979) found still another $PaBr_5$ crystal structure, designated γ, isostructural with β-UCl_5.

Of the possible halides of Pa(III), only PaI_3 has been reported so far (Scherer *et al.*, 1967). It is a dark brown compound (not black as originally reported) (Wilson, 1967), prepared by heating PaI_5, for several days at 10^{-6} torr and 360–380°C. Its tentative identification is based primarily on the similarity of its X-ray powder pattern to that of CeI_3.

All the binary halides are volatile at moderate temperatures, a property that has been used for the separation of ^{233}Pa from irradiated ThO_2 as well as for the

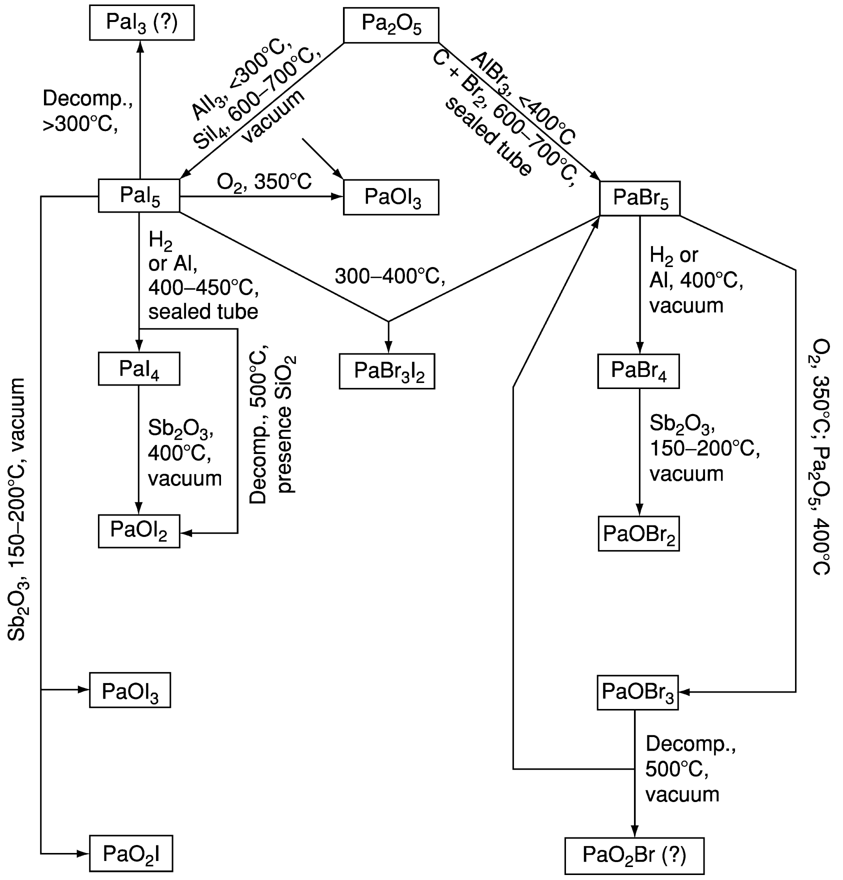

Fig. 4.13 *Preparation of some bromide and iodide derivatives of Pa(IV) and Pa(V) (Muxart and Guillaumont*, 1974; *Pal'shin* et al., 1968*a*).

preparation of radiochemically pure ^{231}Pa and ^{234}Pa (Malm and Fried, 1950; Merinis *et al.*, 1966; Brown, 1971). The vapor pressures of $PaCl_5$ and $PaBr_5$ have been measured by Weigel *et al.* (1969, 1974) in the temperature range 490–635 K; the boiling points, extrapolated to 760 torr, were 420 and 428°C, respectively. The thermal stability studies of Brown and co-workers (1976b) show that PaI_4 is stable up to a temperature of 330°C, and that PaI_5 is stable to 200–300°C.

Numerous alkali fluoro complexes of Pa(v) have been identified (Table 4.10). The first, K_2PaF_7, was prepared by Grosse (1934a) for use in determining the atomic weight of ^{231}Pa. Complexes of the form $MPaF_6$ (M = Li, Na, K, Rb, Cs, Ag, NH_4) can be prepared by crystallization from aqueous HF solutions containing equimolar amounts of Pa(v) and the alkali fluorides, but $LiPaF_6$ and $NaPaF_6$ are best prepared by evaporating the equimolar mixture to dryness and

fluorinating the dried residue (Asprey *et al.*, 1966). The heptafluoroprotactinates, M_2PaF_7 (M = K, NH_4, Rb, Cs), are precipitated by the addition of acetone to a 17 M HF solution containing Pa(v) and an excess of the appropriate alkali fluoride. NaF in a 3:1 molar ratio to Pa(v) yields Na_3PaF_8, but the other octafluoroprotactinates (v) are most easily prepared by the reaction:

$$M_2PaF_7 + MF \rightarrow M_3PaF_8$$

at 450°C in an atmosphere of dry argon or by fluorination of the product obtained by evaporation of an HF solution containing 3:1 MF and Pa(v) (Brown and Easey, 1966).

The fluoro complexes of Pa(IV) are prepared either by H_2 reduction of a Pa(v) complex at 450°C or by heating stoichiometric amounts of the alkali fluoride with PaF_4 in a dry argon atmosphere (Asprey *et al.*, 1967).

$Pa_2O_5 \cdot nH_2O$ reacts vigorously with $SOCl_2$ at room temperature to yield stable solutions containing up to 0.5 M Pa(v). The product is probably $SO(PaCl_6)_2$ which decomposes at 150°C under vacuum. Hexa- and octachloroprotactinates (v) are precipitated when CS_2 is added to $SOCl_2$ solutions containing equal amounts of $PaCl_5$ and MCl (M = $N(CH_3)_4$, $N(C_2H_5)_4$, $NH_2(CH_3)_2$, and $(C_6H_5)_4As$). Hexachloro complexes with Cs^+ and NH_4^+ precipitate when the component halides are reacted in $SOCl_2$/ICl mixtures (Bagnall and Brown, 1964). Hexabromoprotactinate (v) complexes, $MPaBr_6$ (M = $N(CH_3)_4$, $N(C_2H_5)_4$), have been prepared by vacuum evaporation of stoichiometric quantities of $PaBr_5$ and the tetraalkylammonium bromide dissolved in anhydrous CH_3CN (Brown and Jones, 1967b).

Axe and co-workers (Axe, 1960, Axe *et al.*, 1960, Axe *et al.*, 1961) observed the paramagnetic resonance spectrum of Pa^{4+} in single crystal of Cs_2ZrCl_6, crystallized from a melt containing approximately 500 μg of $^{231}PaCl_4$. The $5f^1$ structure was confirmed, as was the nuclear spin of 3/2. The resonance spectrum was found to be isotropic, with a spectroscopic splitting factor $g = -1.14$. Hendricks *et al.* (1971) measured the magnetic susceptibility of $PaCl_4$ from 3.2 to 296 K and found a ferromagnetic transition at about 182 K.

$PaCl_4$ is virtually insoluble in $SOCl_2$, but hexachloro- and hexabromoprotactinates (IV), M_2PaX_6 (X = Cl, Br; M = $N(CH_3)_4$ and $N(C_2H_5)_4$), have been prepared by reaction of PaX_4 with the tetraalkylammonium halide in CH_3CN. Cs_2PaCl_6 is precipitated on the addition of CsCl to a solution of $PaCl_4$ in concentrated HCl. The hexaiodo complex, $[(C_6H_5)_3CH_3As]_2PaI_6$, was also prepared from the component iodides dissolved in CH_3CN (Brown and Jones, 1967a). The electronic structures and optical transition energies of PaX_6^{2-} (X = F, Cl, Br, I) were calculated by quasi-relativistic density functional methods (Kaltsoyannis and Bursten 1995; Kaltsoyannis 1998). Analysis of the $5f^1 \rightarrow 6d^1$ transitions in PaX_6^{2-} (X = Cl, Br) and $ThBr_4:Pa^{4+}$ was reported by Edelstein *et al.* (1988), and the EPR spectra of $ThBr_4:Pa^{4+}$ in the incommensurate phase was detected (Zwanenburg *et al.*, 1988). The fluorescence and absorption spectra between the ground $5f^1$ and the excited $6d^1$ configurations of

Pa^{4+} diluted into a single crystal of Cs_2ZrCl_6 were analyzed (Piehler *et al.*, 1991; Edelstein *et al.*, 1992).

Numerous halide complexes of Pa(IV) and Pa(V) are formed with oxygen donor ligands, such as substituted phosphine oxides (Brown *et al.*, 1966b, 1970a,b), hexamethylphosphoramide (Brown and Jones, 1966a), DMSO (Bagnall *et al.*, 1968b), tropolone (Brown and Rickard, 1970), *N*,*N*-dimethylacetamide (Bagnall *et al.*, 1969), acetylacetone (Brown and Rickard, 1971b), and *N*,*N*-diethyldithiocarbamate (Heckley *et al.*, 1971). In addition, complexes with sulfur and selenium donors have been reported (Brown *et al.*, 1971).

The ground state electronic structures of PaX_6^{2-} (X = F, Cl, Br, I), UX_6^- (X = F, Cl, Br), and NpF_6 have been calculated using both non-relativistic and relativistic implementations of the discrete-variational X alpha (DV-X alpha) method. A significant amount of metal–ligand covalent bonding is found, involving both 6d and 5f metal orbitals. The 5f contribution to the bonding levels increases significantly from PaX_6^{2-} to UX_6^- to NpX_6 but remains approximately constant as the halogen is altered in PaX_6^{2-} and UX_6^-. In contrast, the 6d atomic orbital character of the halogen-based levels increases from UF_6^- to UBr_6^- and a similar, though less marked, trend is observed in PaX_6^{2-}. The electronic transition energies have been calculated using the transition-state method. The relativistic calculations are far superior to the non-relativistic ones in both qualitatively and quantitatively describing the electronic spectra. The stabilization of the metal 5f atomic orbitals with respect to the halogen *n*p levels from Pa to Np results in the more energetic $f \rightarrow f$ transitions in NpF_6 being masked by the onset of a ligand-to-metal charge transfer band. In the remaining molecules, the $f \rightarrow f$ transitions occur well removed from charge transfer bands (Kaltsoyannis, 1998).

Several chloro complexes and one bromo complex for which crystallographic data are available are listed in Table 4.11.

4.7.5 Protactinium pnictides

Protactinium pnictide compounds have been prepared and constitute a new category of Pa compounds that have several features of more than usual interest. The protactinium phosphide, PaP_2, was prepared by reaction of elemental phosphorus with protactinium hydride; thermal dissociation of PaP_2 forms Pa_3P_4 (Table 4.12) (Wojakowski *et al.*, 1982). The diarsenide, $PaAs_2$, can be obtained by heating together PaH_3 and elemental arsenic at 400°C; heating $PaAs_2$ to 840°C results in decomposition of $PaAs_2$ to form Pa_3As_4 (Hery *et al.*, 1978). $PaAs_2$ has a tetragonal structure of the anti-Fe_2As type, and Pa_3As_4 crystallizes in a body-centered structure of the Th_3P_4-type (Table 4.12). Single crystals of $PaAs_2$, Pa_3As_4, PaAs, and Pa_3Sb_4 were prepared from the elements by a Van Arkel procedure using vapor transport; iodine was the transporting agent and deposition occurred on an induction-heated tungsten support (Calestani *et al.*, 1979a,b). Hery and co-workers (1979) have obtained Pa_3Sb_4 and $PaSb_2$ by heating PaH_3 with antimony.

The magnetic susceptibility of $PaAs_2$ and $PaSb_2$ has been measured from 4 K to room temperature. PaAs, $PaAs_2$, and $PaSb_2$ exhibit temperature-independent paramagnetism (Hery *et al.*, 1978). Self-consistent band structure calculations show that PaN and PaAs have about one f-electron, and hence they are expected to be paramagnetic; these results have been confirmed by experiment (Hery, 1979; Brooks *et al.*, 1980).

4.7.6 Miscellaneous compounds

Pa_2O_5 is insoluble in nitric acid but the freshly prepared hydroxide, the pentachloride, the pentabromide, and the complex $SO(PaCl_6)_2$ all dissolve in fuming HNO_3 to form stable solutions of at least 0.5 M Pa(V). Vacuum evaporation of such solutions yields $PaO(NO_3)_3 \cdot xH_2O$ $(1 < x < 4)$. The reaction of Pa(V) halides with N_2O_5 in anhydrous CH_3CN yields $Pa_2O(NO_3)_4 \cdot 2CH_3CN$. Complexes of the type $MPa(NO_3)_6$ (M = Cs, $N(CH_3)_4$, $N(C_2H_5)_4$) have been prepared by reaction of the hexachloroprotactinates (V) with liquid N_2O_5 at room temperature (Brown and Jones, 1966b; Jones, 1966).

When a solution of Pa(V) in a mixture of HF and H_2SO_4 is evaporated until all F^- ion has been eliminated, $H_3PaO(SO_4)_3$ crystallizes almost quantitatively. The analogous selenato complex, more stable in acid (6 M HCl) or basic (NH_4OH) media, is obtained from HF/H_2SeO_4 mixtures. The sulfato-complex decomposes to $HPaO(SO_4)$ at 375°C (Bagnall *et al.*, 1965; Bagnall, 1966b) and to Pa_2O_5 at 750°C (Pal'shin *et al.*, 1968b). The binary chalcogenides, β-PaS_2 and γ-$PaSe_2$, have been prepared by Hery (1979). PaOS was obtained by the reaction of $PaCl_5$ with a mixture of H_2S and CS_2 at 900°C (Sellers *et al.*, 1954). $PaF_2SO_4 \cdot 2H_2O$ is precipitated when a solution of Pa(IV) in 4.5 M H_2SO_4 is added to 3 M HF (Stein, 1966). Crystallographic data for some S and Se compounds are given in Table 4.12.

The addition of hydrochloric acid to a solution of Pa(V) oxalate causes the precipitation of $PaO(C_2O_4)(OH) \cdot xH_2O$ $(x \sim 2)$ (Muxart *et al.*, 1966a). On the other hand, the addition of acetone instead of acid yields $Pa(OH)(C_2O_4)_2 \cdot 6H_2O$ (Davydov and Pal'shin, 1967).

Phenylarsonic acid forms a white flocculent precipitate with Pa(V) in neutral or acid solutions. The compound is believed to have the composition $H_3PaO_2(C_6H_6AsO_3)_2$ (Myasoedov *et al.*, 1968c).

Complexes of the type $[N(C_2H_5)_4]_4PaR_8$ (R = NCS or NCSe) have been prepared by reaction of $PaCl_4$ with stoichiometric amounts of KCNS or KCNSe in anhydrous CH_3CN (Table 4.12) (Al-Kazzaz *et al.*, 1972). The bis(phthalocyaninato)complexes of Pa(IV), $(C_{32}H_{16}N_8)_2Pa$, have been prepared by neutron irradiation of the corresponding thorium $^{233}ThPc_2$ complex by the reactions (Lux *et al.*, 1970, 1971):

$$^{232}ThPc_2(n,\gamma)\,^{233}ThPc_2 \rightarrow {}^{233}PaPc_2 + \beta^-$$

Spectroscopically pure bis(phthalocyaninato)protactinium(IV) ($PaPc_2$) was prepared by reaction between $PaI_4 \cdot 4CH_3CN$ and *o*-phthalic dinitrile in

1-chloronaphthalene followed by purification by sublimation. $PaPc_2$ is isostructural with $ThPc_2$ and UPc_2 (Lux *et al.*, 1980). Tetrakis(cyclopentadienyl)Pa(IV), $(C_5H_5)_4Pa$, was prepared by treating Pa_2O_5 with a mixture of $Cl_2 + CCl_4$ in an argon stream at 600°C, then fusing the reaction product with $Be(C_2H_5)_2$ at 65°C (Keller, 1964b; Baumgartner *et al.*, 1969). Protactinium(IV) tropolone, $Pa(Trop)_4$, has been prepared by reaction of $PaCl_4$ or $PaBr_4$ with lithium tropolonate, Li(Trop) in methylene chloride; in the presence of excess Li (Trop) in dimethyl formamide, $LiPa(Trop)_5$ is formed (Brown and Richard, 1970). However, when protactinium pentethoxide, which is obtained by reaction of $PaCl_5$ with sodium ethoxide in anhydrous alcohol (Maddock and Pires deMatos, 1972; Bagnall *et al.*, 1975), is treated with tropolone, the complex Pa $(Trop)_5$ is obtained. $Pa(Trop)_5$ has been crystallized and its crystal structure parameters are determined (Table 4.12) (Bhandari and Kulkarni, 1979). Complexes of the actinide elements with cyclooctatetrene have been obtained by reaction of an actinide halide with cyclooctatetrene anion. The bis(η^8-tetramethylcyclooctatetradiene) complex of Pa has been prepared by reaction of Pa borohydride, $Pa(BH_4)_4$, with tetramethylcyclooctatetrene dianion (Solar *et al.*, 1980). The preparation of the anhydrous tetraformate, $Pa(HCOO)_4$, has been reported by the reaction of $PaCl_4$ with O_2-free HCOOH at 60°C in an argon atmosphere for 4 h (Table 4.12) (Bohres, 1974; Bohres *et al.*, 1974).

Freshly precipitated Pa(V) hydroxide or peroxide dissolves readily in 14 M H_3PO_4. However, upon aging, the hydrated orthophosphate, $PaO(H_2PO_4)_3 \cdot 2H_2O$, crystallizes out. Calcination of this product yields, successively: the anhydrous orthophosphate, $PaO(H_2PO_4)_3$ between room temperature and 300°C; the trimetaphosphate, $PaO(PO_3)_3$, stable to 900°C; the pyrophosphate, $(PaO)_4(P_2O_7)_3$, at 1000°C; and an unidentified phase with the gross composition $Pa_2O_5 \cdot P_2O_5$ at 1200°C (LeCloarec *et al.*, 1970, 1976; LeCloarec and Muxart, 1971; LeCloarec, 1974). Crystallographic data for several phosphates are given in Table 4.12. Protactinium(V) perrhenate, $PaO(ReO_4)_3 \cdot xH_2O$, has been prepared by reaction of Pa_2O_5 and Re_2O_7 (Silvestre *et al.*, 1977).

Protactinium(IV) borohydride, $Pa(BH_4)_4$, has been prepared by treating PaF_4 with aluminum borohydride, $Al(BH_4)_3$. It is a relatively unstable solid at 20°C, but exhibits high volatility as do other actinide borohydrides. $Pa(BH_4)_4$ is isostructural with $U(BH_4)_4$ (Banks *et al.*, 1978; Banks, 1979; Banks and Edelstein, 1980). The molecular compound, $Pa(BH_3CH_3)_4$, has been synthesized from the reaction of $PaCl_5$ or $PaCl_4$ with $Li(BH_3CH_3)$. Its optical and NMR spectra have been obtained. Because of the T_d symmetry at the Pa^{4+} site, the dipolar shift is zero and the temperature-dependent proton and ^{11}B shifts are attributed to spin delocalization mechanisms. The ^1H NMR peaks of both the bridging and terminal protons shift to lower field as the temperature is decreased. These observations are inconsistent with a spin-polarization mechanism, which assumes that the temperature-dependent shifts are proportional to the average value of the electron spin in the 5f orbitals. In addition, new synthetic routes to $Pa(BH_4)_4$ and $Pa(MeCp)_4$ (MeCp = methylcyclopentadienyl) are described. They are simpler and more convenient than the earlier published methods and take advantage of the unexpected solubility of $PaCl_5$ in aromatic hydrocarbons (Kot and Edelstein, 1995). The 5f–6d absorption spectrum of $Pa^{4+}/CsZrCl_6$ (Edelstein *et al.*, 1992) and magnetic data of tetravalent protactinium(IV) (Edelstein and Kot, 1993) also were reported.

4.8 SOLUTION CHEMISTRY

Two oxidation states, Pa(IV) and Pa(V), have been definitely established in aqueous solution (Haïssinsky and Bouissières, 1948, 1951; Bouissières and Haïssinsky, 1949), but all attempts to demonstrate the existence of Pa(III) in solution have led to negative or inconclusive results (Elson, 1954; deMiranda and Maddock, 1962; Musikas, 1966). Both Pa(IV) and Pa(V) show strong tendencies to hydrolyze in the absence of complexing agents and most studies of the ionic species of Pa in aqueous solution have therefore been carried out at the tracer level. Furthermore, the instability of Pa(IV) toward reoxidation has made it difficult to obtain reproducible data on this oxidation state, so that, until quite recently, little quantitative information has been available about the aqueous chemistry of Pa(IV).

The behavior of protactinium in aqueous solution has been very thoroughly reviewed by Guillaumont, Bouissières, and Muxart (Guillaumont *et al.*, 1968; Bouissières, 1971; Muxart and Guillaumont, 1974) and by Pal'shin *et al.* (1970); those reviews should be consulted for more detail than can be given here. For a general discussion of the techniques used in the determination of stability constants, see Rossotti and Rossotti (1961), Fronaeus (1963), or Ahrland *et al.* (1973).

4.8.1 Hydrolysis of Pa (V) in non-complexing media

The hydrolytic behavior of Pa(V) has been studied by a large number of investigators (Jakovac and Lederer, 1959; Guillaumont, 1966a, 1971; Liljenzin and Rydberg, 1966; Scherff and Hermann, 1966; Suzuki and Inoue, 1966, 1969; Kolarich *et al.*, 1967; Mitsuji and Suzuki, 1967; D'yachkova *et al.*, 1968a; Mitsuji, 1968; Liljenzin, 1970; Cazaussus *et al.*, 1971) whose conclusions are summarized schematically in Figs. 4.14 and 4.15 (Bouissières, 1971).

The hydrolysis of Pa(V) is usually studied in perchloric acid solutions, because ClO_4^- is considered to be a non-complexing anion. However, the presence of small amounts of weakly complexing anions does not affect the results. Thus, <0.5 M HNO_3, <1 M HCl, <0.01 M H_2SO_4, or <0.01 M $H_2C_2O_4$, are all equivalent to $HClO_4$ of the same acidity.

In solutions of constant ionic strength ($\mu = 3$; 10^{-5} M$<$ $[H^+] < 3$ M), the least hydrolyzed cation is $PaOOH^{2+}$. At $[H^+] < 1$ M, $PaO(OH)_2^+$ begins to form and becomes predominant at pH ~3. At higher pH values, the neutral species, $Pa(OH)_5$, is formed. At tracer levels these species are in equilibrium (Fig. 4.14), but, at concentrations of Pa(V) close to saturation, polymers are

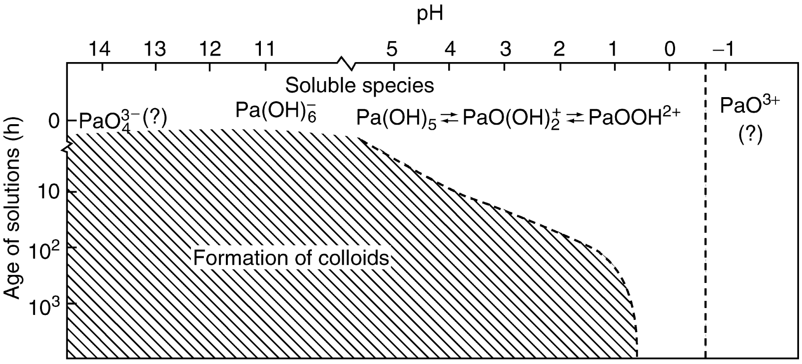

Fig. 4.14 *Hydrolysis of tracer-level Pa(v) in $HClO_4$ solution (Bouissières,* 1971).

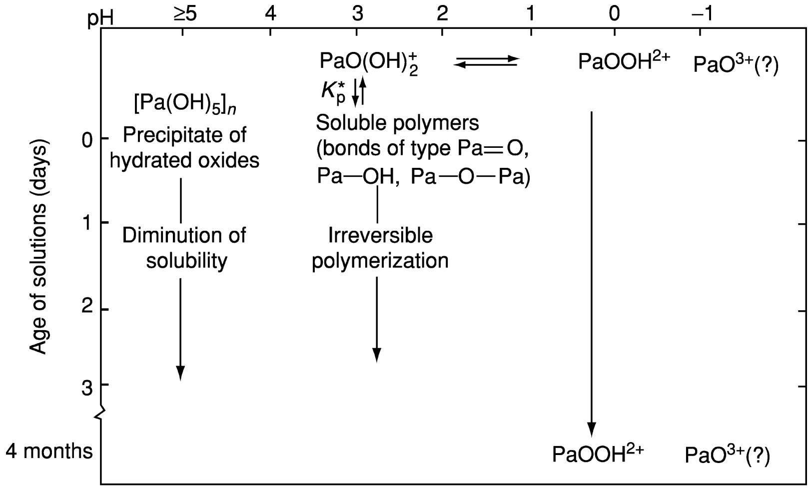

$K_p^* = [Pa_p]/[Pa_{p-1}][PaO(OH_2^+] \approx 3 \times 10^7$, with $Pa_p \equiv$ polymers of p atoms

Fig. 4.15 *Hydrolysis of Pa(v) in $HClO_4$ solution at* $[Pa(v)] = 10^{-5}$ M *(Bouissières,* 1971).

formed, a process that rapidly becomes irreversible (Fig. 4.15). At pH 5–6, the hydrated oxide is precipitated. In alkaline solution ($\mu = 0.1$) minute concentrations of $Pa(OH)_6^-$ are formed, and at $[H^+] \geq 3$ M the existence of PaO^{3+} has been suggested.

The hydrolysis reactions of Pa(v) may be written as:

$$PaO^{3+} + H_2O \leftrightarrow PaO(OH)^{2+} + H^+ \qquad (4.1)$$

$$PaO(OH)^{2+} + H_2O \leftrightarrow PaO(OH)_2^+ + H^+ \qquad (4.2)$$

$$PaO(OH)_2^+ + 2H_2O \leftrightarrow Pa(OH)_5 + H^+ \qquad (4.3)$$

with the corresponding equilibrium reaction constants K_1, K_2, and K_3. Since the species PaO^{3+} has only been suggested but never proven, only the latter two hydrolysis reactions and corresponding hydrolysis constants can be measured. Early studies on Pa(v) hydrolysis were reported by Guillaumont (1966a) and Bouissières (1971).

Recently Trubert *et al.* (Le Naour *et al.*, 2003; Trubert *et al.*, 1998, 2002, 2003) have obtained the hydrolysis constants for Pa(v) at the tracer level ($\sim 10^{-12}$ M using ^{233}Pa) from the variations of the partition coefficient of Pa(v) in the system: TTA/toluene/Pa(v)/H_2O/H^+/Na^+/ClO_4^- . These experiments were performed as a function of the concentrations of TTA and H^+ at ionic strengths of $0.1 \le \mu \le 3$ M and temperatures of 10°C $\le T \le$ 60°C. From the hydrolysis constants obtained under these conditions extrapolations to zero ionic strength were performed using the specific ion interaction theory (SIT) (Grenthe and Puigdomenech, 1997). The equilibrium constants obtained are given in Table 4.13. Thermodynamic data related to the hydrolysis equilibria were derived from the temperature dependence of the hydrolysis constants at infinite dilution and are given in Table 4.14.

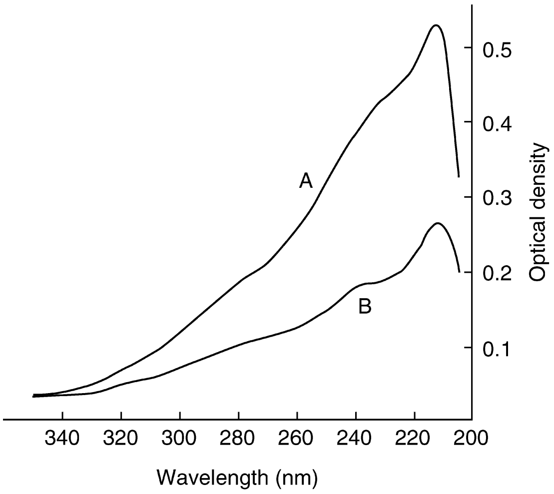

Fig. 4.16 *Absorption spectra of Pa(*v*) in* 11.5 M *$HClO_4$. The solution was prepared by dissolution of the hydroxide. Curve A, fresh solution; curve B, solution aged for* 1 *day or longer.* [*Pa(*v*)*] ~ 10^{-5} M (*Guillaumont*, 1966*c*).

The absorption spectrum of Pa(v) in 11.5 M $HClO_4$ is shown in Fig. 4.16 (Guillaumont, 1966c); similar spectra are obtained at lower acidities. The absorption maximum at about 200–210 nm is attributed to the Pa═O bond in $PaO(OH)_2^+$ and $PaOOH^{2+}$; this bond persists even in sulfuric acid media up to 4 M concentration.

4.8.2 Complexes of Pa(v) in mineral acid solutions

In the absence of strong complexing agents, such as F^- and certain organic reagents, the aqueous complexes of Pa(v) are all oxo- or hydroxo complexes. Consequently, Pa(v) in aqueous solution is rarely present as a single species but rather exists as a mixture of several complexes or hydrolyzed species. These may be characterized by solvent extraction or ion-exchange methods, which, because of differences in the experimental conditions, such as ionic strength, acidity, concentration of the ligand, age of the solution, etc., may yield ambiguous or mutually contradicting interpretations.

The relative complexing tendencies of inorganic anions with respect to Pa(v) are:

$$F^- > OH^- > SO_4^{2-} > Cl^- > Br^- > I^- > NO_3^- \geq ClO_4^-$$

(a) Ionic species of Pa(v) in nitric acid solution

In general, NO_3^- is a poor complexing anion for Pa(v) but freshly prepared solutions, in which [Pa(v)] $\leq 10^{-5}$ M and [HNO_3] ≥ 1 M, are fairly stable. Such systems contain monomeric nitratohydroxo complexes of the form $[\mathrm{Pa(OH)}_n(\mathrm{NO_3})_m]^{5-n-m}$, where $n \geq 2$ and $m \leq 4$ (Hardy *et al.*, 1958). The transition from cationic to anionic forms occurs at $[\mathrm{HNO_3}] \approx$ 4–5 M. Stability constants for several suggested species in this medium are listed in Table 4.15.

(b) Ionic species of Pa(v) in hydrochloric acid solution

Solutions of Pa(v) in hydrochloric acid are generally unstable with respect to hydrolytic condensation when [Pa] $\geq 10^{-3}$ M, although complete precipitation may take as long as several weeks (Kirby, 1966). If the freshly precipitated hydroxide is dissolved in 12 M HCl and then diluted to [Pa] $\leq 10^{-4}$ M and 1 M < [HCl] < 3 M, the solution is reasonably stable and will then contain a mixture of monomeric chloro complexes in thermodynamic equilibrium. It is generally agreed that, for [HCl] < 1 M and [Pa] < 10^{-5} M, the species present are the same as those described above for perchloric acid media, while, for [HCl] $\approx$ 3 M, the predominant species is $\mathrm{PaOOHCl^+}$. The complexes that have been proposed to explain the solvent extraction and ion-exchange behavior of Pa(v) at higher acidities are summarized in Table 4.16. The study of complex formation of Pa in aqueous HCl solutions of medium and high concentrations and the electronic structures of anionic complexes of $[\mathrm{PaCl_6}]^-$, $[\mathrm{PaOCl_4}]^-$, $[\mathrm{Pa(OH)_2Cl_4}]^-$, and $[\mathrm{PaOCl_5}]^{2-}$ have been calculated using the relativistic Dirac–Slater discrete-variational method. The charge density distribution analysis has shown that protactinium has a slight preference for the $[\mathrm{PaOCl_5}]^{2-}$ form or for the pure halide complexes with coordination number higher than six under these conditions. On the other hand, Ta occupies a specific position in the group and has the highest tendency to form the pure halide complex $[\mathrm{TaCl_6}]^-$; niobium has equal tendencies to form the $\mathrm{NbCl_6}$ and $[\mathrm{NbOCl_5}]^{2-}$ species (Pershina *et al.*, 1994).

There are no data on the species of protactinium in HBr and HI solutions. Goble and co-workers (1956, 1958) suggested on the basis of ^{231}Pa extraction from HBr and HI aqueous solutions that bromide and iodide complexes of protactinium are less stable than the chloride complexes.

(c) Fluoro complexes of Pa(v)

The solubility of Pa(v) is relatively high at all concentrations of hydrofluoric acid; thus, 0.05 M HF dissolves 3.9 g $\mathrm{L^{-1}}$ of ^{231}Pa and 20 M HF dissolves at least 200 g $\mathrm{L^{-1}}$ of the pentoxide (Bagnall *et al.*, 1965). The solubility of Pa(v) is estimated to be 11.2 g $\mathrm{L^{-1}}$ in 8 M HCl and 0.6 M HF and at least 125 g $\mathrm{L^{-1}}$ in 8 M HCl and 5 M HF (Chilton, 1964). Solutions of Pa(v) in aqueous HF are very stable with respect to hydrolysis and are probably the only systems that contain no polymeric species.

A great many complexes have been proposed to explain the behavior of Pa(v) in aqueous HF (deMiranda and Muxart, 1965; Bukhsh *et al.*, 1966a,b;

deMiranda, 1966; Guillaumont, 1966a,c; Guillaumont and deMiranda, 1966; Guillot, 1966; Kolarich *et al.*, 1967; Bonnet and Guillaumont, 1969; Plaisance and Guillaumont, 1969); their regions of existence are summarized in Fig. 4.17. Those for which stability constants have been determined are listed in Table 4.17. Only two species exist in a pure state: PaF_7^{2-}, which is present over the range 10^{-3} M < [HF] < 4–8 M, and PaF_8^{3-}, which can exist only when $[F^-] > 0.5$ M and 10^{-7} M $< [H^+] < 10^{-2}$ M. In more acid media, 1 M $< [H^+] <$ 3 M and $[F^-] \approx 10^{-4}$ M, the dominant heptafluoro complex is $HPaF_7^-$; this species would also exist in 10–12 M HF, because the $[F^-]$ is limited to about 10^{-2} M by the equilibrium constants: $K_1 = ([HF]/([H^+] \cdot [F^-])) = 935$ M^{-1} and $K_2 = ([HF_2]/([HF] \cdot [F^-])) = 3.12$ M^{-1} (Plaisance and Guillaumont, 1969). At [HF] $< 10^{-3}$ M, PaF_7^{2-} is replaced by complexes of successively lower F:Pa ratios, then by oxo and hydroxyfluoro complexes and, finally, by uncomplexed species.

(d) Behavior of Pa(v) in sulfuric acid solution

Freshly precipitated Pa(v) hydroxide is readily soluble in moderately concentrated H_2SO_4 and permanently stable solutions, containing up to 90 g L^{-1} of ^{231}Pa in approximately 2.5 M H_2SO_4, have been reported (Thompson, 1952; Kirby, 1959, 1966; Brown *et al.*, 1961; Campbell, 1964; Bagnall *et al.*, 1965; Takagi and Shimojima, 1965; Kirby and Figgins, 1966). The solubility falls off sharply at both ends of the acid concentration range, yielding amorphous hydrated oxides or colloids in <1 M H_2SO_4 and crystalline $H_3PaO(SO_4)_3$ in

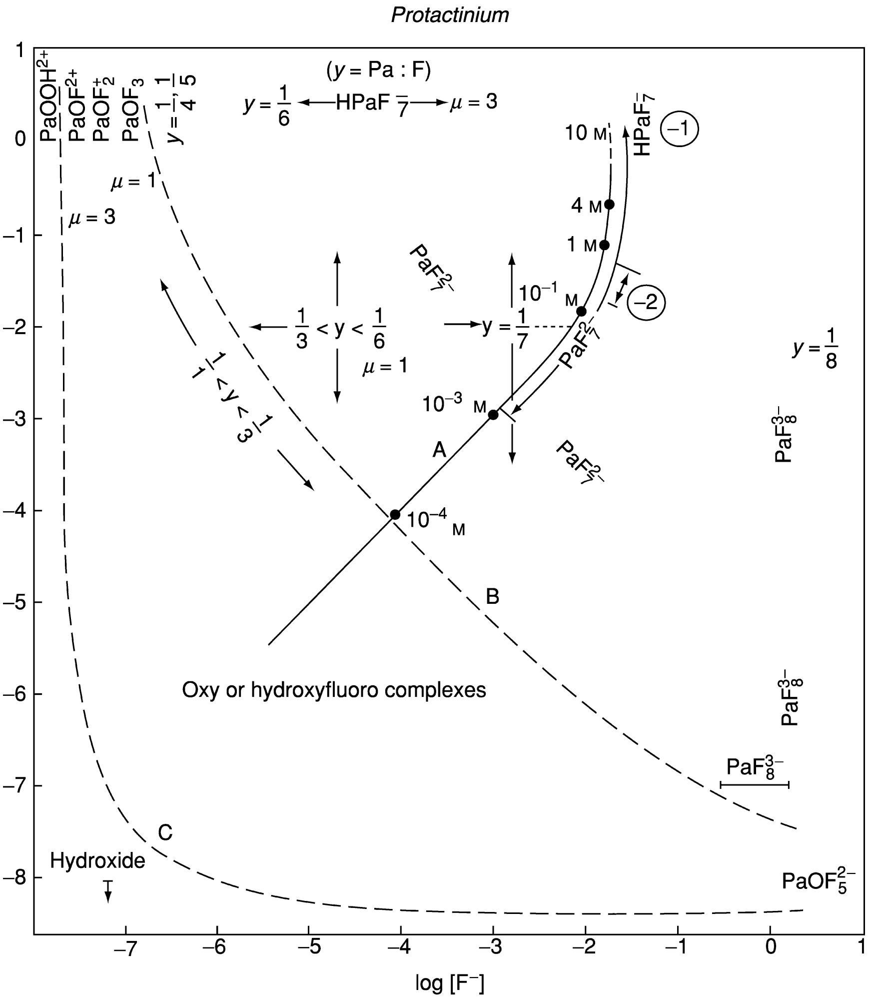

Fig. 4.17 *Fluoro complexes of Pa(*v*) as a function of* [*HF*], [*H*$^+$], *and* [*F*$^-$] (*Guillaumont* et al., 1968).

concentrated H_2SO_4 (Bagnall *et al.*, 1965; Takagi and Shimojima, 1965; Stchouzkoy *et al.*, 1966b, 1968).

The sulfate complexes of Pa(v) that have been deduced from tracer-level studies ([Pa] $\leq 10^{-4}$ M) are listed in Table 4.18. The absorption spectra of Pa(v) in H_2SO_4 are shown in Fig. 4.18 (Guillaumont *et al.*, 1960; Guillaumont, 1966c).

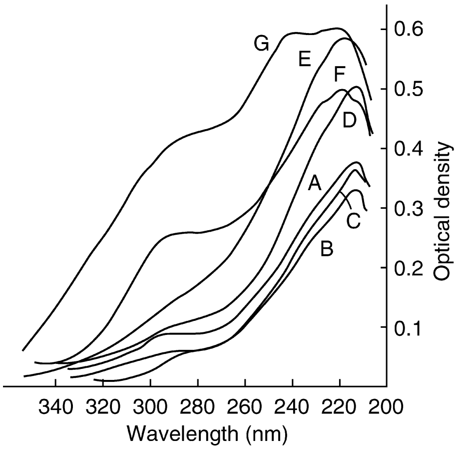
(e) Miscellaneous complexes of Pa(v) with inorganic ligands

The absorption spectra and the formation constants of complexes formed by tracer-level Pa(v) in phosphoric acid solution have been reported by LeCloarec and Muxart (1973), LeCloarec *et al.* (1973), and LeCloarec (1974). The species identified were $PaO(OH)\ ^-(H_2PO_4)^+$, $HPaO(H_2PO_4)_2^{2+}$, $PaO(H_2PO_4)_2^+$, and $PaO(H_2PO_4)_3$.



Curve	$[H_2SO_4]$ (M)	[*Pa(v)*] (M)
A	0.7	0.35×10^{-4}

C	2.2	0.45×10^{-4}
D	4.1	0.42×10^{-4}
E	6.5	0.49×10^{-4}
F	9	0.18×10^{-4}
G	18	0.19×10^{-4}

Fig. 4.18 *Absorption spectra of Pa*(*v*) *in* H_2SO_4 *solution* (*Guillaumont*, 1966*c*).

The addition of ≤ 1 M H_2O_2 to a solution of ^{233}Pa in aqueous $HClO_4$ (1 M $\leq$ $[H^+]$ ≤ 3 M) leads to the formation of the following peroxy complexes: $PaO(OH)(HO_2)^+$, $PaO(OH)(HO_2)_2$, $PaO(HO_2)^{2+}$, and $PaO(HO_2)_2^+$, according to Stchouzkoy *et al.* (1969). Association constants for the 1:1 and 1:2 complexes of Pa(v) with IO_3^- have been reported by Kolarich *et al.* (1967).

Pa(v) forms mixed complexes in solutions containing more than one type of ligand. For example, a species identified as $PaO(H_2PO_4)_3(HSO_4)^-$ is found in a mixture of 0.35 M H_3PO_4 and 0.22 M H_2SO_4 (LeCloarec *et al.*, 1973). Mixed complexes are also formed in hydrochloric or nitric acid solutions containing $\leq 10^{-2}$ M HF (Hardy *et al.*, 1958; Casey and Maddock, 1959b; Shankar *et al.*, 1963; Plaisance and Guillaumont, 1969). Formation constants have been determined for the unidentified mixed complexes formed by Pa(v) in 3–6 M HNO_3 to which HCl, $(NH_4)_2SO_4$, $(NH_4)_2HPO_4$, or H_3AsO_4 was added (Davydov *et al.*, 1966b).

Finally, the existence of a perprotactinate ion with a charge of 3– is suggested by the fact that Pa(v) ($\sim 3 \times 10^{-4}$ M) is soluble in alkaline media in the presence of H_2O_2 (Stchouzkoy *et al.*, 1966a).

4.8.3 Organic complexes of Pa(v) in aqueous solution

Only a few systematic studies have been done of the aqueous complexes of Pa(v) with organic reagents. Galateanu and co-workers (1962a,b, 1966), Moskvin *et al.* (1963) used the ion-exchange method to determine the stability constants of the complexes formed with a number of organic acids (Table 4.19). Stability constants have also been reported for complexation by acetylacetone (Liljenzin and Rydberg, 1966; D'yachkova *et al.*, 1968b; Liljenzin, 1970),

Table 4.19 *Stability constants of complexes formed by Pa(*v*) with various organic acids* ($\mu = 0.25$) (*Galateanu and Lapitskii,* 1962*a,b*; *Moskvin* et al., 1963; *Galateanu*, 1966; *Lapitskii and Galateanu*, 1963).

		Stability constant for Pa:ligand ratio		
Acid	*pH*	1:1	1:2	1:3

[c] cf. Shiokawa *et al.* (1969).

DIAPA (Mikhailov, 1960), and TTA (Guillaumont, 1965a; D'yachkova *et al.*, 1968a).

Oxalic acid has been singled out for special attention because of its importance in the analytical and process chemistry of ^{231}Pa. Davydov and Pal'shin (1967) found that the solubility of Pa(v) at 25°C remained low in <0.05 M $H_2C_2O_4$, but increased sharply from 0.33 to 4 g L^{-1} or more between 0.05 and 0.5 M $H_2C_2O_4$. The low solubility was attributed to the formation of hydroxy complexes with a Pa:C_2O_4 ratio of 1:1, while the higher solubility was explained by the formation of complexes with a 1:2 ratio. Casey and Maddock (1959b) suggested the existence of complexes of the form $Pa(C_2O_4)_3^-$, and $Pa(C_2O_4)_4^{3-}$, but Guillaumont (1966a,c) suggested that these were preceded by the formation of $PaOC_2O_4^+$ and $PaO(C_2O_4)_2^+$.

It was shown that protactinium(v) forms a colored compound with Arsenazo-III in highly acidic solutions with a 1:1 ratio (Pal'shin *et al.*, 1962). Complex compounds formed with a large number of other organic reagents, such as 8-oxyquinoline (Maddock and Miles, 1949; Vernois *et al.*, 1963), BPHA (Cristallini and Flegenheimer, 1963; D'yachkova and Spitsyn, 1964), tannin (Elson *et al.*, 1951; Casey and Maddock, 1959a), 1-phenyl-3-methyl-4-benzoyl-pyrazolone-5 (Myasoedov and Molochnikova, 1968), pyrogallol, catechol, and gallic acid (Casey and Maddock, 1959a), and are used in the analytical chemistry of protactinium. However, literature data on the composition and stability of these compounds are absent.

4.8.4 Redox behavior in aqueous solution

The standard electrode potential of the Pa(v)/Pa(iv) couple has been estimated to be –0.1 V (vs. normal hydrogen electrode [NHE]) by Fried and Hindman (1954) and –0.25 V by Haïssinsky and Pluchet (1962), the latter value being based on a measured electrochemical potential of –0.29 ± 0.03 V in 6 M HCl.

Pa(iv) was prepared by Haïssinsky (Haïssinsky and Bouissières, 1948, 1951; Bouissières and Haïssinsky, 1949), who reduced 0.1–2 mg of ^{231}Pa(v) with solid Zn amalgam or $CrCl_2$ in 1–3 N HCl or H_2SO_4. Brown *et al.* (1959) found that Zn amalgam gave complete reduction in 5–6 h only if the initial solution was ≥ 6 M in HCl; lower acidities led to the formation of colloidal Pa(v), which was difficult to reduce. Mitsuji (1967a,b) used liquid Zn amalgam to obtain complete reduction in a few minutes of 4×10^{-4} M ^{231}Pa(v) in 1–11 M HCl or 0.05–9 M H_2SO_4. Tracer-level Pa(v) could not be completely reduced unless Cr(iii) was added to the system. ^{233}Pa(iv) has also been obtained by dissolution of neutron-irradiated ^{232}Th metal in 1 M HCl by Manier and co-workers (1969, 1970) or of neutron-irradiated $^{232}ThX_4$ (X = Cl, Br, I) in 0.02 M $ThCl_4$ (Carlier, 1971; Carlier and Genet, 1972a,b). In the first case, the yield of Pa(iv) was about 20%; in the second, it varied with the nature of the irradiated halogen and the pH of dissolution, ranging from less than 20% at pH ≤ 3 to approximately 80% for $ThCl_4$ at pH 5.5.

Musikas (1966) has described the electrolytic reduction of 10^{-3} M ^{231}Pa(v) in 8 M HCl, 0.5 M H_2SO_4, and 5 M NH_4F (pH 7.2). Electrolysis at 50 mA for 5 h completely reduced Pa(v) in 8 M HCl to Pa(iv). The reduction of 10^{-13} M Pa(v) on a Pt–H_2 electrode in aqueous solutions of acetylacetone at pH > 7 has also been reported (Liljenzin and Rydberg, 1966).

The polarography of Pa has been studied in various aqueous media (Elson, 1954; deMiranda and Maddock, 1962; Musikas, 1966; Schwochau and Astheimer, 1970; Astheimer and Schwochau, 1973). All solutions gave at least one wave, corresponding to the one-electron change, Pa(v)→Pa(iv), and in some cases a second wave, which might represent either the reduction, Pa(iv)→Pa(iii), or, more probably, the catalytic reduction of H^+. For example, with $[NH_4F] = 3.84$ M, pH 7.2, $[^{231}\text{Pa(v)}] = (2.3–9.5) \times 10^{-4}$ M, the wave height at $E_{1/2} = -1.29$ V (vs. standard calomel electrode [SCE]) was proportional to [Pa], but that of the second wave ($E_{1/2} = -1.57$ V) was not (deMiranda and Maddock, 1962). In DMSO, the reduction of $PaCl_4$ led directly to Pa(0) in a single step ($E_{1/2} = -1.49$ V), with the 3+ oxidation state omitted (Astheimer and Schwochau, 1973).

The behavior of protactinium in the TmI_2–TmI_3–THF system (THF, tetrahydrofuran) was studied by the cocrystallization method. In the presence of Tm^{2+}, microamounts of Pa cocrystallize with the solid phase of TmI_3 solvate, the cocrystallization coefficient (K_c) being nearly 1. A similar K_c for this system was obtained with Ce. Thus, in THF in the presence of Tm^{2+}, protactinium is probably reduced to the oxidation state 3+ (Kulyukhin *et al.*, 1996, 1997). Attempts to reduce Pa(v) to the trivalent state by Sm(ii) or Tm(ii) in chloride melts at high temperatures were reported by Mikheev *et al.* (1992). Using a cocrystallization method of Pa with the Sm(II) and Tm(II) system, the authors proposed that under these conditions the stabilization of the Pa(III) species was obtained. In the system with PrOCl, the Pa(III) reduction to Pa(II) has been detected. The standard redox potential of Pa(III)/Pa(II) couple has been calculated as –2.59 ± 0.1 V (vs. NHE) (Mikheev *et al.*, 1993a,b). Pa(II) also was produced by interaction of ^{233}Pa(V) with the cluster PrI_2 (Kazakevich *et al.*, 1993). It was shown that An = Pa, U, Np, Pu with the electronic configuration ($5f^{n-1}6d$) in the divalent state, were stabilized in clusters of the type $(Pr,An)I_2$ in the $LiI–PrI_2–PrI_3$ system (Kulyukhin and Mikheev, 1998). The influence of the electronic configurations of Pa^{2+} (f^3 and f^2d) and Pa^{3+} (f^2 and fd) upon the stability of divalent and trivalent protactinium and their redox potentials was examined by Guillaumont *et al.* (1996). An analysis of the stabilization of the configuration $5f^26d$ (Pa^{2+}) led to predictions of the relative scale for the $E^{\circ}_{\mathrm{Pa(III)/Pa(II)}}$ potentials which depend on the medium and on ligands. For this purpose the relation between the energy ($f^3 \rightarrow f^2d$) for Pa(II) in water ($Pa^{2+}\cdot aq$) and in solid ($Pa^{2+}:CaF_2$) was established. The values of the redox potentials were discussed on the basis of the 6d electron stabilization of Pa^{2+} and destabilization of Pa^{3+} ions. The standard redox potential $E^{\circ}_{\mathrm{Pa(III)/Pa(II)}}$ was estimated to be around −4.0 V, and for the couple Pa(IV)/Pa(III) about –2.1 V (vs. NHE). This result was confirmed by a measurement of E_{fd} in Pa^{4+}(aq) and by correlation of E_{fd} for Pa^{2+}(aq), Pa^{3+}(aq), and Pa^{4+}(aq) with the corresponding redox potentials (Guillaumont *et al.* 1996). Standard reduction potentials are given in Chapter 19, Fig. 19.9.

Pa(IV) in aqueous solution is rapidly oxidized by air, but the rate of oxidation is decreased by the exclusion of O_2 and by the presence of complexing anions (Brown *et al.*, 1959; Brown and Wilkins, 1961; Guillaumont, 1966b; Bagnall and Brown, 1967; Mitsuji, 1967a). Guillaumont *et al.* (1960) found that the stability of ^{231}Pa(IV) increased with increase in $[H_2SO_4]$ or [HCl], but Myasoedov *et al.* (1966b) reported the opposite effect. The oxidation rate was increased by ultraviolet light or heat. In the absence of air, Pa(IV) in a neutral solution of 2.2 M $N(CH_3)_4F$ was oxidized at the rate of about 1% per day (deMiranda and Muxart, 1964). Mitsuji (1967a) has proposed the reaction:

$$2Pa^{4+} + 2H^+ \leftrightarrow 2Pa^{5+} + H_2$$

The half-life for the oxidation of ^{233}Pa(IV) in the absence of redox buffers decreases exponentially with increase in $[H^+]$, but the formation of complexes tends to stabilize the 4+ oxidation state. The stability of Pa(IV) is greatly enhanced by a decrease in the dielectric constant; thus, in 0.6 M $HClO_4$ (10% H_2O/90% C_2H_5OH), the half-life for oxidation was 40 h, as compared with $\tau_{1/2}$ ~1 h in a pure aqueous solution (Manier *et al.*, 1969; Manier, 1970; Manier and Genet, 1970). The oxidation of Pa(IV) by molecular halogens is first-order with respect to both [^{233}Pa(IV)] and [Cl_2, or Br_2, or I_2] (Carlier, 1971; Carlier and Genet, 1972a).

4.8.5 Aqueous chemistry of Pa(iv)

The most characteristic property of Pa(iv) in aqueous solution is that, unlike Pa(v), it is precipitated by hydrofluoric acid (Haïssinsky and Bouissières, 1948; Bouissières and Haïssinsky, 1949). It is also precipitated by $\mathrm{IO_3^-}$, $\mathrm{PO_4^{3-}}$, $\mathrm{P_2O_6^{4-}}$, phenylarsonate, and saturated $\mathrm{K_2SO_4}$, but forms soluble carbonate, citrate, and tartrate complexes (Haïssinsky and Bouissières, 1951). $\mathrm{PaF_4}$ is soluble in 15 M $\mathrm{NH_4F}$ (Haïssinsky *et al.*, 1961).

The spectrophotometry of Pa(iv) has been investigated in perchloric (Brown and Wilkins, 1961), hydrochloric (Fried and Hindman, 1954; Brown *et al.*, 1959; Guillaumont *et al.*, 1960; Brown and Wilkins, 1961; Bagnall and Brown, 1967; Mitsuji, 1967a), hydrobromic (Brown and Wilkins, 1961), and sulfuric (Guillaumont *et al.*, 1960; Brown and Wilkins, 1961; Myasoedov *et al.*, 1966b; Mitsuji, 1967a) acid solutions and in neutral fluoride media (Haïssinsky *et al.*, 1961; deMiranda and Muxart, 1964; Asprey *et al.*, 1967). The reduction of Pa(v) in acid solutions is accompanied by the disappearance of the prominent absorption band at 210–215 nm (Figs. 4.16 and 4.18) and the appearance of bands at 225–230, 255–265, and 275–290 nm. Beer's law is not followed in hydrochloric acid solutions, but, for (0.65–1.5) × 10^{-4} M Pa(iv) in 0.5–6 M $\mathrm{H_2SO_4}$, the molar extinction coefficient (ε) is about 1500 L $\mathrm{M^{-1}\,cm^{-1}}$ at 290 nm (Myasoedov *et al.*, 1966b). In neutral fluoride media, the spectrum is different according to the nature of the medium: in $\mathrm{NH_4F}$, bands are observed at 355 and 250 nm (Haïssinsky *et al.*, 1961); but in $\mathrm{N(CH_3)_4F}$, the absorption maxima are at 344 and 323 nm, with $\varepsilon = 0.08$ and 0.037 $\mathrm{M^{-1}\,cm^{-1}}$, respectively (deMiranda and Muxart, 1964).

Pa(iv) hydrolyzes less readily than Pa(v). In 3 M $\mathrm{HClO_4}$, the dominant species are $\mathrm{Pa^{4+}}$ and $\mathrm{PaOOH^{2+}}$ (cf. Fig. 4.14). As the acidity is decreased at constant ionic strength ($\mu = 3$), $\mathrm{Pa(OH)^{3+}}$, $\mathrm{PaO^{2+}}$ or $\mathrm{Pa(OH)_2^{2+}}$, and $\mathrm{PaO(OH)^+}$ or $\mathrm{Pa(OH)_3^-}$ appear successively; their hydrolysis constants, as determined by Guillaumont (1965b, 1966b), are 0.725, 0.302, and 0.017, respectively. Estimates of the relative amounts of these species as a function of $[\mathrm{H^+}]$ are indicated in Fig. 4.19.

Mitsuji (1968), however, finds that $\mathrm{Pa(OH)_2^2}$+ is the most probable ionic species at pH 0.4–1.1 ($\mu = 0.5$). Lundqvist (1974c,d, 1975) believes that $\mathrm{PaO^{2+}}$ is more probable, because of the high stability of that ion toward both ethylenediaminetetraacetic acid (EDTA) and acetylacetone. He finds no evidence for species either more or less hydrolyzed than $\mathrm{Pa(OH)_2^{2+}}$ at pH 0–10.

There is, as yet, little information about the complexes formed by Pa(iv). Guillaumont (1966a,c) has calculated the formation constants of the following complexes at $\mu = 3$, $[\mathrm{H^+}] = 3$ M, and $[\mathrm{Cr^{2+}}] = 10^{-2}$ M: $\mathrm{PaCl^{3+}}$ ($K_1 < 1$). $\mathrm{PaCl_2^{2+}}$ ($K_2 = 1$), $\mathrm{PaSO_4^{2+}}$ ($K_1 = 42$), $\mathrm{Pa(SO_4)_2}$ ($K_2 = 153$), $\mathrm{PaF^{3+}}$ ($K_1 = 5.34 \times 10^4$), and $\mathrm{PaF_2^{2+}}$ ($K_2 = 1.8 \times 10^3$). Muxart *et al.* (1966b) found no anionic chloro complexes except at high acidity, e.g. $\mathrm{PaCl_6^{2-}}$ in ~8 M HCl. Mitsuji (1968) finds that $\mathrm{Pa(SO_4)(OH)^+}$ ($K = 320$) is the most probable ionic species formed by $\mathrm{HSO_4^-}$ at

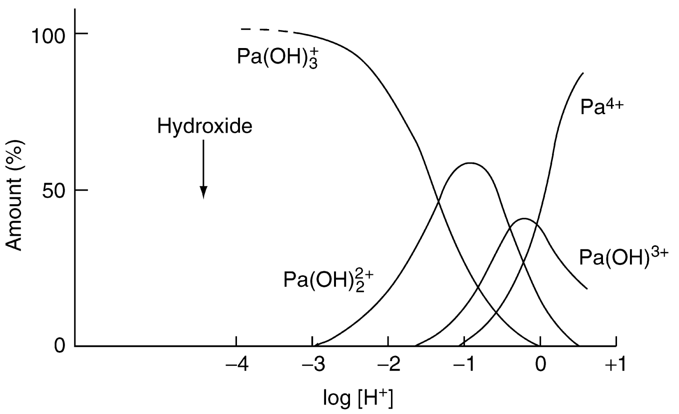

Fig. 4.19 *Distribution of the ionic species of* ^{233}*Pa(IV) as a function of* [H^+] *in non-complexing media of ionic strength* $\mu = 3$ (*Guillaumont*, 1966*a*).

pH 0.4–1.1, $\mu = 0.5$, 10°C. A comparable value is reported by Lundqvist (1974c), who has also determined stability constants for the complexes formed by ^{233}Pa(IV) with acetylacetone (Lundqvist, 1974a; Lundqvist and Rydberg, 1974), TOPO (Lundqvist, 1974b), EDTA (Lundqvist and Andersson, 1974), and benzoylacetone (Lundqvist, 1975).

Recently, the $6d^1 \rightarrow 5f^1$emission spectrum of Pa^{4+} in aqueous acidic solution was reported. The peak maximum was at 460 nm with a half-width of (61.6 ± 1.4) nm and a lifetime of (16 ± 2) ns (Marquardt *et al.*, 2004).

4.9 ANALYTICAL CHEMISTRY

Protactinium determination in natural materials is very complicated because of the extremely small content of Pa in the samples, as well as its tendency to hydrolyze. The presence of other elements, with chemical properties similar to protactinium, highly influences the behavior of protactinium in solutions.

Spectral, spectrophotometric, gravimetric, and other methods are used for the determination of macroquantities of protactinium. However, they are often invalid for the analysis of natural objects that contain very small amounts of protactinium. In these cases radiometric methods are preferable but they need careful purification of protactinium from macroelements and other radioactive materials.

4.9.1 Radiometric methods

The basis of the simplest methods for the determination of the long-lived protactinium isotope, ^{231}Pa, in natural objects (the ores, rocks, waste products), various solutions, and other samples is the measurements of α-activity and

γ-rays. The determination of the artificial protactinium isotope, ^{233}Pa, also is usually carried out by measurements of its γ-rays or β-particles.

(a) The determination of ^{231}Pa by α-counting

The large specific activity of ^{231}Pa isotope, equal to 10^6 alpha decays min^{-1} mg^{-1} of element (Bagnall, 1966a) allows the use of this method for the determination of submicrogram amounts of protactinium after its isolation in the radiochemically pure state.

α-Counters, such as ionization chambers, scintillation or proportional counters, are utilized for the measurements of α-activity of protactinium samples. Absolute quantities of protactinium are determined by comparison of the α-activity of the protactinium sample without other α-emitting isotopes with the activity of standard samples of ^{231}Pa, ^{239}Pu, RaD (^{210}Pb) + RaE (^{210}Bi) + RaF (^{210}Po), ^{210}Po, measured under the same conditions.

Usually protactinium samples for α-counting are prepared by evaporation of a known aliquot of the solution under investigation, after placing it on a platinum, stainless steel, or glass plate.

Thin layers are formed by placing the organic phase directly on a plate for counting, for instance, after extraction of protactinium with DIBK (Scherff and Hermann, 1964; Rona *et al.*, 1966).

Multichannel alpha-spectrometers are used for control of radiochemical purity of isolated samples (Salutsky *et al.*, 1957; Spitsyn and D'yachkova, 1960; Myasoedov and Pal'shin, 1963; Suzuki and Inoue, 1966). ^{231}Pa also can be characterized with enough reliability by its γ-rays spectrum (Salutsky *et al.*, 1956, 1957; Barnett, 1957; Suzuki and Inoue, 1966). Samples for alpha-spectrometers can be prepared by the electrolytic technique (Ko, 1956, 1957; Shimojima and Takagi, 1964; Smith and Barnett, 1965).

The application of alpha-spectrometers with high resolution ($\sim$0.5%) in some cases allows the determination of protactinium without separation from other α-emitters (Glover *et al.*, 1959; Jackson *et al.*, 1960b; Brown and Maddock, 1967). The alpha-spectrum of ^{231}Pa has the following main groups of α-particles: 5.046 (10%), 5.017 (23%), 5.001(24%), 4.938 (22%), and 4.722–4.666 MeV (13%) (Hyde, 1961). So 79% of ^{231}Pa α-particles emitted have energies within the interval 4.85–5.15 MeV. Measurements in this energy range with the alpha-spectrometer, previously calibrated with a pure ^{231}Pa sample, allow the determination of protactinium in the presence of other radioactive elements. Only ^{227}Ac (α-particles energy is 4.947 MeV) slightly influences measurements in this case. The effect of ^{227}Ac may be excluded completely if the protactinium α-particle energies in the interval 5.001–5.041 MeV are measured with a spectrometer that has a silicon detector with resolution of about 0.1%. The alpha-spectrometric method, developed by Glover *et al.* (1959), allows the determination of up to 10^{-4}% of protactinium in various natural objects with a relative precision of ±5%.

(b) The determination of ^{231}Pa by the γ-rays

The measurement of ^{231}Pa γ-rays is widely used for the quick determination of the protactinium concentration in the absence of other radioactive admixtures in solutions, in salts, and compounds of protactinium after their dissolution, and also for control of the protactinium behavior during its separation from waste solutions and solid residue (Barnett, 1957, 1958; Guillaumont *et al.*, 1960; Haïssinsky *et al.*, 1961; Stchouzkoy and Muxart, 1962; Miranda and Muxart, 1964a,b; Guillaumont, 1966a,c; Pissot *et al.*, 1966; Stchouzkoy *et al.*, 1966a,b).

In the γ-ray spectrum of ^{231}Pa there are three maxima, corresponding to the energies of γ-rays 27, 95, and 300 keV. The quantitative determination of protactinium is carried out with γ-spectrometers by comparison of γ-ray intensities from the sample under investigation in the region 300 keV with the intensity of the standard, containing a known amount of radiochemically pure protactinium. The sensitivity of this method is approximately 1×10^{-6} g Pa. So, for instance, it can determine 1.4×10^{-6} g Pa in a 5 g sample. The precision of this method is ±5% (Salutsky *et al.*, 1957). ^{227}Ac (0.095 and 280 keV) and ^{226}Ra (0.080 and 320 keV) prevent the determination.

(c) The determination of ^{234}Pa

The immediate short-lived daughters of U-238 are Th-234 and Pa-234. These nuclides are β^--emitters having energy bands that overlap the uranium bands in a liquid scintillation spectrum. ^{234}Pa is a high-energy β^--emitter that can be further identified and quantified from its Cerenkov radiation. Energy spectra were collected on the Packard 2500AB liquid scintillator analyzer for uranium solutions in diisopropylnaphthalene and pseudocumene-based scintillator cocktails. Calibration curves were prepared for nitric, hydrochloric, and sulfuric acid media (Huntley *et al.*, 1986; Grudpan *et al.*, 1990; Bower *et al.*, 1994).

(d) The determination of ^{233}Pa

Quantitative determination of ^{233}Pa is carried out by β^--particles (Fudge and Woodhead, 1956; McIsaak and Freinling, 1956; McCormac *et al.*, 1960; Sakanoue *et al.*, 1964) as well as γ-rays (Fudge and Woodhead, 1956; Moore and Reynolds, 1957; Arden *et al.*, 1962; Stricos, 1966) by comparison of the intensity of the sample under investigation with the intensity of a standard containing a known amount of ^{233}Pa.

The absolute amount of ^{233}Pa in a standard is determined by the β^--activity measurement on 4π-counters (Fudge and Woodhead, 1956; McCormac *et al.*, 1960).

A method, developed for the determination of absolute amounts ^{233}Pa in irradiated metallic thorium, consists of the measurement of ^{233}Pa β-particles after its chemical separation (McCormac *et al.*, 1960). This method is quick and simple and provides 70–80% protactinium yield and high degree of purification of protactinium from fission elements (10^6 times). For the separation of ^{233}Pa in a radiochemically pure state for its determination in neutron-irradiated thorium, Moore and Reynolds (1957) used the extraction with DIBC from 6 M HCl in the presence of oxalic acid, with almost all admixtures remaining in aqueous phase.

Fudge and Woodhead (1956) carried out the radiochemical purification of protactinium by ^{233}Pa precipitation with niobium tannate in the presence of EDTA. The separation of niobium and protactinium was carried out by paper chromatography or by protactinium precipitation with barium fluorozirconate.

4.9.2 Radioactivation methods

A quite large value of the thermal-neutron cross-section (^{231}Pa, 211 barns) (Smith *et al.*, 1956; Holtzman, 1962) allows the use of the nuclear reaction $^{231}\mathrm{Pa}(n,\gamma)^{232}\mathrm{Pa}$ for protactinium determination. In some cases it is better to measure ^{232}U, the daughter of the ^{232}Pa decay product, after the separation of uranium in a radiochemically pure state. This method allows the determination of 10^{-8} to 10^{-10} g of ^{231}Pa (Sakanoue *et al.*, 1965).

4.9.3 Spectral and X-ray methods

Spectral methods are not practical for the direct determination of protactinium in natural samples and other materials because of the low sensitivity and experimental complications. Usually emission spectral analysis is applied only for the detection of admixtures (Nb, Fe, Mg, Al, Sn, Cu, Si, and others) in pure samples of protactinium (Sackett, 1960; Spitsyn and D'yachkova, 1960; Walter, 1963; Birks *et al.*, 1965; Cunningham, 1966; Kirby and Figgins, 1966; Roberts and Walter, 1966).

The emission spectrum of protactinium has been investigated (Schüller and Gollnow, 1934; Thompson, 1951; Richards and Atherton, 1961, 1963; Richards *et al.*, 1961; Giaechetti, 1966). There are a few thousand lines in the range 2650–25 000 Å, and many of them have hyperfine structure. Tomkins and Fred (1949) observed 263 lines in the range 2640.3–4371.4 Å; the most sensitive and definite lines are at 3957.8, 3054.6, and 3053 Å. The sensitivity of protactinium determination is 0.2 μg Pa by use of these lines with the copper spark method. According to the data of Spitsyn and D'yachkova (1960), lines at 2732.2, 2743.9, and 2755.9 Å are also characteristic for protactinium. The X-ray spectrum of Pa_2O_5 has been investigated by Russell (1913) and Grosse and co-workers (Beuthe and Grosse, 1930; Pierce and Grosse, 1935; Grosse, 1939). Twenty-one lines of the L-series were found in the range 1088.5×10^{-11} to 586.6×10^{-11} cm and 14 lines of M-series in the range 518.2×10^{-11} to 252.2×10^{-11} cm. The information about other lines in these series has been reported in the literature (Dolejsek and

Kunzl, 1936; Cauchois and Hulubel, 1947; Cauchois and Bonnelle, 1966). A more recent compilation is given in Browne *et al.* (1954).

A comparative study of the photoacoustic spectra of lanthanide and actinide oxides (protactinium included) has been given by Heinrich *et al.* (1986).

4.9.4 Electrochemical methods

(a) Polarographic

The application of the polarographic method for the determination of protactinium is limited by the irreversibility of the Pa reduction process on the mercury drop electrode in many media.

(b) Potentiometric and amperometric

An oxidimetric method for Pa(IV) determination in chloride and sulfate solutions by titration with 6.7×10^{-2} M $FeCl_3$ solution was described by Musikas (1966). The final point was determined by a potentiometric method at a given current of 5 μA and an amperometric method at a given potential of 0.2 V. The platinum electrode was used as the indicator electrode, and a saturated calomel electrode was used as reference electrode. The titration was carried out in a special cell with a magnetic stirrer under nitrogen atmosphere.

The relative error for 3.65×10^{-2} to 4.08×10^{-2} M Pa in 6–8 N HCl or 1.0–1.8 N H_2SO_4 was nearly ±3%. The method is used for determination of the extent of Pa(V) reduction by an electrolytic method with the application of an amalgamated silver electrode.

4.9.5 Spectrophotometric methods

(a) Methods based on the Pa light absorption in mineral acids solutions

The absorption spectra of penta- and tetravalent protactinium in aqueous solutions of hydrochloric acid (Fried and Hindman, 1954; Nairn *et al.*, 1958; Brown *et al.*, 1959; Casey and Maddock, 1959a; Guillaumont *et al.*, 1959, 1960; Guillaumont, 1966c), sulfuric (Guillaumont *et al.*, 1960; Brown *et al.*, 1961; Brown and Wilkins, 1961; Guillaumont, 1966c; Myasoedov *et al.*, 1966b), perchloric (Guillaumont *et al.*, 1960; Brown and Wilkins, 1961; Guillaumont, 1966a,c) acids, and in neutral fluoride solutions (Miranda and Muxart, 1964a,b) have been studied rather completely. Protactinium complexes with inorganic ligands highly absorb in the ultraviolet part of spectrum at wavelength <250 nm. Protactinium determination by light absorption in solutions of inorganic acids is used very rarely because of the low sensitivity and selectivity of these methods, and also because of complications connected with work in ultraviolet part of the spectrum. Nevertheless the existence of characteristic bands in the absorption spectra of protactinium allow their use for the determination of protactinium concentration and for identification of protactinium valence state in some cases.

(b) Methods based on reactions with organic reagents

Effective spectrophotometric methods for the determination of microgram amounts of protactinium with application of organic reagents have been described. The advantage of such methods is their high sensitivity and the possibility of protactinium determination without previous separation from other radioactive elements that usually prevent radiometric determination of protactinium. Spectrophotometric methods for the determination in very acidic solutions are especially worthwhile. In this case complications connected with the hydrolysis of protactinium ions are excluded, and the selectivity of determination, reproducibility, and reliability of the methods increase considerably.

Pentavalent protactinium forms a stable complex with Arsenazo-III, hence this reaction is accompanied by the change of the red color of the reagent to green after mixing. The formation of the colored compound takes place in a wide interval of acidity: from slightly acidic media to 10 N H_2SO_4 or HCl and even in more concentrated solutions. Absorbance of the solution of protactinium complex compound reaches a maximum immediately after the reagent addition and does not change for at least 24 h. The reaction of Pa with the reagent is rather sensitive; the molar extinction coefficient at 660 nm is equal to 2.2×10^4 L· M^{-1} cm^{-1}. The error of the protactinium determination at the concentration 0.3–3.1 mg L^{-1} in the absence of interfering elements is ±3.5% (Pal'shin *et al.*, 1962).

According to the data of Pal'shin *et al.* (1962) the complex compound of protactinium with Arsenazo-III is quantitatively extracted by an equal volume of isoamyl alcohol from solutions with sulfuric acid concentration >2 M. The extraction of the protactinium compound from very acidic solutions of sulfuric acid gave high selectivity. In addition there is no necessity for the previous separation of contaminants. The error of the protactinium determination at a concentration 3 mg L^{-1} is less than 3% in the presence of a 10^4-fold amounts of Fe(III), Al, Ni; 10^3-fold amounts of Cr(III), La, Mn(II); 200-fold amounts of Bi(III), Sn(IV), Zr, Nb, Mo(VI), U(VI); and 100-fold amounts of Th and Ti(IV).

Pa(V) forms with TTA a colored complex compound, slightly soluble in aqueous solutions, but very soluble in many organic solvents (Myasoedov and Muxart, 1962a,b; Pal'shin and Myasoedov, 1963). The extraction-photometric method of protactinium determination with TTA is rather sensitive (~1 mg L^{-1} Pa) and highly selective. The molar extinction coefficient of protactinium complex with TTA is equal to 1.4×10^4 and 0.9×10^4 L· M^{-1} cm^{-1} at 430 and 440 nm, respectively. Beer's law is followed for concentrations of Pa in the solution over the range from 1.3 to 8.7 mg L^{-1}.

4.9.6 Gravimetric methods

Gravimetric methods of protactinium determination are used relatively rarely because of their low sensitivity. Nowadays this method is applied mainly for the determination of milligram amounts of Pa in solutions and in compounds. Protactinium is isolated from solutions in the form of insoluble compounds with inorganic or organic reagents. The choice of reagent for precipitation depends on the presence of other elements in solution.

The weighing of Pa_2O_5 is the final operation in most gravimetric determinations of protactinium after its precipitation in the form of hydroxide, peroxide, iodate, phenylarsonate, cupferronate, and following calcinations at 600–1000°C under air for 1–2 h. Pa_2O_5 is suitable and stable weight form for the determination, but it has a large conversion coefficient to protactinium, equal to 0.852. This limits the application of the determination to relatively large amounts of protactinium. The use of phenylarsonate of protactinium is more preferable as the weight form (Myasoedov *et al.*, 1968a). In this case the conversion coefficient is equal to 0.346. The calcinations of the protactinium compounds usually are carried out in platinum crucibles in order to regenerate the element. Concentrated HF or a mixture of HF + H_2SO_4 is used for dissolution of Pa_2O_5.

(a) Protactinium hydroxide

For weight determination protactinium hydroxide is obtained usually by precipitation of protactinium ions from solutions of mineral acids or their mixtures with ammonium hydroxide. The composition of the formed precipitate depends on precipitation conditions and can be represented as $Pa_2O_5 \cdot xH_2O$. Under precipitation by NaOH or KOH solutions it is necessary to wash thoroughly the precipitate to remove the adsorbed alkali metal ions. The precipitation of protactinium hydroxide is often used for analysis of some protactinium compounds (Grosse, 1934c; Sellers *et al.*, 1954; Bagnall and Brown, 1964; Bagnall *et al.*, 1965; Bukhsh *et al.*, 1966a,b; Stchouzkoy *et al.*, 1966a; Davydov and Pal'shin, 1967).

(b) Protactinium phenylarsonate

Phenylarsonic acid precipitates Pa(v) practically quantitatively from neutral solutions and from solutions of HCl, HNO_3, H_2SO_4, and $HClO_4$ at acids concentration <5 N. The precipitate composition, dried at 120–180°C, corresponds to the formula $H_3PaO_2(C_6H_5AsO_3)_2$. The precipitate is stable and is not changed in weight during heating for few hours at the above-mentioned temperature. As described above, protactinium phenylarsonate can be used for gravimetric determination. This compound may also be converted to Pa_2O_5 by calcination at 1000°C.

The precipitation of protactinium as phenylarsonate from acid solutions can be carried out in the presence of Ni, Co, Cr, La, Fe(III), Mn, Cu, Ti, Th, U, and other elements. Zr, Nb, Ta, fluoro-, and phosphate ions prevent the determination (Myasoedov *et al.*, 1968a).

(c) Protactinium peroxide

Hydrogen peroxide precipitates protactinium from solutions of mineral acids (HNO_3, HCl, H_2SO_4, and $HClO_4$) in the form of amorphous white protactinium peroxide, $Pa_2O_5 \cdot 3H_2O$ (Stchouzkoy and Muxart, 1962; Marples, 1965; Stchouzkoy *et al.*, 1966b). This compound is not stable in air, therefore, the protactinium determination is performed with the calcination of the precipitate to Pa_2O_5. The precipitation of protactinium peroxide from acid solutions can be carried out in the presence of Ni, Co, Cr, Mg, Mn, and other elements, and small quantities of iron. La, Th, U, Zr, and F^- ions prevent the determination. Stchouzkoy and Muxart (1962) recommend carrying out the $Pa_2O_5 \cdot 3H_2O$ precipitation from 0.25 M H_2SO_4 solution, obtained by dissolution of freshly precipitated protactinium hydroxide in sulfuric acid or by some other method.

Pal'shin *et al.* (1968a) applied oxalic acid to increase the selectivity of precipitation with hydrogen peroxide. It was shown that the extent of precipitation of protactinium peroxide from oxalic acid solutions increases with increasing HCl concentration. When the molar relation $H_2C_2O_4$:HCl is equal to 1:5 the extent of precipitation reaches a steady value, and at sufficient excess of hydrogen peroxide the precipitation is quantitative. The method allows determining protactinium in complex solutions and also in the presence of large amounts of zirconium, niobium, and tantalum.

(d) Protactinium iodate

Iodic acid and its salts precipitate Pa(V) from acid solutions in the form of a white volumetric precipitate. Upon standing, especially after heating on a water bath, the precipitate is compressed and is transformed into crystalline form. The composition of protactinium iodate precipitate is not established. According to the data of Kirby (1959) the quantitative precipitation of protactinium (~99.5%) occurs from previously heated solution of protactinium in 0.7 M H_2SO_4 under the addition of a drop at a time of excess 15% HNO_3. The weight determination is performed by calcination of the precipitate to Pa_2O_5 at 800°C (Codding *et al.*, 1964; 1966).

(e) Protactinium cupferronate

There is an indication that CP quantitatively precipitates protactinium from tartaric acid solutions (SalesGrande, 1950) and from solutions of mineral acids (Maddock and Miles, 1949). However, conditions of protactinium precipitation and composition of the formed precipitate have not been investigated in detail. The calcination of protactinium cupferronate at 1000°C leads to the formation of Pa_2O_5 that can be used for weight determination of protactinium.

4.9.7 Determination of protactinium in the environment

High-sensitivity mass spectrometric measurements of the naturally occurring radionuclides ^{231}Pa and ^{230}Th in the deep Canada Basin and on the adjacent shelf indicate high particle fluxes and scavenging rates in this region. The data obtained suggest that offshore advection of particulate material from the shelves contributes to scavenging of reactive materials in areas of permanent ice cover (Edmonds *et al.*, 1998). The scavenging of ^{231}Pa and ^{230}Th was investigated also in the Atlantic Sector of the Pacific Ocean (Yang *et al.*, 1986), and Southern Ocean by combining results from sediment trap and *in situ* filtration studies (Walter *et al.*, 2001). The U–Th–Pa model was realized for environment samples aging (Cheng *et al.*, 1998).

A new technique for the determination of ^{231}Pa in silicate rocks by isotope dilution mass spectroscopy was described (Bourdon *et al.*, 1999). This technique permits the determination down to a 100 fg of ^{231}Pa with a 1–2% uncertainty at the 2 sigma level. The first high-precision ^{231}Pa measurements in a manganese crust applying TIMS using the double filament techniques were described (Pickett *et al.*, 1994). The detection limit using TIMS is at least one order of magnitude lower, and the statistical uncertainty – six to eight times better than for alpha-spectroscopy. Thus, the older section of manganese crust from the Northern Equatorial Pacific could be measured precisely for their Pa-231 activity. The data described by Fietzky *et al.* (1999) reveal significant variations in ^{231}Pa activity for the last 150 ka, which corroborate existing alpha-spectroscopy results. If the growth rate was constant between 0 and 450 ka, the protactinium flux from the water column into manganese encrustations must have been variable. Thus, ^{231}Pa is not suitable for dating marine Mn/Fe deposits.

The determination of ^{231}Pa in environmental and soil materials (Harbottle and Evans, 1997) and in uranium ore samples is provided by gamma-ray spectrometer with high-purity germanium (Zhang Qingwen *et al.*, 1991).

LIST OF ABBREVIATIONS

Arsenazo-III	3,6-bis-[(2-arsonophenyl)azo]-4,5-dihydroxy-2,7-naphthalene disulfo acid
BPHA	*N*-benzoylphenylhydroxylamine
CP	Cupferron
HDEHP	bis(2-ethylhexyl)phosphoric acid
DIAPA	di-isoamylphosphoric acids
DIBC	di-isobutylcarbinol

DIBK	di-isobutylketone
DIPC	di-isopropylcarbinol
DIPK	di-isopropylketone
DMSO	dimethyl sulfoxide
DSBPP	di-*S*-butylphenyl phosphonate
EDTA	ethylenediaminetetraacetic acid
fg	femtogram
Hexone (or MIK)	methyl isobutyl ketone
Ka	thousand years ago
ng	nanogram
NCP	neocupferron
NHE	normal hydrogen electrode
PAA	phenylarsonic acid
Pc	phthalocyaninato
PMBP	1-phenyl-3-methyl-4-benzoylpyrazolone
SCE	standard calomel electrode
TBP	tri(*n*-butyl)phosphate
THF	tetrahydrofuran
TIMS	thermal ionization mass spectroscopy
TOA	trioctylamine
TOPO	tri-*n*-octylphosphine oxide
TPPO	triphenylphosphine oxide
TTA	thenoyltrifluoroacetone
UKAEA	United Kingdom Atomic Energy Authority

CHAPTER FIVE

URANIUM*

Ingmar Grenthe, Janusz Drożdżyński, Takeo Fujino,
Edgar C. Buck, Thomas E. Albrecht-Schmitt, and
Stephen F. Wolf

5.1 HISTORICAL

Uranium compounds have been used as colorants since Roman times (Caley, 1948). Uranium was discovered as a chemical element in a pitchblende specimen by Martin Heinrich Klaproth, who published the results of his work in 1789. Pitchblende is an *impure* uranium oxide, consisting partly of the most reduced oxide uraninite (UO_2) and partly of U_3O_8. Earlier mineralogists had considered this mineral to be a complex oxide of iron and tungsten or of iron and zinc, but Klaproth showed by dissolving it partially in strong acid that the solutions yielded precipitates that were different from those of known elements. Therefore he concluded that it contained a new element (Mellor, 1932); he named it after the planet Uranus, which had been discovered in 1781 by William Herschel, who named it after the ancient Greek deity of the Heavens.

---

* Part of this chapter is based on Chapter 5 in the previous edition authored by the late Fritz Weigel.

The name 'Uranus' was first proposed by Johann Elert Bode in conformity with the other planetary names from classical mythology, but this name for the planet did not come into common use until 1850. However, uranium was accepted as the name for the chemical element.

The pure oxide UO_2 isolated by Klaproth by reduction was believed to be the elemental form until 1841, when Eugène-Melchior Péligot (1841a,b) showed that Klaproth's 'partially metallic' substance was in reality the oxide UO_2. Péligot (1841b, 1842, 1844) succeeded in preparing metallic uranium by reducing the tetrachloride with potassium. Péligot may thus properly be considered the founder of modern uranium chemistry; he was the first to use the word 'uranyl' to designate the yellow salts of uranium.

In the elaboration of the periodic table, Mendeleev assigned in 1872 an atomic weight of 240 and a highest valence of six to uranium, rather than the value of 120 that was then commonly used based on the assumption that uranium was trivalent. Mendeleev's reason was that he could not place an element with atomic weight 120 in group III of the periodic table; thus he conferred upon uranium the distinction of having the highest atomic weight in the periodic table. An atomic weight of nearly 240 was firmly established by Zimmerman (1882) by determining the mass ratios of several oxides and sodium uranyl acetate. The valence and atomic weight were confirmed by determination of the vapor density of UCl_4 and later of UF_6 and the atomic number 92 was established (Hahn, 1925) from nuclear decay systematics.

The principal use of uranium during the first century after its discovery (and for the previous two millenia) was as a colorant for ceramics and glasses. The obscurity surrounding the element was permanently dissipated by the discovery of Henri Becquerel (1896) that uranium emits penetrating rays. In connection with investigations of the fluorescence and phosphorescence of uranium salts that had been undertaken by generations of Becquerels (Zhang and Pitzer, 1999), H. Becquerel placed photographic plates that were covered with black paper near any salt or other material containing uranium. Whether the material was phosphorescent or not, he found that the emulsion was blackened by emanations that passed through the paper. He compared this phenomenon to that of X-rays, which had been announced only a few weeks earlier by Roentgen. Later Becquerel showed that the penetrating rays could discharge an electroscope. Shortly thereafter, Marie Curie developed quantitative techniques for measuring the radioactivity of uranium. She and others also found thorium to be radioactive and discovered by chemical separations that there were other elements present at trace levels in the uranium ore. Working with her husband Pierre, she discovered and named polonium and radium and described this property of these heavy elements as 'radioactivity'.

Because the Curies recognized that ores of uranium and thorium are much more radioactive than purified compounds of these elements, they and other radiochemists (e.g. Rutherford, Fajans, and Soddy) separated other radioelements and identified their chemical and nuclear transformations. The luminescent and medical properties of radium created a market for uranium ores and the processed radium that far exceeded the use of uranium as a colorant for glasses.

By 1911, the atomic weight of uranium had been refined to 238.5 (Gmelin, vol. A2, 1980a). The natural isotope ^{235}U was discovered in 1935 by mass spectrometry. The artificial isotope ^{239}U, which is the precursor of ^{239}Np and ^{239}Pu, was postulated and identified by Hahn and coworkers (Hahn *et al.*, 1937; Meitner *et al.*, 1937) as a 23 min half-life intermediate to transuranium elements that were not identified until the famous studies of Seaborg and coworkers 3 years later.

Despite these important discoveries, the crucial importance of uranium was not established until Hahn and Strassman (1939) discovered nuclear fission in late 1938. Since then, the chemistry, materials science, and nuclear properties of uranium have occupied a central position in the field of nuclear energy. Most schemes so far proposed for the release of nuclear energy involve the naturally occurring fissionable ^{235}U, fertile ^{238}U, or the artificial fissionable ^{233}U in one way or another, so that the chemistry and technology of uranium have become of great scientific and technical importance. For these reasons many reviews dealing with uranium chemistry, technology, and metallurgy have been published. The main volume on uranium of the *Gmelin Handbook of Inorganic Chemistry* (Gmelin, 1936) and a chapter by Mellor (1932) are the earliest comprehensive reviews of uranium chemistry prior to the discovery of fission. The Manhattan Project work was summarized in a number of volumes of the National Nuclear Energy Series (Katz and Rabinowitch, 1951, 1958; Seaborg and Katzin, 1951; Vance and Warner, 1951; Katzin, 1952; Warner, 1953; Wilkinson, 1962). These volumes deal with the chemistry of uranium and its compounds, ^{233}U, metallurgy, and technology of uranium, respectively. The most recent monograph on the chemistry of uranium is that by Cordfunke (1969). The most comprehensive treatment of all phases of uranium chemistry is the multi-volume uranium supplement to the *Gmelin Handbook of Inorganic Chemistry* (1975–1996).

5.2 NUCLEAR PROPERTIES

Uranium, as it occurs in nature, consists of a mixture of the three isotopes ^{238}U, ^{235}U, and ^{234}U. The relative abundances of ^{238}U, ^{235}U, and ^{234}U have been measured by various investigators, and 'best values' for the ^{238}U, ^{235}U, and ^{234}U relative abundances have been chosen through a review of the literature by Holden (1977). We have accepted these values and they are listed in Table 5.1. One has to keep in mind, however, that the isotopic ratio of the uranium isotopes in nature may vary as much as 0.1%. By utilizing mass spectrometric and nuclear disintegration data, the (chemical) atomic weight of natural uranium is calculated to be (238.0289 ± 0.0001). The isotope ^{238}U is the parent of the

Table 5.1 *Natural abundance of the uranium isotopes* (*Holden*, 1977).

Abundance (*at%*)		
Mass number	*Range*	*'Best' value*
234	0.0059–0.0050	0.005 ± 0.001
235	0.7202–0.7198	0.720 ± 0.001
238	99.2752–99.2739	99.275 ± 0.002

natural $4n + 2$ radioactive series, and the isotope ^{235}U is the parent of the natural $4n + 3$ radioactive series. ^{234}U arises from ^{238}U by radioactive decay and these two isotopes are thus linked to each other, but ^{235}U appears to be of independent origin.

The isotope ^{235}U, which exists in nature to the extent of 0.72%, and was identified by Dempster (1935) using mass spectrometry. This isotope is of special importance since it undergoes fission with slow neutrons.

Complete fission of ^{235}U gives rise to an energy equivalent of about 2×10^7 kWh kg^{-1} (corresponding to about 200 MeV per fission). Advantage can be taken of the fissionability of ^{235}U not only to generate large amounts of power but also to synthesize other important actinide elements. Uranium with its natural isotopic composition can be used in nuclear reactors to generate neutrons. The chain reaction is sustained by the excess neutrons produced by the fission of ^{235}U, while neutrons in excess of those required to propagate the chain reaction can be captured by the other natural isotope to produce plutonium:

$$^{235}\mathrm{U} + \mathrm{n} \rightarrow \text{fission products} + \text{energy} + 2.5\,\text{neutrons}$$

$$^{238}\mathrm{U} + \mathrm{n} \rightarrow {}^{239}\mathrm{U}$$

$$^{239}\mathrm{U} \xrightarrow{\beta^-} {}^{239}\mathrm{Np} \xrightarrow{\beta^-} {}^{239}\mathrm{Pu}$$

The abundant isotope ^{238}U can in this way be converted to plutonium-239, which, like ^{235}U, is also fissionable with slow neutrons.

A large number of synthetic isotopes of uranium have been prepared. The isotope ^{233}U, which was discovered by Seaborg, Gofman, and Stoughton (Katzin, 1952, paper 1.1), is particularly noteworthy, because it also undergoes fission with slow neutrons. Separation of this isotope from neutron-irradiated ^{232}Th is discussed (Thorex Process) in Chapter 24. Some of the other synthetic isotopes have particular utility as tracers for uranium. This is the case for beta-emitting ^{237}U and alpha-emitting ^{232}U, both of which have found extensive use in chemical and physical studies. The isotope ^{232}U is formed by alpha bombardment on ^{232}Th, or in the decay of the short-lived ^{232}Pa, which in turn may be obtained by neutron irradiation of ^{231}Pa. Procedures for the isolation of ^{232}U from this source have been described (Leuze *et al.*, 1962, 1963; Chilton, 1963).

The naturally occurring ^{234}U appears also in the α decay of ^{238}Pu (87.7 years). Separation of this ^{234}U from its parent furnishes a simple way to obtain isotopically pure ^{234}U (Figgins and Bernardinelli, 1966).

The various isotopes of uranium are listed in Table 5.2.

5.3 OCCURRENCE IN NATURE

The most important oxidation states of uranium in natural environments are 4+ and 6+. Compounds containing tetravalent uranium are insoluble in mildly acidic to alkaline conditions, whereas, those containing the linear uranyl moiety $(O{=}U{=}O)^{2+}$ are highly soluble and mobile. In solution, UO_2^{2+} forms soluble complexes with carbonate, oxalate, and hydroxide; UO_2^{2+} is also highly susceptible to adsorption either by organic matter, Fe oxyhydroxides, or by precipitation with various anions, such as hydroxide, silicate, vanadate, arsenate, and phosphate. In groundwater systems U(VI) is reduced to U(IV) if an effective reductant is present, such as H_2S. Other reducing agents may be fossil plants, methane, and transported humic material. Uranium minerals display an extraordinary wide structural and chemical variability, resulting from the different chemical conditions under which U minerals are formed.

Elucidation of the mechanisms of uranium sorption by mineral surfaces, refinements of complex U-mineral structures, and chemical bonding are needed to improve current models from uranium cycling in the aquo- and geospheres in order to describe the behavior of uranium in the environment. In past years, uranium mineralogy was more concerned with the economic quality of U-deposits; however, today we are equally concerned with the hazard presented by former uranium mines and nuclear waste sites to the local environment and population. This has placed greater emphasis on understanding the role of uranium sorption and for developing accurate thermodynamic and kinetic models for uranium attenuation. There are ~200 minerals that contain uranium as an essential component (Burns, 1999a; Finch and Murakami, 1999). Of these, the U(VI) minerals constitute the largest portion. Burns and coworkers have developed a novel approach for describing and classifying the uranyl phases, based on polymerization of coordination polyhedra of higher bond valence, which permits easy visualization of these extremely complex structures (Burns *et al.*, 1996; Burns, 1999a). Mineral descriptions are divided according to the major anionic component and structural similarities. In Table 5.3 a list of uranium minerals with the current information on composition, space group, and lattice parameters has been provided. Hill (1999) provided a similar list of uranium minerals and related synthetic phases; recent studies have identified new phases and errors in the previous entries.

Improved understanding of uranium mineralogy gives insight into the evolution of uranium deposits, possible mechanisms for uranium and radionuclide retardation following the weathering of nuclear waste materials, and the fate of

other anthropogenic sources of uranium of environmental concern. The long-term behavior of nuclear waste materials such as high-level waste (HLW) glass, spent UO_2 nuclear fuel (SNF), and U-bearing waste forms, can be predicted, in part, by understanding the geochemical behavior of uranium. Other forms of uranium contamination of immediate concern are located at uranium production facilities, mines, and, more recently, battlefields where depleted uranium weapons have been used. Concerns about the fate of uranium in the environment have been addressed by employing several micro-analytical techniques to identify and characterize the nature of the contaminants (Bertsch *et al.*, 1994; Buck *et al.*, 1996; Morris *et al.*, 1996; Duff *et al.*, 1997, 2002).

Burns *et al.* (1997a) have theorized that many of the alteration phases that form during waste form corrosion may be capable of incorporating key radionuclides, including Np, Tc, and Pu. The potential for uranium secondary phases to incorporate radionuclides and thus curtail their migration is of significant scientific interest (Buck *et al.*, 1997; Chen *et al.*, 1999, 2000; Li and Burns, 2001a; Burns *et al.*, 2004a). A key to predicting the thermodynamic properties of these complex U(VI) minerals is to understand the nature of the connectivity between uranium polyhedra. Finch and Murakami (1999) have reported measured and estimated thermodynamic data for 14 uranyl silicate and carbonate minerals. Additional data is published elsewhere on uranium phases (Grenthe *et al.*, 1995), studtite (Hughes-Kubatko *et al.*, 2003), and new experimental thermodynamic measurements have now been obtained from the uranyl carbonates, uranophane, and uranyl phosphates (Hughes-Kubatko *et al.*, 2005). In addition to the natural U-minerals, a wealth of complex synthetic U(VI) phases have now been explored as potential, mesoporous materials, catalysts, and waste forms.

5.3.1 Mineralogy and classification of uranium deposits

Extensive reviews of uranium mineralogy and the origin of uranium deposits have been made by Finch and Murakami (1999) and Plant *et al.* (1999), respectively. Uranium deposits can be classified into 14 groups. These are: unconformity related, sandstone, quartz–pebble conglomerate, veins, breccia complex, intrusive, phosphorite, collapse breccia, volcanic, surficial, metasomatite, metamorphic, lignite, and black shale. Uranium is precipitated in reducing environments, sandstones rich in organic matter or iron sulfides, phosphate-rich sediments, shales where uranium is concentrated in organic matter, and lignite and coals. Enrichment of uranium in lignite or coal can create environmental problems when these sources are burned. Uranium undergoes a series of complex fractionation events, resulting in highly variable levels in different rock types. Owing to its relatively large size (the ionic radius of U^{4+} is 0.940 Å) in eight-fold coordination with oxygen (Farges *et al.*, 1992), tetravalent uranium is incompatible in silicate melts, depending on alkali content and the presence of nonbonding oxygens. Uranium is preferentially partitioned into small volume, low-temperature melts, and becomes progressively more concentrated, so that certain types of highly evolved granite, rhyolite,[1] and alkaline complexes contain significant quantities of uranium (Plant *et al.*, 1999). Uranium is usually present in accessory minerals such as zircon ($ZrSiO_4$), monazite {(Ce, La, Nd, Th)PO_4}, and pyrochlore (general formula AB_2O_7), many of which are also observed in synthetic ceramic HLW forms (Ewing, 1999). Although the levels of Th and U in terrestrial igneous rocks are variable, the Th/U ratio is relatively constant at about 3.8 (Taylor and McLennan, 1985). Although the most important uranium oxidation states of environmental and geological significance are considered to be U(IV) and U(VI), there is increasing evidence for the role of U(V) in uranium minerals (Burns and Finch, 1999; Colella *et al.*, 2005).

There are numerous U-deposits worldwide and some of these have been studied in great detail, some owing to their relevance to HLW disposal and the environmental fate of uranium, as well as being sources for unique uranium minerals. Understanding the geochemical behavior of uranium at these sites provides the basis for predictive modeling of uranium in the environment and also helps build confidence in the feasibility of geological waste isolation. Uranium deposits at Oklo, Peña Blanca, Shinkolobwe, and Koongarra will be described briefly below.

(a) Oklo, Gabon (Sandstone deposit)

The geochemical behavior of the natural fission reactors at Oklélobondo and Bangombé (Oklo), located in a Precambrian[2] sedimentary basin in Gabon (Africa) have been discussed by Brookins (1990), Hidaka and Holliger (1998), and Janeczek (1999). The Bamgombé site in the Oklo region is of particular interest as it is located at shallow depths. Furthermore, as full-scale mining was never commenced, the ore deposit has been left almost intact. Electron microprobe analysis (EMPA) of uraninite in contact with U(VI) phases indicates that the alteration resulted in increased concentrations of Si, P, S, Zr, Ce, and Nd. The dissolution of accessory apatite {$Ca_5(PO_4)_3(OH,Cl,F)$}, monazite and sulfides resulted in the retardation of uranium through the formation of secondary minerals, including phosphatian coffinites and iron–uranyl phosphate hydroxide hydrates (i.e. bassetite {$Fe^{2+}(UO_2)_2(PO_4)_2 \cdot 8H_2O$}). Jensen *et al.* (2002) investigated the mineralogy of the uranium deposits at Bamgombé and compared their experimental observations with thermodynamic predictions based on groundwater conditions. The primary U-minerals at Bamgombé are uraninite and minor coffinite [$U(SiO_4)_{4-x}(OH)_{4x}$]. The uranyl minerals include fourmarierite {$Pb_{1-x}[(UO_2)_4O_{3-2x}(OH)_{4+2x}] \cdot 4H_2O$}, bassetite possibly associated with {$U(HPO_4)_2 \cdot 2H_2O$} or chernikovite {$(H_3O)_2[(UO_2)(PO_4)]_2 \cdot 6H_2O$},

---

[1] Derived from the rapid cooling of a very viscous granitic magma.

[2] Between 2.5 and 1.8 billion years ago.

torbernite $\{Cu[(UO_2)(PO_4)]_2 \cdot 8\text{–}12H_2O\}$, Ce-rich françoisite $\{(Nd,Y,Sm,Ce)(UO_2)_3(PO_4)_2O(OH)(H_2O)_6\}$, and uranopilite $\{(UO_2)_6(SO_4)O_2(OH)_6(H_2O)_6 \cdot 8H_2O\}$. Autunite $\{Ca[(UO_2)(PO_4)]_2 \cdot 11H_2O\}$ has also been reported. Eh–pH diagrams predict that coffinite, $U(HPO_4)_2 \cdot H_2O$, and $UOF_2 \cdot H_2O$ are the only stable U(IV) phases and that uranopilite, torbernite, and bassetite will become stable during oxidative alteration.

(b) Peña Blanca, Chichuhua District, Mexico (Breccia Pipe)

The Sierra de Peña Blanca District, Chihuahua, Mexico consists of a gently dipping Tertiary[3] volcanic pile that covers a calcareous basement of Cretaceous age[4] (Cesbron *et al.*, 1993; Pearcy *et al.*, 1994). Peña Blanca is part of a much more extensive range of volcanic uranium deposits that extend from the McDermitt caldera at the Oregon–Nevada border through the Marysvale district of Utah and Date Creek Basin in Arizona and south into the Peña Blanca (Finch, 1996). In the Nopal I deposit, the ignimbritic tuffs[5] have been hydrothermally altered and U-mineralization is located within a breccia pipe structure at the intersection of several faults. The uraninite deposition under reducing conditions (8 ± 5) Ma ago has precluded the accumulation of significant amounts of lead. Later tectonic forces elevated the deposit above the local water table, exposing it to oxidizing conditions. The site is a convincing geochemical analog of the proposed HLW repository at Yucca Mountain, Nevada. The initial corrosion products from the oxidative dissolution of uraninite are uranyl oxide hydrates, including ianthinite $\{[U_2^{4+}(UO_2)_4O_6(OH)_4(H_2O)_4](H_2O)_5\}$ (Burns *et al.*, 1997b), schoepite $\{[(UO_2)_8O_2(OH)_{12}](H_2O)_{12}\}$, and dehydrated schoepite $\{(UO_2)_4O(OH)_6 \cdot H_2O\}$ (Leslie *et al.*, 1993). Ianthinite is unusual in that it contains both U^{6+} and U^{4+}. The phase has a narrow stability range and will easily degrade. It will form in oxygen-deficient environments, such as under localized reducing environments at Shinkolobwe (Finch and Ewing, 1992).

Uranyl silicates, uranophane $\{Ca(UO_2)_2(SiO_3OH)_2(H_2O)_5\}$, are the predominant U-phases at Nopal I, comprising more than 95% of all U-bearing minerals. They either replace earlier formed U-phases or form euhedral[6] crystals within open voids and fractures. The uranophanes at Nopal I have been dated at 3.2 Ma, suggesting that alteration of the initial uraninite took millions of years under the oxidizing environment. The paragenesis[7] of U-phases was similar to that observed in laboratory tests by Wronkiewicz *et al.* (1992) on synthetic UO_2 apart from the occurrence of the mixed uranium valence phase,

ianthinite that has not been observed in corrosion tests with UO_2 (Wronkiewicz *et al.*, 1996) or SNF (Finch *et al.*, 1999a; Wronkiewicz and Buck, 1999).

(c) Shinkolobwe (Sandstone U-deposit)

Uranium minerals from the 1.8-Ga-old Shinkolobwe deposit, located in the Katanga District of the Democratic Republic of the Congo, have been extensively described and discussed by Finch and Ewing (1992) and in references therein. The deposit has been exposed since Tertiary times and extensive weathering has significantly altered or replaced uraninite. Uranium mineralization occurs along fracture zones where meteoric[8] waters have penetrated. The uranyl silicates, uranophane and cuprosklodowskite $\{Cu(UO_2)_2(SiO_3OH)_2 \cdot 6H_2O\}$, are ubiquitous and replace becquerelite, compreignacite $\{K_2[(UO_2)_3O_2(OH)_3]_2(H_2O)_7\}$, vandendriesscheite $\{Pb_{1.57}[(UO_2)_{10}O_6(OH)_{11}](H_2O)_{11}\}$, fourmarierite, billietite $\{Ba[(UO_2)_3O_2(OH)_3]_2(H_2O)_4\}$ and schoepite by reaction with the silica-rich groundwater. As the groundwater interacts with the host rocks, it becomes increasingly more enriched in silica, resulting in the precipitation of uranophane. Finch *et al.* (1995) argued that the cyclical weather pattern explained the simultaneous occurrence of both becquerelite and uranophane. Becquerelite has been estimated to be 10^5 to 10^6 years old based on the $^{230}Th/^{234}U$ ratios being close to 1.0 in these minerals (Finch *et al.*, 1996b).

(d) Koongarra

Koongarra is located in a tropical monsoon climate with long dry seasons (Edghill, 1991). The host rock is quartz-rich schist[9] and the primary uranium mineral, uraninite, has been subjected to weathering for more than 1 million years. The alteration of chlorite produces Fe^{3+} minerals that become associated with some uranium. In the primary ore deposit uraninite has been altered to curite $\{Pb_3[(UO_2)_8O_8(OH)_6] \cdot 3H_2O\}$, and sklodowskite $\{Mg(H_3O)_2[(UO_2)(SiO_4)]_2 \cdot 4H_2O\}$. However, Murakami *et al.* (1997) have shown that upstream from the deposit, saléeite $\{Mg[(UO_2)(PO_4)]_2 \cdot 10H_2O\}$, has replaced sklodowskite and granular apatite and is the predominant mechanism for fixing uranium. In a transmission electron microscopy (TEM) study by Lumpkin *et al.* (1999) on Koongarra mineral substrates, uranium was observed to preferentially sorb to the iron oxide minerals (goethite, α-FeOOH, and possibly ferrihydrite) rather than the clay minerals.

[9] A thinly layered crystalline rock.

5.3.2 Reduced uranium phases

Uraninite is a common accessory mineral in pegmatites and peraluminous granites and is the most important source of dissolved uranium in groundwaters emanating from weathered granite terrains. Uraninite possesses the fluorite structure, nominally UO_{2+x}. U(IV) is coordinated by eight O atoms in a cubic arrangement, and each O atom bonds to four U^{4+} ions. Stoichiometric UO_2 is unknown in nature and is always partially oxidized in addition to containing radiogenic lead and commonly thorium, calcium, and lanthanides. Stoichiometric UO_2 (a = 5.47 Å) forms a complete solid solution with ThO_2 (a = 5.6 Å) following Végard's Law. Janeczek and Ewing (1992) proposed the formula $\{(U^{4+}_{1-x-y-z}U^{6+}_{x}Ln^{3+}_{y}M^{2+}_{z}\square_{v})O_{2-x-0.5y-z-2v}\}$ (where $\square$ denotes a vacancy).

It is possibly inappropriate to term uraninite (as well as coffinite and brannerite), as a primary uranium mineral as it can precipitate from aqueous solutions under reducing conditions or through microbial processes (e.g. sulfur-reducing bacteria (Spirakis, 1996; Fredrickson *et al.*, 2002)). Primary reduced uranium minerals are usually coarse grained and present in granites and pegmatites. They have high Th and consequently larger unit cells. Hydrothermal vein[10] uraninites typically have minor lanthanides, Y, Ca, and Th absent. Low-temperature sedimentary uraninites are devoid of lanthanides and Th, but may contain Ca, Si, and P. Grandstaff (1976) observed a correlation between dissolution rate and the mole fraction of impurity cations (Pb and Th). The decrease was attributed to the buildup of low-solubility impurities in the surface as U was preferentially leached. Similar processes have been observed in corroded SNF (Buck *et al.*, 2004).

The most common U-ore is fine grained uraninite, sometimes termed pitchblende, similar to the term used for fine-grained quartz (chalcedony); pitchblende is not a mineral name but a textural term. The name 'pitch' does not come from its black, resinous appearance, and botyroidal habit[11] but from the german word 'pech' meaning bad luck (Piekarski and Morfeld, 1997). Radiogenic lead can reach levels of 15–20 wt.% in ancient uraninites. Janeczek and Ewing (1991) observed lead contents of 14 wt.% in an 1800-Ma-old uraninite specimen from the Eldorado mine in Canada. The presence of lead in uraninite results in auto-oxidation and can lead to high U(VI)/U(IV) ratios in uraninite. Auto-oxidation at the uraninite deposit at Cigar Lake has led to U (VI)/U(IV) ratios from 0.02 to as high as ~0.75 according to X-ray photoelectron spectroscopy (XPS) studies by Sunder *et al.* (1996), despite the highly anoxic conditions prevalent in the deposit. Sunder and coworkers also examined uraninites from Oklo and found a similar range of ratios for uraninites.

---

[10] A vein formed by the crystallization of minerals from predominantly hot water solutions of igneous origin.

[11] A globular growth of minerals.

Oxidation of uraninite results in a decrease of the unit cell parameter, whereas α-decay damage has the opposite effect through the formation of defects and voids. Uraninites typically experience more than 10 displacements per atom over periods of millions of years; yet, the high rate of self-annealing prevents metamictization[12] of the uraninite. Cationic substitutions (radiogenic Pb, Th, Ca, and Ln) increase the unit cell parameter (Janeczek and Ewing, 1991). The large ionic radius of Pb^{2+} results in a substantial increase in the unit cell with increasing age of the uraninite. The presence of silicium and phosphorus in partly altered uraninite is due most likely due to the precipitation of phosphatian coffinite.

(a) U(IV) phosphates and molybdates

The UO_2–P_2O_5 system includes uranium meta-phosphate $U(PO_3)_4$, uranium diphosphate UP_2O_7, uranium oxide phosphate $(UO)_3(PO_4)_2$, and uranium oxide diphosphate $(UO)_2P_2O_7$. Douglass (1962) first characterized both orthorhombic $U(PO_3)_4$ and its isostructural plutonium analog. Brandel *et al.* (1996) synthesized two additional phosphates, uranium uranyl phosphate $U(UO_2)(PO_4)_2$, that formed in air at 1000–1200°C, which may be the only mixed valence uranium phosphate known, and diuranium oxide phosphate $U_2O(PO_4)_2$ that was formed at 1350°C in an inert atmosphere. Attempts by Brandel *et al.* (1996) to produce uranium orthophosphate, $U_3(PO_4)_4$, were unsuccessful confirming earlier data, indicating that this phase does not exist (Gmelin, 1981d).

A number of hydrous U(IV) phosphates exist in nature and some of these have been observed in secondary alteration phases formed during laboratory corrosion tests on HLW glass (Bates *et al.*, 1992). These phases have been described as brockite- and rhabdophane-related phases and contain U, Th, Ln, and Pu (Buck and Bates, 1999). Ningyoite, $\{(U^{4+},Ca,Ce)_2[PO_4]_2 \cdot 1\text{–}2H_2O\}$, is a member of the rhabdophane group of phosphates (Gaines *et al.*, 1997). Ningyoite is a translucent brown to greenish mineral observed at the Ningyo-Toge mine, Japan. The phase may form a solid solution with U-bearing brockite, $\{Ca_{z-y}(U^{4+}_{1-x}Th^{4+}_{x})_{y/2}(PO_4)_2 \cdot nH_2O\}$; in addition CO_3 and SO_4 may substitute for PO_4.

Lermontovite $\{U^{4+}(PO_4)OH\}$ and vyacheslavite $\{U^{4+}(PO_4)(OH) \cdot 2.5H_2O\}$ form under reduced conditions in hydrothermal deposits associated with sulfides.

(b) Uranium orthosilicate

Coffinite and the thorium orthosilicate, thorite, $(Th,U)SiO_4$, are widespread in igneous and metamorphic rocks and are important ore minerals in some uranium and thorium deposits (Speer, 1982). These silicates are tetragonal and

---

[12] Process of alteration of crystalline to non-crystalline structure through radioactive decay.

isostructural with zircon (Fuchs and Gebert, 1958). Because they can be primary in origin, they have been used in geochronological studies. Coffinite occurs as a primary uranium ore mineral in unoxidized, uranium–vanadium ores of the Colorado Plateau, USA; however, it is also found in hydrothermal, vein deposits with pitchblende, with variable composition where $(OH)^-$ substitutes for $(SiO_4)^{4-}$. Some studies have suggested that the ubiquitous occurrence of organic matter with secondary coffinite indicates a possible biogenic origin (Spirakis, 1996).

(c) Uranium in silicate melts and glasses

The partitioning of uranium into silicate melts depends on the oxygen fugacity, melt composition, and redox conditions. Under mildly reducing conditions, U(v) is present as an octahedrally coordinated species. Under very reducing conditions, such as that prevailing in silicate magmatic melts, U(iv) is the dominant uranium species. Data obtained by Farges *et al.* (1992) with extended X-ray absorption fine structure analysis (EXAFS) indicated that U(iv) is present in six coordinated sites in silicate glasses with a mean U–O distance of ≈ 2.26–2.29 Å. Uranium(iv) is expected to occupy similar sites in the melt. The solubility of uranium in silicate liquids is enhanced by high alkali content and the presence of nonbonding oxygens (NBO)[13] and non-framework oxygens (NFO).[14] There is a strong correlation between uranium solubility and the NBO/T ratio (where T is the number of tetrahedral cations). Up to 18 wt% U(iv) can be dissolved in sodium trisilicate glass; whereas less than 1 wt% of U(iv) will dissolve in a glass with albite (Na alumino-silicate) composition. The formation of bonds between NBO and NFO is favored because these oxygens have lower bond strength. The solubility of actinides in alkali silicate glasses decreases in the order Th > U > Np > Pu owing to decreasing ionic size and increasing actinide–oxygen bond strength. The solubilities of U(v) and U(iv) are also affected by alkali content due to variation in bond strength. Uranium(iv) and U(v) are generally incompatible with magmatic systems and tend to partition strongly into late stage formed minerals, such as zircon, titanite, or apatite. Farges *et al.* (1992) suggest that if melts have a heterogeneous distribution of bonding oxygens (BO) and NBO, uranium will become enriched in the NBO-enriched regions. With increasing magmatic differentiation,[15] the BO content of the melt increases, as a consequence U(iv) will partition to late crystallizing minerals, such as pyrochlore or zircon.

Farges *et al.* (1992) determined the U–O bond lengths in U(vi)-containing silicate glasses as $U–O_{ax} \approx 1.77$–1.85 Å and $U–O_{eq} \approx 2.18$–2.25 Å, characteristic

[14] Oxygen bonded exclusively to cations other than Si^{4+}.
[15] The process of chemical and mechanical evolution of a magma in the course of its crystallization such that different rock types are formed from the same original magma.

of the uranyl species. U(VI) is the dominant oxidation state observed in radioactive borosilicate waste glasses. XPS measurements performed on SON68-type borosilicate waste glass by Ollier *et al.* (2003) revealed two oxidation states in the glass: about 20% U(IV) and 80% U(VI) present in two different environments, uranate- and uranyl-sites, respectively. As a consequence of bond strength considerations, U(VI) also bonds primarily to NBO and NFO in both crystalline and amorphous silicates. U(V) is six-coordinated with a mean U–O bond distance of 2.19–2.24 Å (Farges *et al.*, 1992).

Karabulut *et al.* (2000) have investigated the local structure of uranium in a series of iron phosphate glasses with EXAFS and determined that the all uranium was present as U(IV).

(d) Uranium niobates, tantalates, and titanates

There are a number of complex tantalum, niobium, and titanium oxides that may contain uranium as an essential element. These phases are mainly observed in granitic rocks and granite pegmatites[16] and have been difficult to characterize as they commonly occur in the aperiodic metamict state owing to their age and radionuclide content. A common feature of these minerals is that niobium, tantalum, and titanium atoms occupy octahedral sites, and a structural framework that is formed by octahedral corner or edge sharing (Finch and Murakami, 1999).

The structures of the ixiolite, samarskite, and columbite groups, ideally $A^{3+}B^{5+}O_4$, are all derivatives of the α-PbO_2 structure. Ishikawaite $\{(U^{4+},Fe,Y,Ce)(Nb,Ta)O_4\}$ is the U-rich variety of samarskite and calciosamarskite is the Ca-rich variety. Because these minerals are chemically complex, metamict, and pervasively altered, their crystal chemistry and structure are poorly understood (Hanson *et al.*, 1999). Many of these phases are of interest because of their occurrence in designer crystalline ceramic waste forms for immobilization of actinides (Gieré *et al.*, 1998; Ewing, 1999). In particular, zirconolites, pyrochlores, and brannerites have been proposed for immobilizing transuranics. These phases will be discussed in more detail.

(*i*) *Zirconolite*

Zirconolite is an accessory mineral crystallizing under different geological conditions and in a wide range of generally SiO_2-poor rock types (Gieré *et al.*, 1998). Zirconolite has been found in mesostasis areas of ultrabasic cumulates, in granitic pegmatites, in carbonatites,[17] in nepheline syenites, and in other igneous formations. Zirconolite has been observed commonly in lunar late-stage

---

[16] Late stage crystallization from an igneous intrusion.

[17] Rock consisting of >50% carbonate minerals.

mesostasis areas of lunar basalts.[18] It is also a common constituent of designer titanate ceramic waste forms (Gieré *et al.*, 1998; Ewing, 1999). Natural zirconolite is a reddish-brown mineral with an appearance similar to that of ilmenite; however, the grains are typically anhedral and <0.1 mm in diameter, and easily overlooked.

Zirconolite, $CaZrTi_2O_7$, belongs to a group of anion-deficient superstructures of the fluorite-type, which have been found to be the most versatile phases for the incorporation of HLW elements. Zirconolite is termed the aristotype of the group (i.e. the structurally simplest member of the series). All have the general formula $[A_2B_2X_7]$ (A = Ca, Na, Ln, U, Th, Zr, Ti; B = Ti, Nb, Ta, Al, Fe; X = O, F) (Mazzi and Munno, 1983; Bayliss *et al.*, 1989). Zirconolite does not appear to incorporate uranium and lanthanides by isomorphic substitution; rather, distinct phases form depending on the particular elements present in the mineral. Elements may not be distributed uniformly throughout the zirconolite but concentrated in extended defects, which can lead to the formation of zirconolite polytypes (White, 1984). These are constructed by stacking modular units in a variety of orientations with respect to the arrangement of the interlayer cations. Each module consists of two hexagonal tungsten bronze layers and interposed cations. The zirconolite-type phases have been described in the literature as zirconolite, zirkelite, pyrochlore, and polymignyte. The three natural zirconolites are orthorhombic zirconolite, known as zirconolite-3O, trigonal zirconolite, known as as zirconolite-3T, and the more common monoclinic zirconolite called zirconolite-2M. The cubic form is termed zirkelite and for metamict minerals, the name polymignyte is used.

Geochemical studies by Lumpkin and coworkers (Lumpkin *et al.*, 1988, 1995; Lumpkin and Ewing, 1995) have shown that zirconolite is highly durable in the presence of hydrothermal fluids and low-temperature groundwaters. Uranium in zirconolite is mobilized only under conditions of high temperature and pressure in hydrothermal fluids. At lower temperatures alteration takes place because previous radiation induced damage; this may result in the release of radiogenic lead. However, uranium remains relatively unaffected by the alteration process.

(*ii*) *Pyrochlore*

Minerals of the pyrochlore group have the general formula $A_{1-2}B_2O_6X_{0-1}$ (Greegor *et al.*, 1989). Three subgroups are defined on the basis of the major B-site cations. The B-site is occupied by Ti, Nb, or Ta; however, Al, Fe^{3+}, Zr, Sn, and W may also be possible. Microlite and natural pyrochlore both contain more niobium and tantalum than titanium (see Fig. 5.1a). The H_2O content in

---

[18] Zirconolite was reported in rocks collected on Apollo 10 (mare basalt) and Apollo 14 (recrystallized breccia) moon missions.

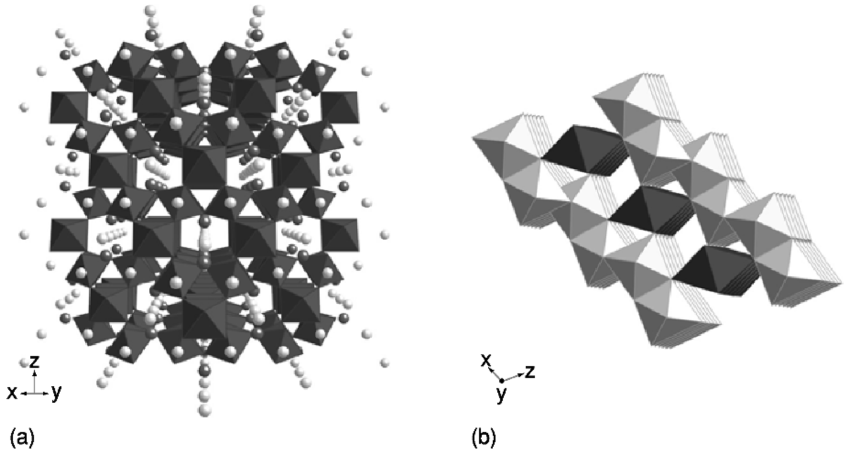

Fig. 5.1 *Structure of* (*a*) *pyrochlore* (*diagram displays grey circles = A site, dark circles = B site, and* TiO_6 *octahedra*) *and* (*b*) *brannerite* (*diagram shows uranium as dark-colored polyhedra and* TiO_6 *octahedra as gray*) (*courtesy of Prof. R. Gieré, University of Freiberg, Germany*).

the natural minerals ranges from 10 to 15 wt%, but will increase if the mineral has undergone alteration. These groups can be further subdivided based on the A-site occupation which can be Na, Ca, Mn, Fe^{2+}, Sr, Sb, Cs, Ba, rare earths, Pb, Bi, Th, and U. Natural pyrochlore minerals occur predominantly in three host rock categories: carbonatites, nepheline syenites, and granitic pegmatites.

(*iii*) *Evidence for U*(*V*) *in pyrochlores and zirconolite*

Fortner *et al.* (2002) used X-ray absorption spectroscopy near-edge structure (XANES) analysis to suggest that U(v) is present in a synthetic pyrochlore ceramic produced under reducing (Ar/H_2) conditions. The authors argue that uranium substitutes for titanium on the B-site in pyrochlore and suggest that this will also occur in natural pyrochlore-type minerals. This result is partially supported by findings by Vance *et al.* (2001) who determined that zirconolite, ($CaU_xZr_{1-x}Ti_2O_7$) oxidized at 1400°C in air, formed U(v) at the expense of U(IV) and that zirconolites with available charge-compensating lanthanides, also resulted in U(IV) to U(v) oxidation, even when sintered in an argon gas environment. The oxidation of U(IV) to U(v) is accompanied by a significant decrease in ionic size, suggesting that uranium is unlikely to enter the calcium site, but rather prefers the zirconium site. Although the presence of significant amounts of U(v) in these titanate phases has not been established by quantitative EMPA data on synthetic (Gieré *et al.*, 2002) and natural zirconolites and pyrochlores (Gieré *et al.*, 1998), the strong observed correlation between Ca and U in natural zirconolites, indicates substitution on the A-site rather than the B-site.

(*iv*) *Brannerite*

After uraninite and coffinite, brannerite is the most important uranium ore mineral. At the large uranium deposit of the El'kon District of the Aldan Shield, Siberia, brannerite is the dominant uranium phase (Miguta, 1997). Ifill *et al.* (1996) report that brannerite at the Elliot lake U-deposit in Canada formed mainly by replacement of uranium in TiO_2-rich relicts of magnetite–ilmenite intergrowths. The uranium was derived from diagenetic dissolution of uraninite. Brannerite, ideally $\{(U,Th)_{1-x}Ti_{2+x}O_6\}$, is a monoclinic accessory phase that is completely metamict (amorphous) as a result of the α-decay damage from the constituents uranium and thorium. As with many of these metamict U-minerals, the structure can be recrystallized on heating. Many cation substitutions have been identified for both uranium (Pb, Ca, Th, Y and Ce) and titanium (Si, Al, Fe) in natural brannerites (Vance *et al.*, 2001) (see Fig. 5.1b).

Brannerite is also formed in the titanate-based nuclear waste-form crystalline ceramics under reducing conditions. Finnie *et al.* (2003) and Colella *et al.* (2005) examined synthetic U(v) phases and natural brannerites with XPS and electron energy-loss spectroscopy. The average valence state in the natural brannerites was close to 5.0.

5.3.3 Uranium(VI) phases

Carbonate dominates the speciation of uranium in alkaline environments, while sulfate complexation is of importance in slightly acidic oxidizing media. The U(VI) phases represent an extremely diverse and complex series of minerals. In this section, the U(VI) minerals will be discussed by first introducing the various uranium mineral structures and then their occurrence on the basis of the major complexing anion, and finally a mention of uranium sorption on soil minerals.

Uranyl oxyhydroxides that form in U-rich aqueous solutions can be represented by the general formula $\{M_n[(UO_2)_xO_y(OH)_z](H_2O)_m\}$, where M represents divalent cations, including Ca^{2+}, Pb^{2+}, Ba^{2+}, and Sr^{2+}. However, uranyl oxyhydroxides are only stable in groundwaters devoid of carbonate, sulfate, and/or vanadate ligands.

(a) Bonding in uranyl polyhedra

Burns *et al.* (1996) developed a hierarchical structural classification for U(VI) minerals and other inorganic phases, based on the polymerization of coordination polyhedra. The linear uranyl (Ur) ion is coordinated by four, five, or six anions (ϕ: O^{2-}, OH^-, H_2O), with the oxygen atoms of the uranyl ion forming the apices of square ($Ur\phi_4$), pentagonal ($Ur\phi_5$), and hexagonal ($Ur\phi_6$) bipyramids. The equatorial U–O bond lengths for $Ur\phi_4$, $Ur\phi_5$, and $Ur\phi_6$, are 2.26(8), 2.34(10), and 2.46(12) Å, respectively. The polyhedra possess very asymmetrical charge distributions, $O_{Ur} \sim -1.7$and $U–O_{eq} \sim -0.5$ as discussed in more detail in

Section 5.8. Uranyl minerals with uranium as the only high-valence cation invariably contain sheets [the exception being studtite (Burns and Hughes, 2003)], as do the naturally occurring uranyl vanadates, uranyl molybdates, and most uranyl sulfates. A majority of the uranyl silicates contain sheets except for soddyite $\{(UO_2)_2[SiO_4](H_2O)_2\}$ and weeksite $\{K_{1.26}Ba_{0.25}Ca_{0.12}[(UO_2)_2(Si_5O_{13})]H_2O\}$ (Jackson and Burns, 2001), which involve frameworks of U(VI) polyhedra. Uranyl carbonates are exceptional because they often contain isolated uranyl tricarbonate clusters, although rutherfordine, UO_2CO_3 (cf. Fig. 5.54), and roubaultite $\{Cu_2(UO_2)_3(CO_3)_2O_2(OH)_2](H_2O)_4\}$, contain uranyl carbonate sheets. The uranyl selenites demesmaekerite $\{Cu_5Pb_2(UO_2)_2(SeO_3)_6(OH)_6(H_2O)_2\}$, and derriksite, $\{Cu_4[(UO_2)(SeO_3)_2](OH)_6]\}$, contain chains of polyhedra, whereas guillemenite, $\{Ba[UO_2)_3(SeO_3)_2O_2](H_2O)_3\}$, and haynesite, $\{(UO_2)_3(OH)_2(SeO_3)_2 \cdot 5H_2O\}$, both contain uranyl selenite sheets. Uranyl arsenates either contain autunite-type sheets or chains, as in the structures of walpurgite, $\{(UO_2)Bi_4O_4(AsO_4)_2 \cdot 2H_2O\}$, and orthowalpurgite, $\{(UO_2)Bi_4O_4(AsO_4)_2 \cdot 2H_2O\}$.[19] Relatively few uranium minerals are based upon chains, although recent structural refinements indicate that these types of U^{6+} minerals are more common that previously thought. Examples include: the only know peroxide mineral, studtite (Burns and Hughes, 2003); the uranyl tellurides, moctezumite $\{PbUO_2(TeO_3)_2\}$, derriksite, and demesmaekerite; the uranyl sulfate uranopilite; the uranyl arsenates, walpurgite, orthowalpurgite, and their phosphate analog, phosphowalpurgite $\{(UO_2)Bi_4O_4(PO_4)_2 \cdot 2H_2O\}$ (Sejkora *et al.* 2004); and parsonsite $\{Pb_2[(UO_2)(PO_4)_2]\}$. Locock *et al.* (2005a) have also shown that the synthetic arsenic-bearing analog of parsonsite, hallimondite $\{Pb_2[(UO_2)(AsO_4)_2]\}$, is also a chain structure.

(b) Geometries of uranyl polyhedra

The crystal chemistry of U(VI) is rich in diversity, yet it is relatively rare for uranyl solids to form frameworks. The distribution of bond strengths within uranyl bipyramidal polyhedra generally permits polymerization only through the equatorial ligands, resulting in chains or sheets. Linkages in the third dimension may be facilitated by additional polyhedra such as silicate, molybdate, vanadate, or phosphate.

The U(VI) minerals that are based on infinite polyhedra sheets with edge- and corner-sharing polyhedra can be better described by the topological arrangement of anions that occur within the sheets (Miller *et al.*, 1996; Burns and Hill, 2000a). Similar to a method described by Aléonard *et al.* (1983) for U_3O_8 structures, the procedure is as follows: Each anion that is not bonded to at least two cations within the sheet, and not an equatorial anion of a bipyramid or

---

[19] The compositions of orthowalpurgite and walpurgite as written are identical; however, the structures are not (Mereiter, 1982b; Krause *et al.*, 1995).

pyramid within the sheet, is removed from further consideration. Cations are removed along with all cation–anion bonds, leaving an array of unconnected anions. Anions are joined by lines, with only those anions that may be considered as part of the same coordination polyhedra being connected. Anions are removed from further consideration, leaving a series of lines that represent the anion topology. The anion topology does not contain any information about the cation population of the sheet from which the topology was derived (see Fig. 5.2). The P chain is composed of edge-sharing pentagons, the R chain contains rhombs, and the H chain contains edge-sharing hexagons. The arrowhead chains (U and D), which have a directional aspect, contain both pentagons and triangles, arranged such that each triangle shares an edge with a pentagon and the opposite corner with another pentagon in the chain. Generation of anion topologies using chain-stacking sequences is an elegant method for describing the relationships among the complex U(VI) sheet recently found in several minerals. The following describes a number of the possible anion topologies in the U(VI) minerals (see Burns, 1999a for a more complete list).

(*i*) *Protasite* (α-U_3O_8) *anion topology*

The protasite anion topology is the basis of sheets that occur in protasite $\{Ba[(UO_2)_3O_3(OH)_2](H_2O)_3\}$, becquerelite (Burns and Li, 2002), billietite (Pagoaga *et al.*, 1987), richetite $\{M_xPb_{8.57}[(UO_2)_{18}(OH)_{12}]_2(H_2O)_{41}\}$ (Burns, 1998b), compreignacite (Burns, 1998c), agrinierite $\{K_2(Ca_{0.65}Sr_{0.35})[(UO_2)_3O_3(OH)_2]_2\cdot 5H_2O\}$ (Cahill and Burns, 2000), and masuyite $\{Pb[(UO_2)_3O_3(OH)_2](H_2O)_3\}$ (Burns and Hanchar, 1999), as well as a synthetic cesium uranyl oxide hydrate (Hill and Burns, 1999). As such, it is apparent that sheets based on this topology are compatible with a range of interlayer configurations involving Ba, Ca, Pb, K, and Cs. This simple anion topology contains only triangles and pentagons (see Fig. 5.2a).

Only P and D chains are required to develop the protasite anion topology, with the repeat sequence PDPD... The protasite anion topology does not distinguish between O^{2-} and OH^- anions and the distribution of anions is not identical between different minerals possessing the protasite structure type. Becquerelite, billietite, and compreignacite have identical anion distributions, $[(UO_2)O_3(OH_3)]^-$ but masuyite and protasite do not.

(*ii*) *Fourmarierite anion topology*

Sheets based upon the fourmarierite anion topology (see Fig. 5.2b) occur in fourmarierite (Piret, 1985) and schoepite (Finch *et al.*, 1996a). In schoepite, the sheets are neutral, with H_2O groups being the only constituents of the interlayer. In fourmarierite, the sheets have a different distribution of O and OH^-, resulting in a charged sheet that is balanced by Pb^{2+} in the interlayer. The anion topology can be obtained with a chain-stacking sequence involving P, D, and U chains, with the sequence PDUPUD.... Li and Burns (2000a) have refined the structures of several fourmarierite specimens from various localities. All the crystals are orthorhombic.

(*iii*) *Vandendriesscheite anion topology*

Vandendriesscheite is the most common Pb-bearing uranyl oxyhydroxide, occurring at numerous weathered uraninite deposits, often in association with schoepite. The anion topology of vandendriesscheite (see Fig. 5.2c) is exceptionally complex, with a primitive repeat of 41.4 Å (Burns, 1997). Only vandendriesscheite contains a sheet based upon this topology, which can be constructed using P, U and D chains in the sequence PDUPUPUPU DPDPDPDUPUPUP.... It contains sections that are identical to the PDPD... (or PUPU...) repeats of the protasite anion topology, with the junction between such sections involving the DU sequence of the fourmarierite anion topology. Thus, the vandendriesscheite anion topology is a structural intermediate between these two simpler anion topologies.

(*iv*) *Sayrite anion topology*

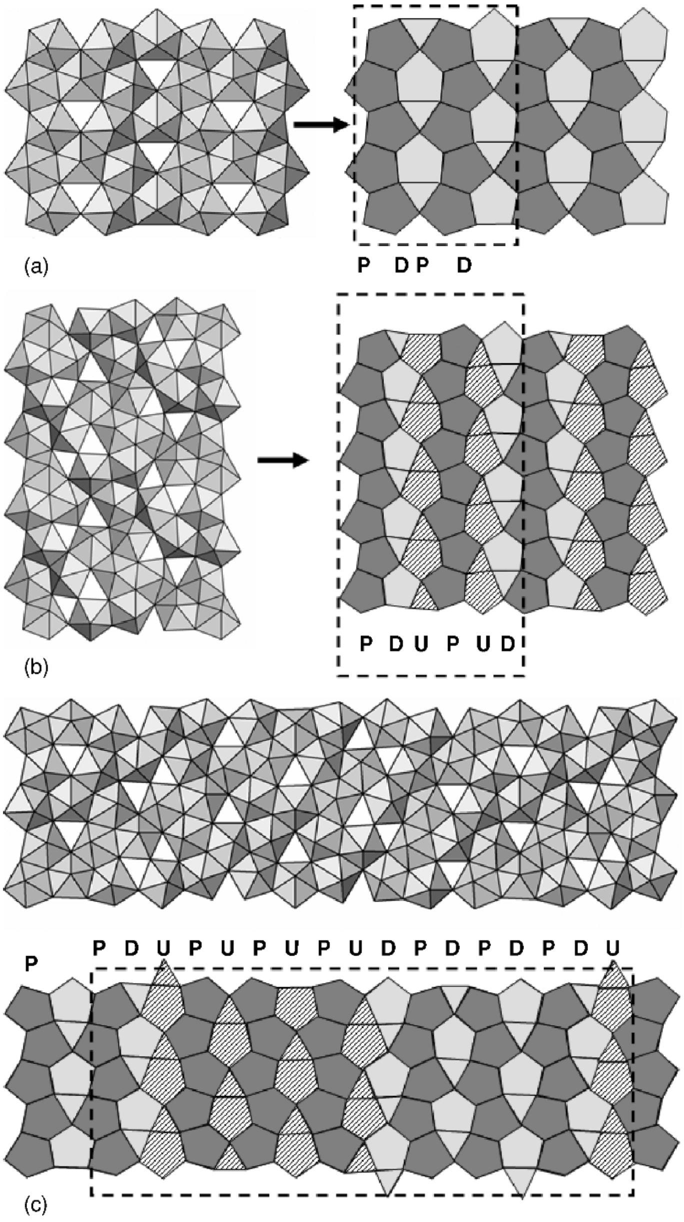
Sayrite $\{Pb_2[(UO_2)_5O_6(OH)_2](H_2O)_4\}$ (Piret *et al.*, 1983), is the only mineral that contains sheets based upon the sayrite anion topology, which involves U, D, P and R chains. The chains are arranged in such a way that each P chain is flanked by two arrowhead chains with the same sense (direction), giving UPU or DPD sequences. These two sequences alternate in the anion topology, and are separated by R chains, giving the sequence RUPURDPDRUPU...

(*v*) *Curite anion topology*

The structure of curite (Taylor *et al.*, 1981; Li and Burns, 2000b) contains sheets based upon the curite anion topology, which cannot be described as a simple chain-stacking sequence using only the U, D, P and R chains. A chain with pentagons, triangles, and squares is required. It has a directional sense owing to the presence of an arrowhead (a pentagon and a triangle sharing an edge), and is designated U_m and D_m, for up and down (modified) pointing chains, respectively. The curite anion topology can be characterized by the chain-stacking sequence U_mDU_mD...

(*vi*) *β-U_3O_8 anion topology*

The β-U_3O_8 sheet anion topology (see Fig. 5.2d) is the basis of the sheets in ianthinite (Burns *et al.*, 1997b), as well as the sheets in β-U_3O_8. This topology can conveniently be described using a chain-stacking sequence involving U, D, and R chains with the repeat sequence DRUDRU...



(a)

P D U P U D
P
P D U P U P U P U D P D P D P D U
(c)

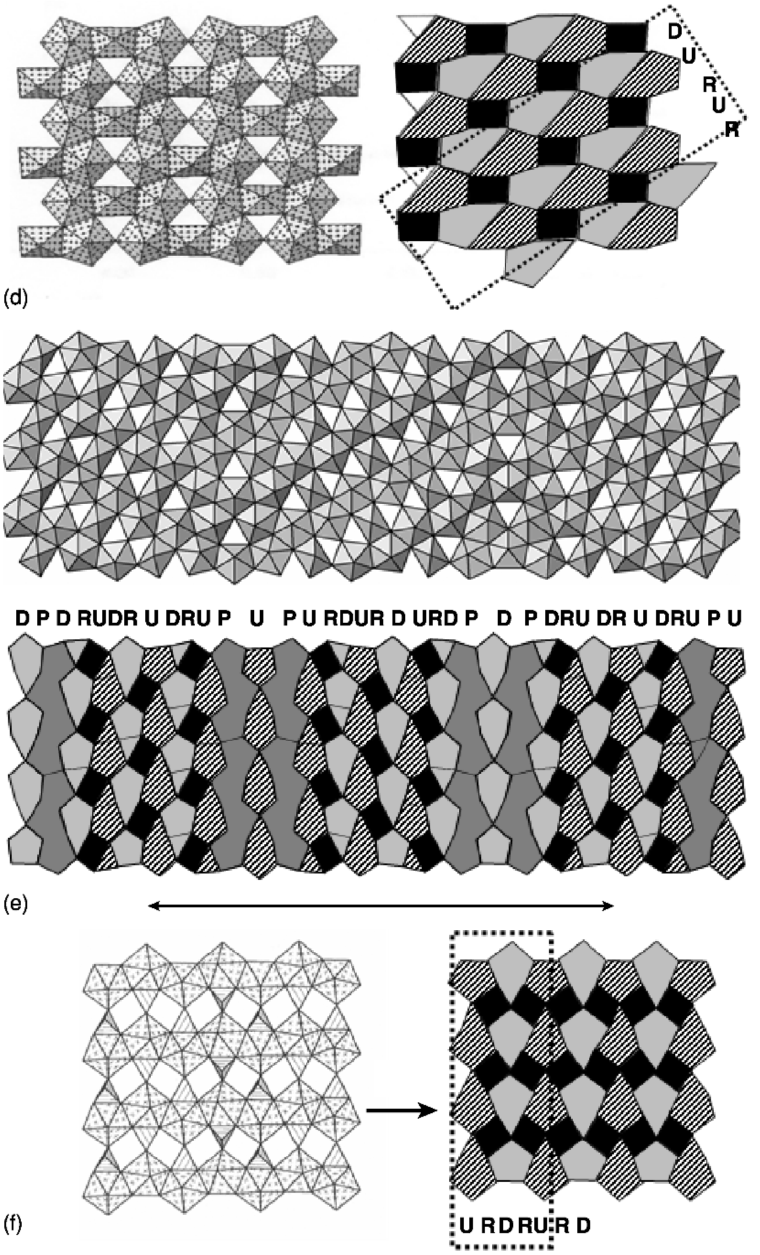

Fig. 5.2 (*a*) *Protasite* (α-U_3O_8) *structure and anion topology with anion repeat* (*adapted from Burns,* 1999). (*b*) *Fourmarierite structure and anion topology, showing the structural repeat.* (*c*) *Vandendriesscheite structure and anion topology.* (*d*) β-U_3O_8 *structure and anion topology* (*adapted from Brugger* et al., 2004). (*e*) *Wölsendorfite anion topology and the complex anion topology.* (*f*) *Uranophane anion topology showing anion repeat* (*adapted from Burns*, 1999).

(*vii*) *Wölsendorfite anion topology*

The versatility of this method for visualizing complex structures is beautifully demonstrated in the description of the structure of wölsendorfite (Burns, 1999b). The structure contains unique $Ur\phi_4$ square bipyramids and six unique $Ur\phi_5$ pentagonal bipyramids that link by sharing equatorial corners and edges to form infinite sheets that are parallel to (100). The interlayer between the uranyl sheets contains Pb^{2+} and Ba^{2+} cations, as well as H_2O groups that are either bonded to the interlayer cations or are held in the structure by H-bonding only. This complex anion topology possesses a primitive repeat of 56 Å (see Fig. 5.2e). It may be constructed using R, D, P, and U chains, with the repeat sequence DRUDRUDRUPDPDRUDRUDRUPDP... The repeat sequence involves the strings DRUDRUDRU and PDP, which are slabs of the β-U_3O_8 and protasite anion topologies, respectively. Thus, the wölsendorfite anion topology is structurally intermediate between the β-U_3O_8 and protasite anion topologies.

(*viii*) *Uranophane anion topology*

All minerals based on the uranophane topology contain pentagons of the anion topology (see Fig. 5.2f).

The uranophane sheet consists of chains of $Ur\phi_5$ bipyramids linked by bridging, isolated SiO_4 tetrahedra, and is common to uranophane, boltwoodite $\{K_{0.56}Na_{0.42}[(UO_2)(SiO_3OH)](H_2O)_{1.5}\}$, cuprosklodowskite, kasolite $\{Pb[(UO_2)(SiO_4)](H_2O)\}$, and sklodowskite. The difference between α-uranophane and β-uranophane depends on the orientation of the silicate tetrahedron. In kasolite, the apical O atoms of the SiO_4 tetrahedra bond to two Pb^{2+} cations in the interlayer (Catalano and Brown, 2004).

(c) Prediction of crystal morphology of U(VI) sheet minerals

The bond valence approach is commonly used to evaluate the analysis of a crystal structure. It provides a means to check bond lengths, the valence state of ions with the structure, as well as providing a method to describe hydrogen bonding (Burns, 1999a). The bond valence approach can be used to identify the valence state of the U cation in well-refined crystal structures. Schindler *et al.* (2004) and Schindler and Hawthorne (2004) have developed a method for predicting the stability of sheet uranyl minerals using the bond-valence deficiency of the sheet edges. Schindler *et al.* (2004) have shown that the surface structure of an edge is characterized by the bond-valence deficiency of anion terminations along chains of polyhedra parallel to the edge, and by the shift and orientation of adjacent layers. The stability of the edges also depends on the arrangement of the interstitial cations between the layers. The edges of the sheet-like uranyl minerals are more reactive than the basal surfaces because the equatorial O-atoms on the edges bond to fewer U^{6+} atoms than oxygen in the sheet, and hence must satisfy their individual bond-valence requirements through a higher degree of protonation (Schindler *et al.*, 2004). The interaction of the uranyl mineral edge surface with aqueous species controls crystal growth, dissolution, and sorption of other species, including other actinides. These interactions depend on the surface structure of an edge, the pH, and saturation index with respect to the mineral.

(d) Uranyl oxyhydroxides

The uranyl oxyhydrates are not only of importance in the geochemistry of uranium, but they are also one of the primary phases generated during the oxidative dissolution of SNF. Uranyl oxyhydroxides form in U-rich aqueous solutions and develop early during the oxidative dissolution of uraninite ores deposits; hence, they are expected to be the older U(VI) minerals in an oxidized deposit. The complexity of these structures combined with their propensity to dehydrate made their structure characterization difficult; Finch *et al.* (1996a) reported the full structure determination of schoepite and Weller *et al.* (2000) refined the structure of meta-schoepite $\{(UO_2)_4O(OH)_6 \cdot 5H_2O\}$. The uranyl oxyhydroxides are based on electrostatically neutral polyhedral sheets of the form $[(UO_2)_xO_y(OH)_z]$ and no interlayer cations. Water molecules occupy the interlayer sites, linking adjacent sheets through H-bonds. Meta-schoepite possesses one less water molecule than schoepite, leading to 2.8% reduction in the *c*-axis and 0.6 and 0.9% in the *a*- and *b*-directions, respectively. Hughes-Kubatko *et al.* (2005) have shown that meta-schoepite is thermodynamically unstable relative to dehydrated schoepite and have suggested that sodium may be an essential element in natural meta-schoepite. The $U–O_{ax}$ and $U–O_{eq}$ bond lengths in schoepite vary with pH. Allen *et al.* (1996a) determined that $U–O_{ax}$ distances are 1.80, 1.84, and 1.86 Å and $U–O_{eq}$ distances are 2.38, 2.36 and 2.32 Å, at pH 7, 9, and 11, respectively. At pH 11, the uranyl group becomes elongated and the $U–O_{eq}$ bond contracts, such that the structure resembles a clarkeite-like alkali metal uranate. Clarkeite-like sodium uranates have been observed during dissolution of soddyite (Giammar and Hering, 2002) and in the highly caustic environment of the Hanford tank wastes in Washington, USA (Deutsch *et al.*, 2004). Pseudomorphic replacement of pegamatic uraninite by clarkeite $\{(NaCa_{0.5}Pb_{0.5})[(UO_2)O(OH)](H_2O)_{0-1}\}$ may occur during metasomatic alteration by oxidizing hydrothermal fluids (Finch and Ewing, 1997).

The alkali uranyl oxyhydroxides may play an important role in attenuating radionuclides in the environment, including neptunium (Li and Burns, 2001a; Burns *et al.*, 2004a), strontium (Burns and Li, 2002), and cesium (Hoskins and Burns, 2003).

(e) Pb–uranyl oxyhydroxides

As uranium decays to lead, the lead enters cation vacancies in the interlayer, leaving a uranium vacancy in the structural sheet. Although Pb–uranyl oxyhydroxides will form directly from uraninite alteration, many Pb–uranyl minerals are formed though the accumulation of radiogenic lead in nominally Pb-free uranium phases. Accumulation of lead will also destabilize the structure of some U(VI) minerals. For example, Finch and Ewing (1997) have demonstrated that clarkeite will eventually transform to wölsendorfite or curite. Lead is not incorporated into rutherfordine, soddyite, or uranophane, minerals that may replace early-formed lead uranyl oxyhydroxides. However, several uranyl phosphates and arsenates will incorporate lead. Indeed, Finch and Ewing (1992) suggested that curite, one of the last minerals remaining after complete oxidative dissolution of uraninite, may act as substrate for nucleation of certain phosphates. Burns and Hill (2000b) have synthesized a strontium analog of curite that may be relevant to HLW disposal.

Spriggite, $\{Pb_3[UO_2)_6O_8(OH)_2](H_2O)_3\}$, has been identified by Brugger *et al.* (2004). The structure is based on $[(UO_2)_6O_8(OH)_2]^{6+}$ sheets of uranyl polyhedra of the β-U_3O_8 anion topology with Pb^{2+} and H_2O in the interlayer. Spriggite has the highest Pb:U ratio (1:2.00) of all known lead uranyl oxide hydrates. Finch and Murakami (1999) have suggested a reaction pathway for increasing alteration of hydrated lead uranyl oxyhydroxides where the molar proportion of PbO can be correlated with the molar proportion of H_2O. With increasing PbO content, charge compensation in the sheet structure results in OH^- substitution for O^{2-}. The U–O_{eq} bonds in the $Ur\phi_5$ pentagonal bipyramids are considerably longer and of lower bond valence than the U^{6+}–O bonds in the $Ur\phi_4$ square bipyramids. The change in uranyl ion coordination from pentagonal to square helps satisfy bond-valence requirements of OH^- in the anion site. Hence, the spriggite adopts $Ur\phi_4$ square bipyramids, whereas the structure of vandendriesscheite (Pb:U = 1:6.36) consists entirely of $Ur\phi_5$ pentagonal bipyramids. Vandendriesscheite, one of the most common Pb-bearing uranyl oxyhydroxides, contains two symmetrically distinct Pb^{2+} cations in the interlayer; both bonded to H_2O groups. The two Pb^{2+} cations (Pb(1) and Pb(2)) are bonded to five and six O_{ur} atoms of adjacent sheets of uranyl polyhedra, respectively. Richetite possesses an extraordinarily complex structure (Burns, 1998b). The phase has been reported at the Shinkolobwe and Jáchymov U-deposits.

(f) Uranyl peroxides

The U-bearing phases, studtite and meta-studtite $\{(UO_2)O_2(H_2O)_2\}$, are the only known peroxide minerals that form during the buildup of α-generated H_2O_2 on the surface of natural uraninite (Walenta, 1974; Deliens and Piret, 1983a; Finch and Ewing, 1992). Burns and Hughes (2003) determined that the structure of studtite is monoclinic, contains one symmetrically distinct U^{6+} cation and four O atoms, two of which occur as H_2O groups. The U^{6+} cation occurs as part of a linear uranyl ion, and each U^{6+} cation is bonded to six additional O atoms, two of which are H_2O groups, and four that are O atoms of the peroxide groups. Unlike all other uranyl oxide hydrate minerals, studtite is not based upon sheet of uranyl polyhedra, but contains polymerized uranyl polyhedra in only one dimension. The occurrence of chains rather sheets in U(VI) minerals is usually due to distortions in the polyhedra, normally the result of lone pairs (e.g. in Se- and Bi-bearing uranium minerals); however, in studtite, the presence of peroxide at the equatorial positions of the uranyl polyhedra results in distorted hexagonal bipyramids, with the peroxide O–O edge length of 1.46 Å. Typical O–O edge length in uranyl hexagonal bipyramid is 2.4 Å with nitrate or carbonate ligands. This distortion may prevent the formation of two-dimensional layer structures (see Fig. 5.56a).

Radiolysis of water at spent nuclear fuel may create an additional complexity for predicting UO_2 paragenesis in a geological repository (Satonnay *et al.*, 2001; Amme, 2002). Studtite and meta-studtite have been identified by McNamara *et al.* (2003) on the surface of corroding commercial spent fuel replacing the meta-schoepite that precipitated earlier. As the H_2O_2 concentration increased with time, studtite and meta-studtite became the dominant alteration phases. H_2O_2 is consumed in the presence of carbonate (Sunder *et al.*, 2004), forming peroxo complexes with H_2O_2 and U(VI) (Amme, 2002).

(g) Uranyl carbonates and calcite

Uranyl carbonates tend to form in evaporative environments or under high p_{CO_2} conditions. They are structurally diverse and only relatively few of the uranyl carbonates (rutherfordine (Finch *et al.*, 1999b), roubaultite, bijvoetite $\{[M_8^{3+}(H_2O)_{25}(UO_2)_{16}O_8(OH)_8(CO_3)_{16}](H_2O)_{14}\}$, where M is Y or Ln (Li *et al.*, 2000), and wyartite (Burns and Finch, 1999) consist of sheets of polyhedra that contain a cation of high valence. Other uranium carbonates contain isolated clusters similar to those observed in solution (Allen *et al.*, 1995). The optical signature of the UO_2^{2+} bands in liebigite $\{Ca_2UO_2(CO_3)_3 \cdot 11H_2O\}$, andersonite $\{Na_2Ca[(UO_2)(CO_3)_3](H_2O)_5\}$, and schröckingerite $\{NaCa_3(UO_2)(CO_3)_3(SO_4)F \cdot 10H_2O\}$, that all contain uranyl tricarbonate clusters, are almost identical (Čejka, 1999).

The uranyl monocarbonates (rutherfordine, joliotite $[UO_2CO_3 \cdot nH_2O]$, blatonite $[UO_2CO_3 \cdot H_2O]$, and urancalcarite $\{Ca(UO_2)_3CO_3(OH)_6 \cdot 3H_2O)\}$) are thermodynamically stable, having solubilities comparable to some uranyl oxide hydrates. The uranyl carbonate mineral grimselite, $\{K_3Na[(UO_2)(CO_3)_3](H_2O)\}$ (Li and Burns, 2001b), contains uranyl tricarbonate complexes of composition $[(UO_2)(CO_3)_3]^{4-}$, which occur as an isolated polyhedra in each of the structures, cf. Fig. 5.53. Schröckingerite contains $Na\phi_6$ octahedron, an SO_4 tetrahedron, and three symmetrically distinct $Ca\phi_8$ polyhedra (Hayden and Burns, 2002). The structure contains isolated units of uranyl tricarbonate and sulfate tetrahedra that are coordinated to low-valence cations. Bayleyite, $\{Mg_2[(UO_2)(CO_3)_3](H_2O)_{18}\}$, contains three symmetrically distinct $Mg(H_2O)_6$ octahedra, as well as a $(UO_2)(CO_3)_3$ cluster, and six symmetrically distinct H_2O groups. Swartzite, $\{CaMgUO_2(CO_3)_3 \cdot 12H_2O\}$, contains $Ca\phi_8$ polyhedra and a $Mg(H_2O)_6$ octahedron.

At a partial pressure of $CO_2 > 10^{-2.2}$ atm, rutherfordine becomes the stable uranium phase with respect to dehydrated schoepite; however, the schoepite–rutherfordine equilibrium indicates that p_{CO_2} must be $>10^{-1.9}$ atm before schoepite becomes unstable with respect to rutherfordine. Schoepite is thus expected to be the U-solubility-controlling phase in waters exposed to atmospheric conditions. Rutherfordine would be expected to replace schoepite in environments where the p_{CO_2} pressure is higher, possibly in a repository environment or in saturated soils. Replacement of schoepite by rutherfordine has been observed at the Shinkolobwe U-deposit (Finch and Ewing, 1992). The structure of rutherfordine was elucidated by Finch *et al.* (1999b) and can be represented by an anion topology that consists of edge-sharing hexagons that share corners, creating pairs of edge-sharing triangles. The rutherfordine sheet is obtained by populating all the hexagons in the anion topology with uranyl ions and one half of the triangles are populated with CO_3 groups. The sheets are held together via van der Waals forces. An identical sheet structure occurs in synthetic $(UO_2)(SeO_3)$.

Burns and Finch (1999) reported the structure of a mixed uranium valence mineral, wyartite that contains U(v) and U(vi). The structure of wyartite contains three symmetrically distinct U positions. The U1 and U2 cations are each strongly bonded to two O atoms with U–O bond lengths of ~1.8 Å, consistent with a linear uranyl ion, whereas the U3 site has seven anions at the corners of a pentagonal bipyramid, with U–O bond lengths of 2.07 and 2.09 Å. A bond valence analysis showed that the U3 site is coordinated by six O atoms and one H_2O group. Two of the O atoms of the bipyramid are shared with a CO_3 group and the sum of bond valences incident at the U3 site is 5.07, in agreement with the assignment of U(v) in this site. Urancalcarite is structurally similar to wyartite and commonly associated with wyartite in nature. Finch and Murakami (1999) suggest that wyartite may oxidize to uranocalcarite. Schindler and coworkers (Schindler and Hawthorne, 2004; Schindler *et al.*, 2004) proposed the formation of the mixed U(v)–U(vi) mineral, wyartite II, on surface of calcite during interaction of acidic and basic uranyl-bearing solutions with calcite.

The structure of fontanite, $\{Ca[(UO_2)_3(CO_3)_2O_2](H_2O)_6$, has been refined by Hughes and Burns (2003) as a monoclinic phase that consists of two symmetrically distinct $Ur\phi_5$ units, one $Ur\phi_6$ unit, and two CO_3 triangles. It is observed in the weathered zone of the Rabejac uranium deposit in Lodève, Hérault, France, where it is associated with billietite and uranophane. Both fontanite and roubaultite possess anion topologies similar to phosphuranylite $\{KCa(H_3O)_3(UO_2)[(UO_2)_3(PO_4)_2O_2]_2(H_2O)_8\}$.

Several uranyl carbonates that contain lanthanides have been described. Bijvoetite is found in association with uraninite, sklodowskite, and uranophane in the oxidized zone at the Shinkolobwe mine (Li *et al.*, 2000). The structure of bijvoetite is extremely complex and contains 16 unique carbonate groups, 39 symmetrically distinct H_2O groups, and 8 unique M^{3+} sites that are occupied by variable amounts of yttrium, dysprosium, and other lanthanides. Astrocyanite $\{Cu_2(Ce,Nd,La)_2UO_2(CO_3)_5(OH)_2 \cdot 1.5H_2O\}$, is another rare earth-bearing uranyl carbonate that is observed as an oxidation product of uraninite. These complex rare earth uranyl carbonates may play an important role in the long-term behavior of released transuranic elements following corrosion of nuclear materials in a geologic repository.

The occurrence of trace amounts of uranyl ions in natural calcite has posed a long-standing problem in crystal chemistry because of speculation that the size and shape of the uranyl ion may preclude its incorporation in a stable lattice position in calcite. The incorporation of uranium in calcite and aragonite provides the basis for U-series age-dating which are commonly adopted for marine and terrestrial carbonates. Uranium is enriched in aragonite relative to calcite owing to the nature of the coordination environment in U-bearing aragonite. Reeder *et al.* (2000) have demonstrated using EXAFS that the dominant aqueous species $UO_2(CO_3)_3^{4-}$ is retained by the uranyl in aragonite, essentially intact. In contrast, a different equatorial coordination occurs in calcite, characterized by fewer nearest oxygens at a closer distance, reflecting that the CO_3 groups are monodentate. The uranyl ion has a more stable and well-defined local environment when co-precipitated with aragonite; however, Reeder *et al.* (2000) argue that as aragonite is metastable with respect to calcite, retention of U(VI) by calcite is likely to be temporary. In contrast, Kelly *et al.* (2003) examined a 13 700-year-old U-rich calcite from a speleothem in northernmost Italy. X-ray absorption spectroscopy data indicated substitution of U(VI) for a Ca^{2+} and two adjacent CO_3^{2-} ions in calcite. This data implied that uranyl has a stable lattice position in natural calcite and suggested that uranium may become incorporated in calcite over long time scales.

Sturchio *et al.* (1998) reported the occurrence of U^{4+} in calcite based on XANES core spectroscopic analysis and concluded that this explained the anomalously high concentrations of uranium observed in calcite in reducing environments. Substitution of Ca^{2+} by Na^{+} was suggested as a possible mechanism to charge balance the structure. The calculated U–O distances reported by Sturchio *et al.* (1998) were (2.21 ± 0.02) Å and (2.78 ± 0.03) Å for U^{4+} in calcite, whereas Reeder *et al.* (2001) estimated $U–O_{eq}$ to be 2.33 Å and $U–O_{ax}$ as 1.80 Å. Interestingly, Sturchio *et al.* (1998) showed a good match of their measured U–O bond lengths with a natural brannerite, where U–O bond lengths were reported as 2.28 and 2.82 Å. However, natural brannerite minerals have recently been shown to be U(V) phases (Finnie *et al.*, 2003; Colella *et al.*, 2005).

(h) Uranyl sulfates

Uranyl sulfates are important in systems where sulfides (e.g. pyrite) are being oxidized. Initial oxidation causes an increase in acidity of the system; however, the acidity may be buffered by the dissolution of carbonate in the surrounding rock, leading to the formation of gypsum. Uranyl sulfates usually occur where uranyl carbonates are absent (and vice versa), owing to the different pH conditions where these minerals will dominate. Uranyl sulfate minerals typically occur as microcrystalline crusts, finely intergrown with other uranyl sulfates and/or monocarbonates. They are common at uranium mines where they form during evaporation of acid sulfate-rich mine drainage waters.

Burns (2001a) and Burns *et al.* (2003) have performed structural refinements on a number of monoclinic zippeite-group U(VI) phases, including zippeite

$\{K_3(H_2O)_3[(UO_2)_4(SO_4)_2O_3(OH)]\}$, sodium-zippeite $\{Na_5(H_2O)_{12}[(UO_2)_8(SO_4)_4O_5(OH)_3]\}$, Mg-zippeite $\{Mg(H_2O)_{3.5}[(UO_2)_2(SO_4)O_2]\}$, Zn-zippeite $\{Zn(H_2O)_{3.5}[(UO_2)_2(SO_4)O_2]\}$, and Co-zippeite $\{Co(H_2O)_{3.5}[(UO_2)_2(SO_4)O_2]$. Each structure contains the zippeite-type layers that consist of chains of edge-sharing $Ur\phi_5$ units that are cross-linked by vertex sharing with sulfate tetrahedra. Marecottite, $\{Mg_3(H_2O)_{18}[(UO_2)_4O_3(OH)(SO_4)_2]_2(H_2O)_{10}\}$, is based on uranyl layers composed of chains of edge-sharing $Ur\phi_5$ biyramids that are linked by vertex-sharing sulfate tetrahedra, identical to zippeite (Brugger *et al.*, 2003). Marecottite and zippeite can co-exist as has been observed in samples from the Jáchymov mine in the Czech Republic. Uranopilite is the only known uranyl sulfate mineral to form chains. The structure consists of clusters of six distinct $Ur\phi_5$ bipyramids that are linked together into a chain by sulfate tetrahedra bonded to two oxygens from each cluster. Adjacent chains are only hydrogen-bonded (Burns, 2001a).

(i) Uranyl silicates

Because of the ubiquity of dissolved silica in most groundwaters, uranyl silicates are the most abundant U(VI) minerals. The uranyl silicates are divided into three groups based on their U:Si ratios (Stohl and Smith, 1981). Accordingly, the structural trends in the uranyl silicates are also dependent on the U:Si ratio (Stohl and Smith, 1981; Finch and Murakami, 1999; Burns, 2001b). In phases with the U:Si ratio of 2:1 and 1:1, no polymerization of the SiO_4 tetrahedra occurs, whereas phases with 1:3 ratios contain chains of vertex-sharing silica tetrahedra. As the U:Si ratio approaches 1:4, the structures contain sheets of SiO_4 tetrahedra. In soddyite, with a ratio of 2:1, each silica tetrahedron shares two of its edges with other uranyl polyhedra, but in structures with the ratio 1:1, only one edge of each silica tetrahedron is shared with a second uranyl polyhedron and each silica tetrahedron is linked to other uranyl polyhedra by vertex sharing.

Uranophane is one of the most common uranyl minerals, and its ubiquity suggests that the uranyl silicates are important phases controlling uranium concentrations in groundwater (Finch and Ewing, 1992). α-Uranophane and β-uranophane have distinctly different crystallographic data and stabilities. Differences in stability were amply illustrated in the study by Cesbron *et al.* (1993) where they failed to synthesize β-uranophane whereas α-uranophane was produced. Both calcium uranyl silicates are common in most oxidized uranium deposits.

The 1:3 silicates (weeksite and haiweeite) are only known from Si-rich environments such as tuffaceous rocks but are commonly observed during the laboratory weathering of borosilicate waste glasses (Ebert *et al.*, 1991; Feng *et al.*, 1994). The structure of weeksite, originally described by Outebridge *et al.* (1960), has been refined by Jackson and Burns (2001). Haiweeite, named for the Haiwee reservoir, California, USA, has been identified at the Nopal I deposit in Peña Blanca, Mexico, where it is associated with uranophane. The structure of weeksite consists of chains of edge-sharing $Ur\phi_5$ pentagonal bipyramids that share edges with SiO_4 tetrahedra. The chains are linked through disordered SiO_4 tetrahedra to form complex sheets, which in turn form a framework through linkage with SiO_4 tetrahedra (Burns, 1999b).

The only known thorium uranyl silicate mineral, coutinhoite, has been described by Atencio *et al.* (2004) as being isostructural with weeksite. The open channels created by the silicate framework structure are thought to permit the incorporation of Th^{4+}. Oursinite, $\{(Co_{0.86}Mg_{0.10}Ni_{0.04})\cdot O_2\cdot UO_2\cdot 2SiO_2\cdot 6H_2O\}$, was first reported by Deliens and Piret (1983b) from Shinklolobwe. The phase formed from the oxidation of Co- and Ni-bearing sulfides and demonstrates the ability for U(VI) phases to incorporate a range of elements. Lepersonnite, $\{CaO(Gd,Dy)_2O_3\cdot 24UO_3\cdot 8CO_2\cdot 4SiO_2\cdot 60H_2O\}$, is a pale yellow uranyl silicate from the Shinkolobwe mine that was first described by Deliens and Piret (1982). The reported compositions of oursinite, lepersonnite, and coutinhoite have immediate implications for radioactive waste disposal for the possible retention of radionuclides, including plutonium, in the environment.

Soddyite is the only known mineral with a U:Si ratio of 2:1; it is also the most common of the uranyl minerals that have structures based on frameworks of polyhedra of higher valence. The structure of soddyite consists of $Ur\phi_5$ units that share equatorial edges to form chains. The chains are cross-linked by sharing edges with SiO_4 tetrahedra in such a way that each tetrahedron shares two of its edges with adjacent chains (Burns, 1999b). Based on observations at the Nopal I site, Pearcy *et al.* (1994) suggested that the precipitation of soddyite may be kinetically more favorable than the formation of other U^{6+} silicates. Soddyite may form from uranophane exposed to dilute metoric waters that are low in carbonate and with a pH below 7. Uranosilite, $\{(Mg,Ca)_4(UO_2)_4(Si_2O_5)_{5.5}(OH)_5\cdot 13H_2O\}$, has only been reported in nature at a site in Menzenschwand, Germany (Walenta, 1983). Burns *et al.* (2000) reported the occurrence of a new U(VI) silicate from the corrosion of a borosilicate glass with formula $\{KNa_3(UO_2)_2(Si_4O_{10})_2(H_2O)_4\}$, with a U:Si ratio of 1:4. This phase was demonstrated to be structurally distinct from the phase synthesized by Plesko *et al.* (1992). Burns and co-authors suggested that this novel U(VI) silicate may incorporate Np(V).

(j) Uranyl phosphates and arsenates

Uranyl phosphates and arsenates constitute about one-third of the ~200 described uranium minerals (see Table 5.3); yet only a fraction of these have well-defined structures. In groundwaters where $\log\{[PO_4^{3-}]_T/[CO_3^{2-}]_T\} > -3.5$, uranyl phosphate complexes dominate over uranyl carbonate complexes (Sandino and Bruno, 1992). Finch and Ewing (1992) suggested that the occurrence of uranyl phosphates in the most weathered zones of the Koongarra U-deposit indicated that higher oxidation potentials may be necessary for uranyl phosphate precipitation, as uranyl silicates were observed at depth. However, saléeite ($Mg(UO_2)_2(PO_4)_2\cdot 10H_2O$) was observed on the surface of apatite where the groundwater was undersaturated with respect to saléeite, indicating that the mineralization occurred by local saturation (Murakami *et al.*, 1997).

Laboratory studies have demonstrated that surface mineralization of saléeite on fluoro-apatite where localized release of Ca and P facilitates autunite formation and U^{6+} uptake (Ohnuki *et al.*, 2004).

Uranyl arsenates are often structurally analogous to the corresponding uranyl phosphates; e.g. the isostructural mineral species abernathyite, $\{K[(UO_2)(AsO_4)](H_2O)_3\}$, and meta-ankoleite, $\{K[(UO_2)(PO_4)](H_2O)_3\}$. Many of the natural uranyl phosphates and arsenates may exhibit complete solid solution formation between end-members. However, in hügelite, $\{Pb_2[(UO_2)_3O_2(AsO_4)_2](H_2O)_5\}$, the presence of arsenic makes the unit cell four times larger than that reported for dumontite, $\{Pb_2[(UO_2)_3(PO_4)_2(OH)_4](H_2O)_5\}$ (Locock and Burns, 2003b). Both structures possess the phospuranylite anion topology. In hügelite, the interlayer contains four symmetrically distinct Pb^{2+} cations. Unlike the lead uranyl oxyhydroxides, hügelite contains only $Ur\phi_5$ and $Ur\phi_6$ polyhedra; yet, it possesses a high U:Pb ratio.

Uranyl arsenates and phosphates may be divided into groups depending on the U:P or U:As ratio. However, a structural classification is more encompassing. The uranium phosphates and arsenates can be separated into four groups: (i) autunite structure; (ii) 3:2 phosphuranylite structure; (iii) uranophane structure; and (iv) chain structures.

(*i*) *Autunite structures*

The most important uranyl phosphates in terms of natural abundance are the autunites and meta-autunite groups. The autunite group of minerals is tetragonal uranyl arsenates and phosphates. The group possesses the general formula $M(UO_2)_2(XO_4)_2 \cdot 8\text{–}12H_2O$ where M may be Ba, Ca, Cu, Fe^{2+}, Mg, Mn^{2+} or $\frac{1}{2}(HAl)$ and X is As or P. Takano (1961) obtained unit cell parameters for an autunite specimen from Ningyo Pass, Japan ($a = 6.989$ Å and $c = 20.63$ Å). These were virtually identical to those obtained by Locock and Burns (2003a) on a synthetic autunite. The Pb uranyl oxide hydrate, curite is commonly associated with uranium phosphates such as autunite, torbernite, and parsonsite (Vochten and Deliens, 1980). Finch and Ewing (1992) suggested that the (010) face of curite consists of $\equiv (UO_2) - OH_2^+$ surface species that may provide a reactive pathway for attachment of $(HPO_4)^{2-}$ groups, forming $\equiv (UO_2)\text{-}OPO_3\text{-}H_3O^0$. This species, once deprotonated, would have the equivalent stoichiometry of chernikovite. Heinrichite $\{Ba[(UO_2)(AsO_4)]_2(H_2O)_{10}\}$ was originally assumed by Gross *et al.* (1958) to be tetragonal, despite the observation of biaxial optical properties. Locock *et al.* (2005b) have refined the structures of several of the barium-bearing phases that possess the autunite sheet structure, including heinrichite and meta-uranocircite $\{Ba[(UO_2)(PO_4)]_2(H_2O)_7\}$ type I and II. There is only the loss of one H_2O group and a slight decrease in the interlayer spacing, from $d_{020} = 8.82$ Å to $d_{020} = 8.43$ Å from going from meat-uranocircite I to II; however, there is a significant re-arrangement in the Ba atomic positions. Table 5.3 lists new refinements from Locock *et al.* (2005b) for these autunite structures; however, because of the difficulties in obtaining suitable natural specimens, some are based synthetic phases and predictions. These have been listed owing to the apparent inconsistencies in earlier published data. Locock *et al.* (2005c) have published a refinement of uranospathite $\{Al_{1-x}\square_x[(UO_2)(PO_4)]_2(H_2O)_{20+3x}\, F_{1-3x}\}$ with $0 < x < 0.33$ and confirmed the presence of fluorine, the absence of H_3O^+, and a higher Al content in the structure; the empty square in the formula indicates a vacancy. Locock *et al.* (2005c) have described uranospathite as the "Dogwood sandwich" of the autunite group with an interlayer spacing, d_{200} of 15.01Å, possessing 21 H_2O groups per formula unit (*pfu*). The discovery that uranospathite and other aluminum uranyl phosphates possess a number of different hydration states has called into question the traditional division of these minerals into autunite and meta-autunite sub-groups based on the 10-12 H_2O *pfu* and 6-8 H_2O *pfu*, respectively.

(*ii*) *Phosphuranylite structures*

The phosphuranylite group consists of mainly orthorhombic phases with structure sheets of the composition $[(UO_2)_3(O,OH)_2(PO_4)_2]$. Phosphuranylite is remarkable because it contains all three types of Ur polyhedra. The $Ur\phi_5$ and $Ur\phi_6$ occur in the uranyl sheet and the $Ur\phi_4$ occur in the interlayer (Burns, 1999a). It is one of the few minerals with uranium in an interlayer position. Torbernite and meta-torbernite are hydrous copper uranium phosphates, the only difference between the two being the number of water molecules present; the length of the *c*-axis depends on the water content. The structure of monoclinic bergenite, the barium phosphuranylite phase $\{Ca_2Ba_4[(UO_2)_3O_2(PO_4)_2]_3(H_2O)_{16}\}$, has been refined by Locock and Burns (2003c).

(*iii*) *Uranophane structures*

The uranophane structure type occurs in only a few uranium phosphates and arsenates. Ulrichtite, $Cu[Ca(H_2O)_2(UO_2)(PO_4)_2](H_2O)_2$, and the mixed valence arsenite–arsenate uranyl mineral, Séelite, $\{Mg(UO_2)(AsO_3)_{0.7}(AsO_4)_{0.3}\cdot 7H_2O\}$. The name ulrichite was once used as a term for pitchblende; however, the structure of this $Ca–Cu^{2+}$ mineral has now been refined by Kolitsch and Giester (2001).[20] The structure consists of elongated CuO_6 octahedra that are corner linked by two PO_4 octahedra, edge- and corner-sharing $Ur\phi_5$, CaO_8, and PO_4 polyhedra. These form heteropolyhedral sheets parallel to (001) that are linked by the elongated CuO_6 octahedra.

(*iv*) *Chain structures*

Chain structures occur in walpurgite, orthowalpurgite, phosphowalpurgite, hallimondite, and parsonsite. Burns (2000) solved the structure of parsonsite

---

[20] Problems with the ulrichite structure as described by Birch *et al.* (1988) were recognized by Burns (1999a).

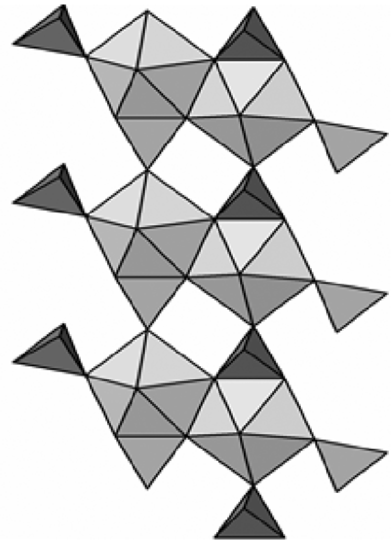

Fig. 5.3 *Parsonsite, the chain uranyl phosphate phase* (*adapted from Locock and Burns*, 2003).

and found that it was composed of uranyl phosphate chains rather than sheets as observed in the autunite and phosphuranylite minerals. The structure consists of Urϕ_5 polyhedra edge-sharing dimers that are cross-linked with two distinct phosphate tetrahedra by edge- and vertex- sharing. Two symmetrically distinct Pb^{2+} cations link the uranyl phosphate chains (see Fig. 5.3).

One of the Pb positions, Pb(1) is coordinated by 9 oxygen atoms, with Pb–O bond lengths ranging from 2.35 to 3.16 Å. Pb(2) is coordinated by 6 oxygens with a distinctly one-sided polyhedral geometry owing to the presence of a lone pair of electrons on the Pb cation. The Pb(2)–O bond lengths range from 2.28 to 3.15 Å. Common to other uranium phases, the lone pair distortion may be responsible for the formation of chains rather than sheets.

Based on structural refinements and infrared spectroscopy, Locock *et al.* (2005a) have shown that parsonsite does not contain any structural water. In most uranyl phosphates and arsenates, water occurs as a hydrate H_2O, either coordinating interlayer cations, or occurring as interstitial H_2O groups. Although Locock *et al.* (2005a) detected water in hallimondite, this was determined not to be critical to structural integrity.

(*v*) *Synthetic uranyl phosphates and arsenates*

Synthetic varieties have also revealed structural differences between phosphate and arsenate uranyl phases that contain the large alkali cations cesium and rubidium. These phosphate and arsenate phases are not isostructural. For example, cesium uranyl arsenates are not isostructural with cesium uranyl phosphates, but show a homeotypic framework with identical coordination geometries and polyhedral connectivity. The presence of arsenic expands the framework relative to phosphorus and so the cesium uranyl arsenate has a unit-cell volume ~7% greater than the corresponding phosphate.

(*vi*) *Uranium*(*VI*) *phosphates in the environment*

Because of their low solubilities, phosphate and arsenate minerals are of considerable environmental importance for understanding the mobility of uranium in natural systems and they may control the concentration of uranium in many groundwaters. In alkaline environments, dewindite {$Pb(UO_2)_3(PO_4)_2(OH)_2 \cdot 3H_2O$} is stable at low lead concentrations; whereas dumontite is the stable phase in Pb-rich environments. In acid environments, parsonsite is prevalent at high lead levels and przhevalskite {$Pb_2(UO_2)_3(PO_4)_2(OH)_4 \cdot 3H_2O$} occurs under low lead concentrations (Nriagu, 1984). Jerden and Sinha (2003) examined the long-term sequestration of uranium by U(VI) phosphate mineral precipitation at the Coles Hill uranium deposit in Virginia, USA where uranium is released by the oxidation and chemical weathering of an apatite-rich, coffinite–uraninite orebody. Meta-autunite was observed by Buck *et al.* (1996) and Morris *et al.* (1996) in contaminated soils from a former uranium processing plant at Fernald, Ohio, USA.

Significant uraniferous phosphorite deposits occur in Tertiary sediments in Florida, Georgia, and North and South Carolina and in the Hahotoé-Kpogamé U-deposits in Togo, West Africa (Gnandi and Tobschall, 2003). The Florida Phosphorite Uranium Province has yielded large quantities of uranium as a by-product of the production of phosphoric acid fertilizer (Finch, 1996). The discovery that bacteria can reduce U(VI), which appears to precipitate as uraninite, has led to the concept of *in situ* bioremediation of U-contaminated groundwater; however, another possible microbial process for uranium immobilization is the precipitation of U-phosphates. Macaskie *et al.* (2000) have demonstrated that *Citrobacter* sp. will bioprecipitate uranyl phosphate with exocellularly produced phosphatase enzyme. In a similar study by Basnakova *et al.* (1998) a nickel uranyl phosphate was observed in experiments with *Citrobacter* sp.

(k) Uranyl vanadates

Uranyl vanadates comprise some of the most insoluble uranyl minerals, forming whenever dissolved uranium comes in contact with dissolved vanadate anions. The K-bearing uranyl vanadate, carnotite, is possibly the most important source of secondary (U^{6+}) uranium ore minerals, providing ~90% of the uranium production from secondary deposits. It is a lemon-yellow mineral with an earthy luster, a yellow streak, and a specific gravity of about 4. It occurs most commonly in soft, powdery aggregates of finely crystalline material or in thin films or stains on rocks or other minerals. The most noted occurrences of carnotite are in the Colorado Plateau (Zhao and Ewing, 2000), on the western edge of the Black Hills, South Dakota, USA, and in the Ferghana basin in Kyrgyzstan. It occurs in sandstones in flat-lying, irregular, partially bedded ore bodies. If present in sufficient quantity, carnotite will color the rock bright yellow; but in poorer deposits, particularly below 0.20 percent U_3O_8, it may be difficult to distinguish the uranium mineral from the sandstone itself.

Using solid state reactions, Dion *et al.* (2000) synthesized two new alkali uranyl vanadates, $M_6(UO_2)_5(VO_4)_2O_5$ with M = Na, K, by and determined their structures from single-crystal XRD. Both structures consisted of $[(UO_2)_5(VO_4)_2O_5]^{6-}$ corrugated layers parallel to the (100) plane. The layers contained VO_4 tetrahedra, $Ur\phi_5$ pentagonal bipyramids, and distorted $Ur\phi_4$ octahedra. The $Ur\phi_5$ units were linked by sharing opposite equatorial edges to form zigzag infinite chains parallel to the *c*-axis. These chains were linked together on one side by VO_4 tetrahedra and on other side by $Ur\phi_4$ and $Ur\phi_5$ corner-sharing units.

(l) Uranyl selenites and tellurites

In nature, uranyl selenite minerals form where Se-bearing sulfides are undergoing oxidative dissolution. Selenium occurs as Se(IV), in the selenite anion, SeO_3^{2-}, however, Finch and Murakami (1999) suggested that Se(VI) minerals may be expected under sufficiently oxidizing conditions. Natural uranyl selenites and tellurites include the minerals derriksite, demesmaekerite, guilleminite, larisaite $\{Na(H_3O)(UO_2)_3(SeO_3)_2O_2\cdot 4H_2O\}$ (Chukanov *et al.*, 2004), and marthozite, $\{Cu[(UO_2)_3(SeO_3)_2O_2](H_2O)_8\}$. The three known uranyl tellurites are cliffordite $\{UO_2(Te_3O_7)\}$, moctezumite $\{PbUO_2(TeO_3)_2\}$, and schmitterite $\{UO_2(TeO_3)\}$. The selenites and tellurites are based upon infinite chains of polymerized polyhedra of higher valence. The chain structures observed with moctezumite and derriksite contains $Ur\phi_5$ and $Ur\phi_4$ bipyramids as well as $Te^{4+}O_3$ and $Se^{4+}O_3$ triangles. They are strongly distorted owing to the presence of a lone pair of electrons on the cation. The crystal structure of marthozite has been refined by Cooper and Hawthorne (2001). There are two unique selenium sites, each occupied by Se^{4+} and coordinated by three O atoms, forming a triangular pyramid with Se at the apex, indicative of the presence of a stereoactive lone pair. The Se–O bond length is $\sim$1.70 Å. The structure possesses one Cu site coordinated by 4 H_2O groups and two O atoms. The structural unit is a sheet of composition $[(UO_2)_3(SeO_3)_2O_2]$, which is topologically identical to the structural unit in guilleminite $\{Ba[(UO_2)_3(SeO_3)_2O_2](H_2O)_3\}$. Adjacent sheets are linked through interstitial Cu^{2+} cations *via* Cu^{2+}-O bonds and *via* H-bonds that involve both (H_2O) groups bonded to Cu^{2+} and interstitial (H_2O) groups.

A number of uranyl selenites containing alkaline metals (Almond *et al.*, 2002), as well as Ag and Pb (Almond and Albrecht-Schmitt, 2002) have been prepared. The structures consist of $[(UO_2)(SeO_3)_2]^{2-}$ sheets constructed from $Ur\phi_5$ units that are linked by SeO_3^{2-} anions, similar to the natural minerals. Synthetic $Sr[(UO_2)_3(SeO_3)_2O_2]\cdot 4H_2O$ prepared in supercritical water was found to possess the same anion topology as is found in guilleminite and marthozite; however, this phase could not be prepared under ambient or hydrothermal conditions (Almond and Albrecht-Schmitt, 2004).

(m) Uranyl molybdates

Uranyl molybdates are common minerals formed by weathering of uraninite and Mo-bearing minerals (Finch and Murakami, 1999). Umohoite $\{[(UO_2)(MoO_2)](H_2O)_4\}$, is commonly partially replaced by iriginite $\{[(UO_2)(MoO_3OH)_2(H_2O)](H_2O)\}$, which also consists of polyhedra sheets. Iriginite, however, has a distinctive anion-topology arrangement of chains of pentagons and squares that share edges, and zigzag chains of edge sharing squares and triangles (Krivovichev and Burns, 2000a). In the structure of iriginite, each pentagon of the anion topology is populated by an $Ur\phi_5$ polyhedron, two-thirds of the squares are populated with $Mo^{6+}O_6$ octahedra that occur as edge-sharing dimers; the triangles, as well as one-third of the squares, are empty. There have been reports of substantial variability of the *c* dimension of umohoite possibly due to variation of the H_2O content or polytypism that may account for the observed variation in unit-cell parameters (Krivovichev and Burns, 2000b).

The sheets of uranyl and molybdate polyhedra in iriginite and umohoite have features in common. The umohoite to iriginite transformation during alteration of U–Mo deposits, corresponding to a change of the U:Mo ratio from 1:1 to 1:2, involves a change of anion topology to one with a smaller number of edges shared between coordination polyhedra. The uranophane anion-topology is the basis of the umohoite sheet. Construction of the anion topology requires the U and D arrowhead chains as well as the R chain, with the chain-stacking sequence URDRURDR... The iriginite anion-topology contains the same chains as the umohoite (uranophane) anion-topology, but the chain-stacking sequence is DRRRURRRDRRRURRR... The ratio of arrowhead (U and D) chains to R chains in the umohoite and iriginite anion topologies is 1:1 and 1:3, respectively. In the umohoite sheet, all rhombs of the R chains are populated with Mo^{6+} cations, whereas in the iriginite sheet, only two-thirds of the rhombs contain Mo^{6+}, with the remaining third empty. The result is U:Mo ratios of 1:1 and 1:2 in the umohoite and iriginite sheets, respectively. The iriginite anion-topology may be derived from that of umohoite by expansion of the umohoite anion-topology along a vector within the sheet that is perpendicular to the arrowhead chain, together with the insertion of two additional **R** chains between adjacent arrowhead chains. This transformation mechanism requires addition of Mo^{6+} to populate the rhombs of the **R** chains. Another mechanism for obtaining the iriginite anion-topology from that of umohoite is the replacement of every second URD sequence in the umohoite anion-topology with an **R** chain. This mechanism requires the removal of the U^{6+} that populated the **D** and **U** arrowhead chains. Krivovichev and Burns (2000a,b) have suggested that this may appear to be the most likely mechanism of the umohoite-to-iriginite transformation (see Fig. 5.4).

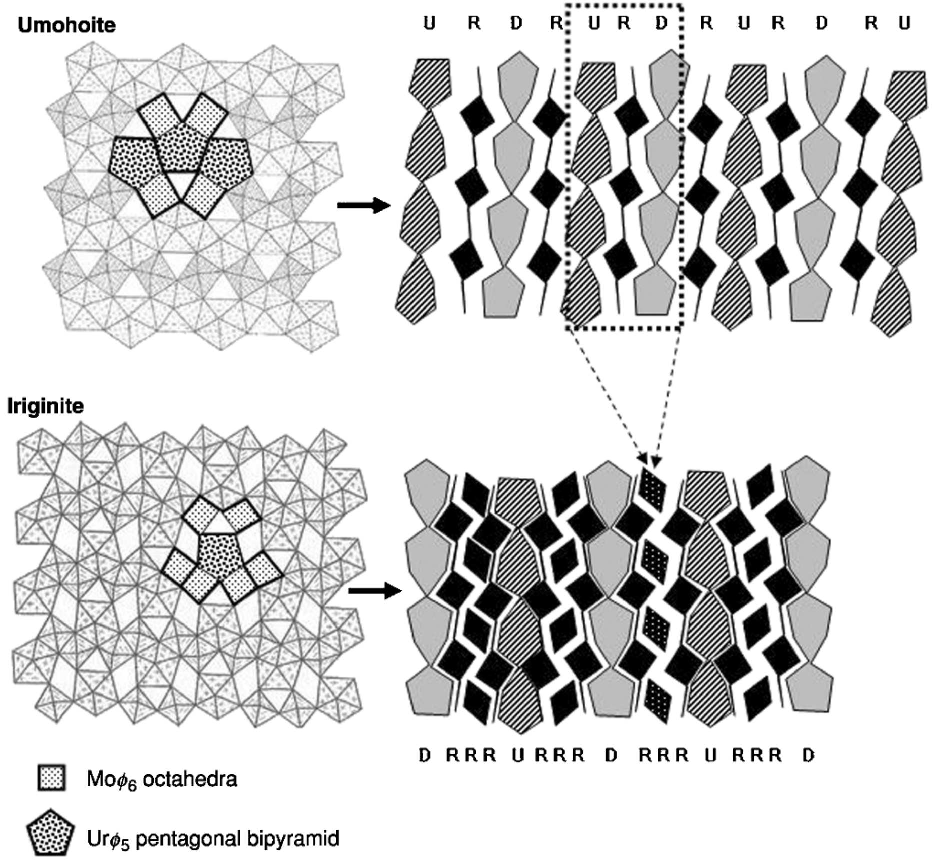

Fig. 5.4 *Diagram showing a possible mechanism for the umohoite to iriginite transformation* (*adapted from Krivovichev and Burns*, 2000a,b). *The iriginite structure can be obtained from umohoite through the replacement of every second URD sequence in the unmohoite anion topology with an R chain. This mechanism requires removal of the* U^{6+} *that occupied the D and U arrowhead chains.*

Mourite {$U^{4+}Mo^{6+}{}_5O_{12}(OH)_{10}$}, is a rare U^{4+} mineral containing molybdenum that is observed in oxidized zones in association with umohoite occurring as dark violet crusts and scaly aggregates in the Kyzylsai uranium deposit in Kazakhstan associated with umohoite. Krivovichev and Burns (2002a–c, 2003a) have described several synthetic uranyl molybdates, including Rb, Cs, Ag, and Tl species, respectively.

(n) Uranyl tungstates

Only one natural uranium tungstate is known, uranotungstite {$(Fe^{2+},Ba,Pb)(UO_2)_2WO_4(OH)_4(H_2O)_{12}$}; however, there are a wealth of synthetic U(IV) and U(VI) tungstates that have been reported in the literature. The phase UO_2WO_4 is isostructural with UO_2MoO_4, suggesting that the W^{6+} cations are tetrahedrally coordinated by O atoms. Given the structural similarities of Mo(VI) and W(VI), it might be expected that a variety of U(VI)–W(VI) phases should form. The phases $UO_2W_3O_{10}$ and $Na_2UO_2W_2O_8$, has been described but their structures are unknown. U(IV) tungsten bronzes have received considerable attention. The structures consist of ReO_3-type slabs of corner-sharing $W^{6+}O_6$ octahedra. A number of lithium uranyl tungstates ion conductors, such as $Li_2(UO_2)(WO_4)_2$ and $Li_2(UO_2)_4(WO_4)_4O$, have been prepared by high-temperature solid state reactions (Obbade *et al.*, 2004).

(o) Uranium association with clay minerals and zeolites

Chisholm-Brause *et al.* (2001) have identified four distinct uranyl complexes on montmorillonite that co-exist under certain conditions. Inner sphere and exchange-site complexes persist over a range of solution conditions. The uranyl ion sorbs onto montmorillonite at low pH *via* ion exchange, leaving the inner-sphere uranyl aquo-ion structure intact (Dent *et al.*, 1992; Sylwester *et al.*, 2000). At near neutral pH and in the presence of a competing cation, inner-sphere complexation with the surface predominates. Adsorption of the uranyl onto silica and γ-alumina surfaces appears to occur *via* an inner-sphere, bidentate complexation with the surface, with the formation of polynuclear surface complexes occurring at near-neutral pH (Sylwester *et al.*, 2000). Pabalan *et al.* (1993) have performed laboratory tests on the sorptive properties of zeolitic materials for uranium; the sorption is strongly dependent on pH. At near neutral pH U(VI) was strongly sorbed but under conditions where carbonate- and ternary hydroxyl-carbonate-complexes are present the sorption decreased substantially. Della Ventura *et al.* (2002) have discovered a new lanthanide borosilicate minerals of the hellandite group where uranium appears to be incorporated into a borosilicate cage structure. The phase, called ciprianiite {$Ca_4[(Th,U)(REE)]Al_2(Si_4B_4O_{22})(OH,F)_2]$}, formed with a syenitic ejectum[21] collected close at

---

[21] Literally, the violent volcanic explosion of mainly alkali feldspar (syenite) intrusive rock.

Tre Croci within a pyroclastic formation belonging to the Vico volcanic complex (Latium, Italy). Uvarova *et al.* (2004) reported another U^{4+} bearing silicate, arapovite $\{U(Ca,Na)_2(K_{1-x}\square_x)Si_8O_{20}\}$ from the Dara-i-Pioz moraine, Tien-Shan Mountains, Tajikistan.

The thorium and uranium uptake from their aqueous solutions by pristine and NaCl-pretreated zeolite-bearing volcanoclastic rock samples from Metaxades (Thrace, Greece) has been studied using a batch-type method (Misaelides *et al.*, 1995). The concentration of the solutions varied between 50 mg L^{-1} and 20 g L^{-1}. The NaCl pretreatment of the materials improved the thorium, but not the uranium, uptake. The absolute thorium uptake by the pretreated material, determined using neutron activation and X-ray fluorescence techniques, reached 12.41 mg g^{-1}, whereas the uranium uptake by the raw material was 8.70 mg g^{-1}. The distribution coefficients (K_d) indicated that the relative thorium and uranium uptake is higher for initial concentrations below 250 mg L^{-1}. The zeolitic materials were very stable despite the initial low pH of the solutions used; however, the pH increased significantly with time due to the simultaneous hydrogen-ion uptake. The thorium and uranium uptake is a complex function of the aqueous chemistry of the elements, the nature of the constituent minerals, and the properties of the zeolitic rock specimens. The various metal species are bound through different sorption processes such as ion-exchange, adsorption, and surface precipitation. Microporous minerals (zeolites, phyllosilicates) are mainly responsible for the large sorption capacity of the rock samples studied.

5.4 ORE PROCESSING AND SEPARATION

Because of the complexity of many uranium ores and the usual low concentrations of uranium present, the economic recovery of uranium often poses a difficult problem for the chemist. Physical concentration methods (flotation, gravitational, electromagnetic, etc.) have met with only limited success for uranium. The chemical methods used for the recovery of uranium from ores thus have to be designed to treat large ore volumes economically. Because of this and because uranium is a very electropositive metal, most direct pyrochemical methods are not applicable and processes usually involve modern aqueous extractive metallurgy. In this section the more important aspects of the extractive metallurgy of uranium will be described with emphasis on the chemical principles involved.

Uranium ores vary in chemical complexity from the relatively simple pitchblendes, which are accompanied by perhaps 10 other minerals, to exceedingly complex and refractory uranium-bearing titanites, niobates, and tantalates containing rare earths and many other metals. Included are uranium minerals accompanied by major admixtures of ill-defined organic compounds. Some pitchblende ores may have as many as 40 elements present from which uranium must be separated. Many uranium deposits are variable in composition, resulting in an almost daily variation in the composition of the starting materials. Such variations are minimized by stockpiling methods. Nevertheless there have been many *ad hoc* procedures elaborated to meet special chemical situations. Most such highly specialized methods will have little interest for this discussion. The general features common to most procedures will, however, be pertinent. All methods that have been commonly used comprise the following steps: (1) pre-concentration of the ore; (2) a leaching operation to extract the uranium into an aqueous phase – this step frequently being preceded by roasting or calcination to improve the extraction; and (3) recovery of the uranium from the pregnant leach liquors by ion exchange, solvent extraction, or direct precipitation, and in the case of ion-exchange or solvent extraction products by a final precipitation. Special methods may be used for recovery of by-product uranium. The product of these operations is a high-grade concentrate, which is usually further purified at a site other than the uranium mill.

The extractive metallurgy of uranium has been discussed in detail in various books (Vance and Warner, 1951; Clegg and Foley, 1958; Harrington and Ruehle, 1959; Chervet, 1960; Bellamy and Hill, 1963; Gittus, 1963; Galkin and Sudarikov, 1966; Merritt, 1971) and in collections of papers (United Nations, 1955, 1958, 1964; IAEA, 1966, 1970). There is also a bibliography on feed materials (Young, 1955). The most comprehensive collection of data is the multi-volume supplement to the *Gmelin Handbook of Inorganic Chemistry* (Gmelin, 1975–1996), more particularly its volume (A3) on Technology and Uses (Gmelin, 1981a). Many other references can be found in these sources.

5.4.1 Pre-concentration

Most uranium ores contain only small amounts of uranium, and because leaching is a relatively expensive operation, much effort has been expended to reduce the magnitude of the leaching operation by pre-concentration of the ore. Physical concentration methods (gravitational, electrostatic, flotation) and various sorting methods have been either used or proposed for upgrading of uranium ores. Unfortunately such beneficiation methods have not achieved great success, only a few of the uranium ores processed being amenable to physical beneficiation processes. Only in a few cases can appreciable concentration of uranium be achieved without excessive loss to tailings.

Uranium minerals as well as other minerals, with which they are closely associated, are denser than many gangue materials and successful gravity separation methods are sometimes possible. Such gravity separations are complicated by the fact that uranium minerals tend to concentrate in the fines upon crushing or grinding of some ores. This property has been used to some advantage in that a certain degree of mechanical concentration can be achieved by a gentle grinding followed by screening. Electrostatic methods generally give low recoveries or low concentration factors. Magnetic separation methods have generally been used to remove gangue materials such as magnetite, ilmenite, garnet, etc. Flotation methods have received considerable laboratory attention although they do not appear to have been widely applied. Flotation of undesirable gangue materials such as sulfides has met with some success, but no flotation agents have been developed for uranium minerals that give concentration factors approaching those obtained in the processing of sulfide minerals. Flotation has met with some success in splitting carbonate-containing ores into a carbonate and a non-carbonate fraction so that the former fraction can be leached by the carbonate method and the other with sulfuric acid. Both manual and mechanical sorting methods have been applied to the upgrading of uranium ores. In this procedure individual lumps of ore are sorted either by hand or by mechanical devices usually on the basis of radiation readings for the individual lumps. Merritt (1971) reviewed various mechanical upgrading techniques in some detail.

5.4.2 Roasting or calcination

It is frequently desirable to subject ores to high-temperature calcination prior to leaching. Several functions can be performed by such roasting operations. An oxidizing roast can remove carbonaceous material and put the uranium in soluble form. It can oxidize sulfur compounds to avoid subsequent polythionate and sulfur poisoning of ion-exchange resins. It removes other reductants, which might consume oxidant during the leaching step. Reducing roasts can convert uranium to the reduced state and prevent dissolution of uranium during by-product recovery.

Roasting also improves the characteristics of many ores. Many of them contain clays (particularly of the montmorillonite class), which cause thixotropic slurries and create problems in leaching, settling, and filtering. Dehydration of these clays alters their physical properties and decreases these problems.

Roasting with sodium chloride is commonly used with vanadium-containing ores to convert the vanadium to a soluble form. Sodium vanadate is formed, which is believed to form soluble uranyl vanadates (Merritt, 1971). Salt roasting has also been used to convert silver to silver chloride for easier separation from soluble components.

5.4.3 Leaching or extraction from ores

The object of this procedure is to extract the uranium present in the ore into solution, usually aqueous, from which the recovery and purification of the uranium from accompanying metals can be carried out. The leaching operation is usually the first of the chemical manipulations to which the ore is subjected, and all present chemical processing methods for any type of ore involve digestion of the ore with either acid or alkaline reagents. The acid reagent may be generated *in situ* by bacterial or high-pressure oxidation of sulfur, sulfides and Fe(II) in the ore to sulfuric acid and ferric [Fe(III)] species. The choice of a reagent for a particular case will be determined primarily by the chemical nature of the uranium compounds present in the ore and the gangue materials that accompany them.

The extraction of uranium from the majority of the ores is generally more complete by acid leaching than with alternative leaching procedures and is therefore used in most mills. While other acids can be used, sulfuric acid is employed because of its lower price, except when hydrochloric acid is available as a by-product of salt roasting. As a general principle only uranium (VI) minerals are readily dissolved in sulfuric acid. For uranium minerals, such as uraninite, pitchblende, and others, containing uranium in lower oxidation states, oxidizing conditions must be provided to ensure complete extraction. Oxidizing conditions are provided by agents such as manganese dioxide, chlorate ion, ferric ion, chlorine, or molecular oxygen. Manganese dioxide and chlorate ion are most commonly used and iron must be present in solution as a catalyst in order for either of them to be effective.

Manganese dioxide to the extent of perhaps 5 kg per ton (but typically about one-half of this in U.S. practice) or up to 1.5 kg $NaClO_3$ per ton of ore are usually adequate for all but the very refractory ores. Free ferric-ion concentrations larger than 0.5 g L^{-1} generally give adequate dissolution rates. Sufficient iron is normally provided by the ores themselves and by the ore-grinding process. Typical dissolution reactions are

$$UO_2 + 2Fe^{3+} \rightarrow UO_2^{2+} + 2Fe^{2+}$$

$$2Fe^{2+} + MnO_2 + 4H^+ \rightarrow 2Fe^{3+} + Mn^{2+} + 2H_2O$$

$$6Fe^{2+} + ClO_3^- + 6H^+ \rightarrow 6Fe^{3+} + Cl^- + 3H_2O$$

To avoid excessive consumption of oxidant this is in general not added to the acidified ore until the reaction with free iron and sulfides is practically complete. Manganese can be recovered at later stages as manganese(II) hydroxide followed by ignition in air at 300°C to the dioxide. When only a small fraction of the uranium is in reduced form, agitation with air is often sufficient to maintain oxidation by ferric ion. Various other oxidants are effective, including chlorine, permanganate, bromine, etc., but cost or difficulty of handling (corrosiveness, etc.), have relegated their use to very special situations. Proper addition of oxidizing agent can be controlled by an empiric potentiometric measurement of the redox potential. If the potential between a platinum and a calomel electrode inserted into the digesting ore mixture is adequately controlled, the iron will be present principally as Fe^{3+} and suitable oxidizing conditions will have been imposed (Woody and George, 1955).

The most common form in which acid leaching is applied is in the form of aqueous leaching with agitation. The sulfuric acid concentration is adjusted so that it close to pH 1.5 at the end of the leaching period; the period of extraction is generally 4–48 h, in U.S. practice typically 4–24 h. Elevated temperatures and higher acid concentrations increase the rate of extraction but are often uneconomic and result in higher reagent consumption, increased corrosion, and increased dissolution of non-uranium minerals. Counter-current leaching in several stages is sometimes used but is less common than single stage processes. Recycle circuits have also been devised to use the acid leachant more efficiently. A less common procedure is acid pugging, in which a small amount of dry, ground ore is mixed with a more concentrated acid to form a plastic mass, which is allowed to cure and then leached with water. Percolation leaching, in which solution percolates slowly through an ore bed, is well-suited to ores in which the uranium minerals occur as coatings on sand grains, particularly when the ore is of low grade. A variation of percolation leaching that has important application to low-grade ores is heap leaching, in which 5–10 m deep piles of ore of about 100 m length are leached by slow percolation of an acid solution that is collected in the pile drainage. *In situ* leaching is another method that has been applied to certain ore bodies with low permeability of the rock underlying the deposit and adequate porosity of the ore body itself. In this procedure, wells are drilled into the ore body and leachant is pumped into some of these while the enriched solutions are pumped from other wells.

Two acid leaching methods require no reagent addition in some ores containing sulfides or sulfur. These methods are pressure leaching, in which air is the oxidant at elevated temperatures ($\sim$150°C) and pressures, and bacterial leaching, where air is also the oxidant but at temperatures near ambient. In both cases uranium dissolution is brought about by the oxidation of iron and sulfur compounds to Fe^{3+} and sulfuric acid. Typical reactions in pressure leaching are

$$\begin{aligned}&4FeS_2 + 15O_2 + 2H_2O \rightarrow 2Fe_2(SO_4)_3 + 2H_2SO_4\\&UO_2 + Fe_2(SO_4)_3 \rightarrow UO_2SO_4 + 2FeSO_4\\&4FeSO_4 + 2H_2SO_4 + O_2 \rightarrow 2Fe_2(SO_4)_3 + 2H_2O\end{aligned}$$

Similar overall reactions occur in bacterial leaching through the action of bacteria, such as *Thiobacillus ferrooxidans* and others, on ferrous ion, sulfur, and sulfides. Although there are several reported advantages of high-pressure leaching, such as improved extraction and shorter extraction times, particularly with refractory ores, there is also larger corrosion and higher maintenance costs and the method has received little actual use. Bacterial leaching appears to be particularly attractive as a low-cost recovery method for very low-grade ores when used with heap or *in situ* leaching.

While acid leaching is excellent for many ores, and is essential for primary refractory ores such as euxenite, davidite, and brannerite, it is subject to certain limitations. Most uranium minerals are soluble in dilute sulfuric acid with an oxidant present, but many ores contain other minerals such as calcite, dolomite, and magnesite, which consume sufficient amounts of acid to make acid leaching uneconomic. In such cases, carbonate solutions are used to extract uranium.

Carbonate leaching is usually carried out with sodium carbonate. The utility of carbonate solutions arises from the high stability of the uranyl(VI) tricarbonate ion, $UO_2(CO_3)_3^{4-}$, in aqueous solution at low hydroxide-ion concentration. Uranium(VI) is thus soluble in carbonate solution, unlike the vast majority of other metal ions, which form insoluble carbonates or hydroxides in these solutions. The sodium carbonate leaching is thus inherently more selective than the sulfuric acid procedure. In general, compounds of uranium(VI) are readily soluble in carbonate leach solutions although silicates dissolve, albeit with some difficulty. Minerals containing uranium in its lower oxidation states are insoluble in carbonate solutions, and oxidants are required. Under oxidizing conditions, simple uranium oxides and some other uranium(IV) minerals such as coffinite can be leached, particularly at elevated temperature.

In addition to the advantage of low reagent consumption in carbonate-containing ores, carbonate leaching is relatively (but not completely) specific for uranium and carbonate solutions, which are moderately non-corrosive. Disadvantages include lower uranium extraction than by acid leaching and that the method is not suitable for ores having high gypsum or sulfide content. Important refractory minerals such as euxenite, brannerite, and davidite are not attacked significantly without a prior fusion step. Since few ore components other than uranium minerals are attacked to any appreciable extent by carbonate solutions, any uranium imbedded in gangue will escape leaching. A carbonate leach thus requires sufficiently fine grinding to liberate the uranium. Economics dictate that the reagents must be recovered and recycled in the carbonate leach process.

Oxygen (often under pressure) is the commonly used oxidant in carbonate leaching and the dissolution of simple uranium oxide follows the reactions (Merritt, 1971).

$$2UO_2 + O_2 \rightarrow 2UO_3$$

$$UO_3 + H_2O + 3CO_3^{2-} \rightarrow UO_2(CO_3)_3^{4-} + 2OH^-$$

$$OH^- + HCO_3^- \rightarrow CO_3^{2-} + H_2O$$

As shown in the equations above, bicarbonate is used to prevent increase in the hydroxide concentration, which would result in precipitation of uranates or polyuranates by the reaction

$$2UO_2(CO_3)_3^{4-} + 6OH^- + 2Na^+ \rightarrow Na_2U_2O_7 + 6CO_3^{2-} + 3H_2O$$

The detailed dissolution mechanisms are more complex than represented here and several possible alternatives have been proposed (Clegg and Foley, 1958; Wilkinson, 1962; Merritt, 1971). Although air is the most commonly used oxidant in carbonate leaching, other oxidants have been used. Potassium permanganate was commonly used in the past but was expensive and replaced by pressurized leaching at 95–120°C in air. This was followed by the use of cupric–ammonia complexes, a catalyst for air oxidation, but current practice is toward simply using air at atmospheric pressure and longer dissolution times at about 75–80°C in Pachuca-type (air-agitated) tanks (Merritt, 1971). Pure oxygen has been used (Woody and George, 1955) in place of air with some advantages. Other oxidants that have been considered are NaOCl, H_2O_2, and $K_2S_2O_8$. Various catalysts such as $MgCl_2$, Ag_2SO_4, $K_3Fe(CN)_6$, copper–cyanide complexes, and copper–, nickel–, and cobalt–ammonia complexes have also been studied.

Although sodium carbonate is the only reagent used commercially in alkaline leaching, ammonium carbonate has been extensively tested in the laboratory and pilot plant (Merritt, 1971). Since the concentrations of sodium carbonate and bicarbonate used are typically 0.5–1.0 M, the recovery of reagents is necessary. The specificity of carbonate leaching for uranium is such that the uranium can usually be recovered from the leach solution by precipitation as sodium polyuranates ('diuranate') with sodium hydroxide. The filtrate is then treated with carbon dioxide to regenerate the desired carbonate/bicarbonate ratio.

While the amounts of carbonate, bicarbonate, and oxygen consumed during leaching are usually very small, side reactions may occur with other constituents of the ores, which consume substantial amounts of carbonate. Particularly important parasitic reactions are due to sulfide minerals and gypsum and, at higher temperatures and pressures, silica and alumina:

$$2FeS_2 + 15/2O_2 + 8CO_3^{2-} + 7H_2O \rightarrow 2Fe(OH)_3 + 4SO_4^{2-} + 8HCO_3^-$$

$$CaSO_4 + CO_3^{2-} \rightarrow CaCO_3 + SO_4^{2-}$$

$$SiO_2 + H_2O + 2CO_3^{2-} \rightarrow SiO_3^{2-} + 2HCO_3^-$$

$$Al_2O_3 \cdot 3H_2O + 2CO_3^{2-} \rightarrow 2AlO_2^- + 2HCO_3^- + 2H_2O$$

Flotation may be used to reduce the initial sulfide content to tolerable limits.

Organic materials in some ores cause difficulties in the carbonate leach process and various schemes for handling this problem are reviewed by Merritt (1971). A simplified flow sheet for carbonate leaching is shown in Fig. 5.5.

Clarification is the separation of ore slimes from the aqueous uranium extract and constitutes the final step in ore extraction of uranium. It is a necessary step except when the resin-in-pulp ion-exchange process is used, in which case only partial clarification is necessary, and when *in situ*, heap, or percolation leaching has been used, since the ore itself acts as an effective filter medium in these leaching techniques and clear solutions are obtained. Solution clarification has in the past been one of the most difficult problems in uranium recovery, but flocculants have been developed (Clegg and Foley, 1958) to improve settling of clays and other slimy ore constituents. These have greatly improved liquid–solid separation technology and most ores can now be handled satisfactorily in liquid–solid separation equipment with the proper choice and use of flocculants.

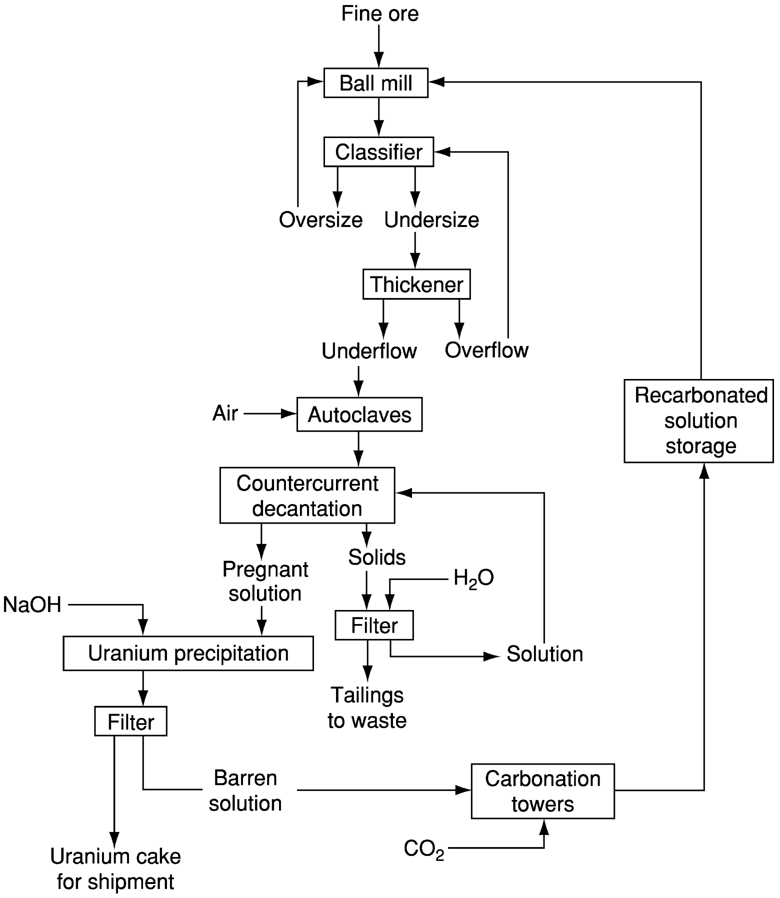

Fig. 5.5 *Flow sheet of raw ore leach for unoxidized or primary uranium of Eldorado Mining and Refining Ltd, Beaverlodge, Saskatchewan* (*Stephens and McDonald*, 1956).

Flocculants used include polyacrylamides, guar gums, and animal glues. For the resin-in-pulp process, only the coarser ore particles (325 mesh) are removed and slime contents of 5% to as high as 20% solids can be handled depending on exact process design. Clegg and Foley (1958) and Merritt (1971) review clarification in detail.

5.4.4 Recovery of uranium from leach solutions

The recovery of uranium from leach solutions can be achieved by a variety of methods including ion exchange, solvent extraction, and chemical precipitation. Each of the various procedures listed above can be applied to acid or alkaline leach liquors, although in general they will not be equally applicable. Although various precipitation methods were extensively used in the past, they were generally cumbersome and complex if significant uranium purification was to be achieved. Currently operating uranium mills, with the exception of some that employ carbonate leaching, all use ion exchange or solvent extraction, or both, to purify and concentrate the uranium before a final product precipitation. Because of the selectivity of carbonate leaching, precipitation from carbonate leach solutions produces a fairly pure uranium concentrate, but for acid leach solutions, ion exchange or solvent extraction is always employed.

(a) Ion exchange

The recovery of uranium by ion exchange is of great importance. Uranium(VI) is selectively absorbed from both sulfate and carbonate leach solutions as anionic complexes using anion-exchange resins. The loaded resin is rinsed, and the uranium eluted with a sodium chloride or an acid solution. The uranium is then precipitated from the eluate and recovered as a very pure uranium concentrate. This process can be carried out with either stationary columns of ion-exchange resin through which clarified leach liquors are passed; alternatively the resin may be moved through the leach liquor in agitated baskets. This resin-in-pulp process does not require complete clarification of the leach liquor.

The degree of purification of the uranium by these ion-exchange processes is related to the selectivity of the anion-exchange resins for the anionic uranyl sulfate or carbonate complexes relative to that of impurity species. Cationic impurities are not absorbed and many anionic species are absorbed less strongly than are the uranyl complexes and are displaced by them. The impurities can be left in the ion exchangers during uranium elution, but often they are so strongly absorbed as to act as exchanger poisons that require elaborate removal steps.

The uranyl species absorbed by the exchangers from carbonate solution appears to be exclusively the $UO_2(CO_3)_3^{4-}$ complex, but from sulfate solutions more than one species is absorbed (Ryan, 1962). Although it has been reported (OECD-NEA, 1982) that below pH 2 the only uranyl sulfate complex in the resin is $UO_2(SO_4)_3^{4-}$, spectral studies of the resin phase (Ryan, 1962) indicate that, although $UO_2(SO_4)_3^{4-}$ is present over at least the pH range 0.5–4.5, it is not the only uranyl species. The ratio of uranyl species in the resin phase changes with pH but is almost unaffected by change in total aqueous phase sulfate concentration at any given pH. Even if the affinity of anion-exchange resins for complex anions may be very high, high distribution coefficients do not necessarily mean that an appreciable fraction of the uranium is present as anionic species in the aqueous phase. Both weak-base or strong-base resins can be used with the sulfate system, but only the strong-base resins in the basic carbonate solutions. In practice, the resin choice is governed by several factors, including absorption and elution kinetics, resin particle size, the physical and chemical stability of the resin, the selectivity and ease of removal of resin poisons, hydraulic characteristics, and exchange capacity. Typically, resins of moderately low cross-linking and moderately large particle size are used and several resins have been marketed specifically for uranium processing.

Elution of the uranium from anion-exchange resins in either the sulfate or the carbonate processes is normally made with approximately 1 M sodium or ammonium chloride or nitrate solutions. In the sulfate process the eluent is acidified, and in the carbonate process some carbonate or bicarbonate is added to prevent hydrolysis. Special elution techniques are used for vanadium recovery when it is co-absorbed in the carbonate process (Merritt, 1971).

Although uranyl sulfate and carbonate complexes have a higher affinity for the resin than most impurity ions, they are not extremely strongly sorbed and some impurity ions are more strongly absorbed. In the acid system such ions include pentavalent vanadates, molybdenum sulfate complexes, polythionates, and in South African ores treated for gold recovery, cobalt cyanide complexes and thiocyanate. Vanadates are more strongly absorbed than uranium in the carbonate process except at high pH values. In addition, some other weakly sorbed ions may be present in sufficiently high concentration to compete for resin sites, resulting in decreased uranium loading; some of these may also alter absorption kinetics. Some of the strongly held ions and others such as silicate, titanium, thorium, hafnium, niobium, antimony, and arsenate and phosphate complexes, which polymerize or hydrolyze in the resin phase, are not readily removed during the normal elution process. They gradually build up in the resins where they act as poisons and require special removal procedures (Merritt, 1971).

Merritt (1971) and Clegg and Foley (1958) have reviewed the uranium ion-exchange processes in detail along with the various specialized problems encountered and their treatment. They have discussed specific flow sheets, processing rates, back-cycle methods for reagent conservation, and processing equipment for fixed-bed, moving-bed, basket resin-in-pulp, and continuous resin-in-pulp ion-exchange processes.

(b) Solvent extraction

Solvent extraction has a distinct advantage over ion exchange for uranium purification from leach liquors because of the ease with which it can be operated in a continuous counter-current flow process. It has a disadvantage, however, in the incomplete phase separation, due to emulsion formation, third-phase formation, etc. In addition solvent losses constitute both a monetary loss and a potential pollution problem in the disposal of spent leach liquor. Because solvent losses are related to overall solution volume, solvent extraction usually has an advantage for leach solutions with concentrations above about 1 g U per liter, and ion exchange has an advantage for low-grade solutions with concentrations appreciably less than 1 g U per liter (Merritt, 1971). Solvent extraction processes are not economically advantageous for carbonate leach solutions. Two types of alkyl phosphoric acids and secondary and tertiary alkylamines, have been used industrially for uranium extraction from sulfate leach liquors. These extraction reagents are normally used as relatively dilute solutions in an inert diluent such as kerosene. Modifiers such as long-chain alcohols and neutral phosphate esters are typically added to prevent third-phase formation to increase amine salt solubility in the diluent, and to improve phase separation.

Amine extraction from sulfate leaching is analogous to anion exchange in that anionic uranyl sulfate complexes are extracted by the alkylammonium cations. The species extracted, at least by tertiary amines, is predominantly the $UO_2(SO_4)_3^{4-}$ complex in the pH range ($1 < pH < 2$) normally used in commercial processing. The concentration of other uranyl species increases with decreasing pH (Ryan, 1962). There is considerable variation in affinity and selectivity for uranium with the structure of the amine. Typical commercially used tertiary amines give extraction coefficients of 100–140, whereas *N*-benzylheptadecylamine gives extraction coefficients as high as 8000 (Merritt, 1971). Such specialized amines, if made available at a reasonable cost, will be capable of recovering uranium from very dilute leach solutions but might require more complex stripping procedures. Amines extract other anions to varying degree and thereby decrease uranium extraction efficiency. Nitrate interference is severe and chloride interference is more severe for secondary than for tertiary amines. These factors are important for the choice of stripping agent and the recycling of solutions. Molybdenum is extracted more strongly than uranium. It builds up as a poison in the amine, finally causing serious problems by precipitating at the organic–aqueous interface, and special molybdenum stripping procedures are used to counteract this problem (Merritt, 1971). Vanadium is also extracted to some extent. Various ions are effective in stripping uranium from the solvent. Nitrate has such high affinity for the amine that it must be removed in the carbonate or hydroxide regeneration step before the next extraction cycle; however this is not necessary in solutions containing chloride, except with secondary amines having high chloride affinity. Another procedure uses ammonium sulfate with pH carefully controlled in the range 4.0–4.3, since poor stripping or poor phase separation occurs outside this range. Direct precipitation of uranium from the organic phase has been proposed (Brown *et al.*, 1958).

The alkylphosphoric acid extractants have the advantage over amines of fewer phase separation problems due to suspended solids and of having good extraction efficiency in the presence of dilute nitrate, chloride, and sulfate. On the other hand, they suffer from lower selectivity for uranium since the alkyl phosphates extract cations and many of the impurities including iron in the leach solutions. Special methods for removing or rendering these impurities non-extractable have been devised. Alkylphosphoric acid extraction has been referred to as 'liquid cation exchange'. The dialkyl phosphates appear to be dimers and four dialkyl phosphates are required to extract one uranyl ion (Baes *et al.*, 1958; Blake *et al.*, 1958). Addition of neutral phosphate esters increases the uranium extraction coefficient of alkylphosphoric acids (synergistic effect). Stripping of bis(2-ethylhexyl)phosphoric acid is normally carried out with carbonate solution, but monodecylphosphoric acid requires 10 M HCl for stripping.

In addition to the solvent extraction procedures discussed above, mixed amine–alkylphosphoric acids have also been used. Other processes include both ion-exchange and solvent-extraction steps as well as special methods for removing and in some cases recovering interfering ions such as molybdenum. Solvent extraction methods have also been studied in cases where the leach solution is not clarified, solvent-in-pulp, but solvent losses are then very high. Merritt (1971) has reviewed the commercial practice in detail and gives many further references.

(c) Chemical precipitation

Before the use of ion-exchange and solvent extraction methods for the removal and purification of uranium from leach liquors, precipitation techniques were used on clarified leach liquors. Much effort was spent during the late 1940s to develop selective precipitation processes; most of these techniques are obsolete and will not be discussed here but they are reviewed by Wilkinson (1962) and by Merritt (1971).

The product from typical acid process anion-exchange or solvent extraction processes is an acid solution of mixed nitrate or chloride and sulfate. The two principal methods of precipitation of uranium from these are neutralization with sodium hydroxide, magnesia, or ammonia, or the precipitation of the peroxide $UO_4 \cdot xH_2O$ in the pH range 2.5–4.0 with hydrogen peroxide. In the neutralization procedure a preliminary pH adjustment to 3.5–4.2 is made to precipitate and remove iron if it exceeds specifications. Phosphate, if present, is also removed in this step as iron phosphate. Uranium precipitation is then accomplished at a pH of 6.5–8.0. Since the cations used (Na^+, M^{2+}, or $NH_4{}^+$) contaminate the product by formation of insoluble polyuranates, the choice of precipitant will depend on cost, physical nature of the precipitate formed, product specifications, etc. Most U.S. plants now use ammonia, which can be removed by heating of the product, but there is also some use of magnesia. The peroxide precipitation process is more specific although the cost is somewhat higher, a higher-purity product is obtained. Ferric ions must be removed to a concentration less than 0.5 g L^{-1} in order to prevent catalytic decomposition of hydrogen peroxide in a preliminary precipitation step; alternatively the decomposition is prevented by precipitation from very cold solutions or by complexing the iron. The precipitates (‘yellow cake’) are dried, and in the case of the ammonia, precipitated material of composition approximately $(NH_4)_2U_2O_7$ (ammonium diuranate) may be heated to form U_3O_8 or UO_3, depending on temperature. The magnesium and sodium polyuranates are stable to low-temperature calcination.

Precipitation from alkaline solution is carried out with either clarified carbonate leach solution or with alkaline eluting or stripping solutions from ion exchange or solvent extraction. The three methods include addition of strong base, acidification followed by CO_2 removal and neutralization, and reduction to U(IV). The latter method is the only one capable of direct recovery of any vanadium present; the other ones do not result in complete recovery or complete separation. Sodium hydroxide does not completely precipitate uranium from carbonate solution; despite this, the filtrate is recarbonated and recycled. The product consists of sodium polyuranates. Acidification, carbon dioxide removal by boiling, and neutralization (usually with ammonia or magnesia) is preferred for the high-uranium-concentration carbonate strip solutions from solvent extraction since the volume is low and recycling of reagents is not so important. Reduction of uranyl(VI) carbonate solutions results in precipitation of hydrated U(IV) oxide. Reduction methods include hydrogen reduction under pressure in the range 100–200°C with appropriate catalyst, electrolytic reduction, and sodium amalgam reduction. Vanadium is reduced and co-precipitated with uranium. Merritt (1971) has reviewed precipitation conditions, flow sheets, and plant practice in detail.

(d) By-product uranium

In South Africa, uranium is recovered as a by-product of gold recovery by conventional methods after the recovery of gold by cyanide leaching. Uranium has also been recovered as a by-product from crude phosphoric acid by both ion exchange and solvent extraction methods. In anion exchange, U(VI) is absorbed and concentrated by absorption of uranyl phosphate complexes, but resin capacities are uneconomically low. Solvent extraction has normally involved use of alkyl pyrophosphate extraction of U(IV) (Greek *et al.*, 1957), but other schemes utilize extraction of U(VI) and synergistic combinations of phosphates. References to previous work in this field are given in a paper on this subject (Deleon and Lazarević, 1971).

(e) Refining to a high-purity product

The normal product of uranium milling operations, ‘yellow cake’ or calcined ‘yellow cake’, is not sufficiently pure to be of nuclear grade and is normally further refined to produce nuclear-grade material (IAEA, 1980). There has been some emphasis on further upgrading in the mill to produce a high-grade product by using multiple stages of solvent extraction and/or ion exchange, special stripping methods, more selective precipitation methods, or combinations of these (see Merritt, 1971 for further detail). The usual refining operation has normally been carried out either by tri(*n*-butyl)phosphate (TBP) extraction from nitric acid solutions or by distillation of uranium hexafluoride, since this is the feed for isotope enrichment plants.

Solvent extraction and fluoride volatility processes are currently used for uranium refining. A schematic flow diagram of a typical TBP/kerosene extraction process is shown in Fig. 5.6; a fluoride volatility process flow sheet is shown in Fig. 5.7. The TBP extraction from nitric acid solution makes use of the very selective tendency of actinides to form nitrate- or mixed nitrate–solvent complexes, as discussed further in Chapters 23 and 24. This process replaces the earlier and more hazardous diethyl ether extraction from nitrate solution. The extraction reaction is

$$\mathrm{UO_2(NO_3)_x^{2-x} + (2-\mathit{x})NO_3^- + 2TBP \rightarrow UO_2(NO_3)_2(TBP)_2}$$

where $x = 0\text{–}2$. Thorium is the only normally encountered impurity element having an appreciable distribution coefficient into a kerosene-TBP phase from nitric acid solution, but its distribution is sufficiently low that it can be transferred to the aqueous phase by high uranium loading of the organic phase.

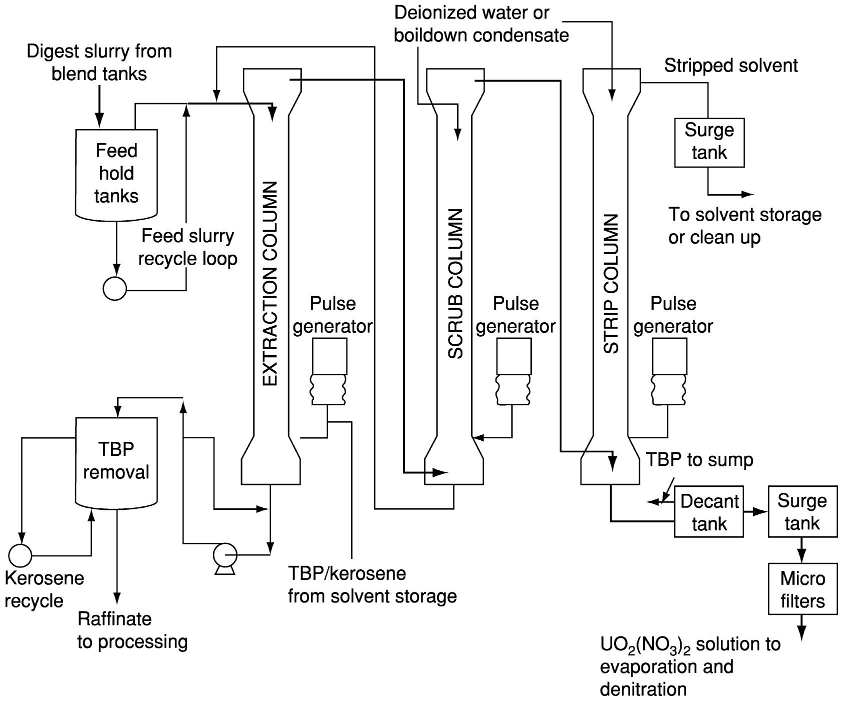

Fig. 5.6 *Schematic flow diagram: TBP/kerosene extraction system at the Fernald refinery* (*Harrington and Ruehle*, 1959).

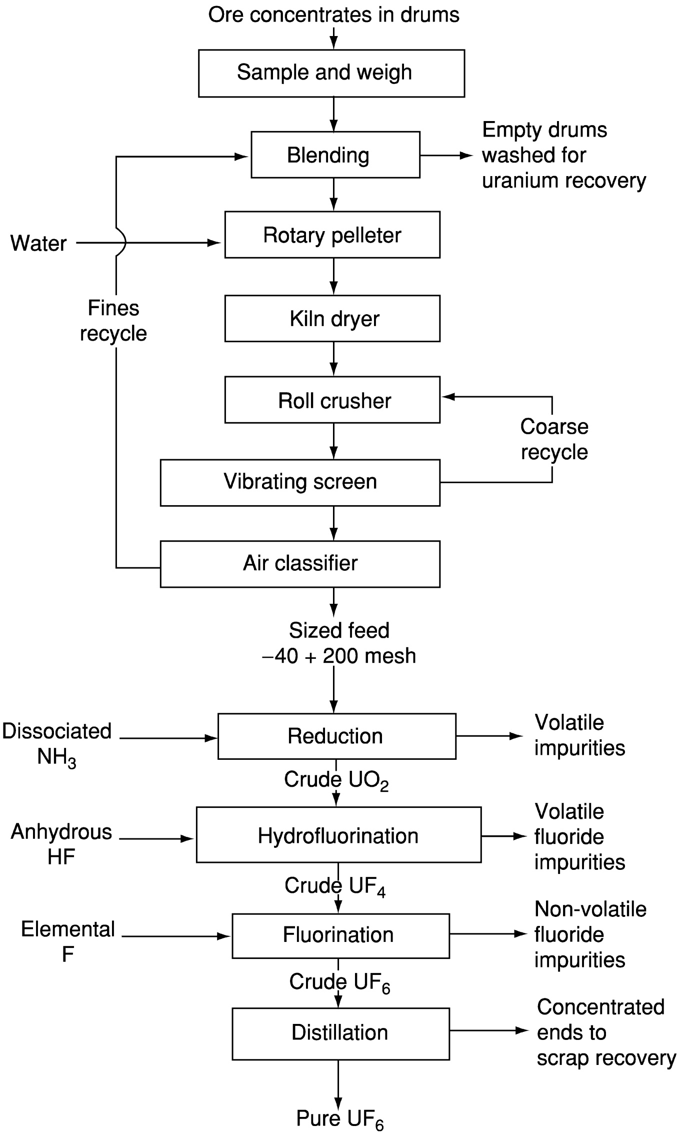

Fig. 5.7 *Overall process flow diagram for fluoride volatility process for the refining of ore concentrates* (*Ruch* et al., 1959).

The purified uranium is stripped from the organic phase with water, converted to UO_3, reduced with hydrogen to UO_2, and converted to UF_4 with hydrogen fluoride at elevated temperatures. The UF_4 can either be reduced to uranium metal for natural uranium reactors or be fluorinated to UF_6 for isotopic enrichment for production of other types of reactor fuel. The fluoride volatility process makes use of reduction to UO_2 followed by direct fluorination, using the cheaper hydrogen fluoride to make UF_4 followed by F_2 to prepare UF_6. The UF_6 is fractionally distilled to produce a high-purity UF_6 for isotopic enrichment. The chemistry and operating conditions of the TBP refining process, the conversion to UO_3, UO_2, and finally to UF_4 are reviewed in detail in the book edited by Harrington and Ruehle (1959). Ruch *et al.* (1959) have described the refining of ore concentrates by uranium hexafluoride distillation.

Hyman *et al.* (1955) have converted uranium ore concentrates to UF_6 by means of liquid-phase fluorination using bromine trifluoride, BrF_3 (b.p. 126°C). While not applicable to raw ore, the procedure may be readily applied to concentrates. Results of experiments along these lines are summarized in Table 5.4. Since fluorine in the form of BrF_3 is rather expensive, it is worthwhile to introduce as much fluorine as possible via the inexpensive reagent hydrogen fluoride (which cannot, of course, be used to convert lower uranium fluorides to uranium hexafluoride), and then to complete the fluorination process with bromine trifluoride. This reduction of fluorine consumption may be readily accomplished by a preliminary hydrofluorination at 600°C. This treatment fluorinates silica and other gangue materials present in the ore concentrate and converts uranium(IV) to UF_4. Thus, two-thirds of the fluorine in the final UF_6 product is introduced by the relatively inexpensive hydrogen fluoride rather than by bromine trifluoride. Since uranium hexafluoride is used for the isotope separation of uranium, chlorination procedures have not received nearly as extensive investigation, because of the serious corrosion problems created by the use of chlorine at elevated temperatures.

Table 5.4 *Fluorination of various ore concentrates with BrF_3 (Hyman* et al., 1955).

Ore concentrate			
Source	*U content* (%)	*Uranium retained by residue*[a,b] (%)	*F_2 consumption*[a,c] (cm^3 *F_2(STP) per* g U)
rand concentrate	68.1	0.16, 0.07	383, 419
rand concentrate	68.1	0.73, 0.10[d]	133, 138[d]
intermediate plant concentrate	23.3	1.45, 0.81	805, 767
intermediate plant concentrate	32.6	0.55, 1.00	552, 735

[a] Duplicate runs are given for each sample and treatment.

[b] (Grams U in residue/grams U in initial concentrate) × 100.

[c] To form UF_6 from 1 g U as metal requires 282.5 cm^3 F_2; to form UF_6 from 1 g U as UF_4 requires 94.2 cm^3 F_2.

[d] After hydrofluorination.

5.5 PROPERTIES OF FREE ATOMS AND IONS

Uranium, being one of the elements with the largest atomic number, has a very complex electronic structure. This is manifested in its spectral properties as they appear in the X-ray, UV/visible and fluorescence spectra. Details of the electronic energy levels deduced experimentally and from quantum chemical calculations are discussed in detail in Chapter 16 and in the following sections where the properties of compounds and complexes are described. The focus in Section 5.9 is on the interpretation of solid state spectra using the crystal field model and in Section 5.10 on solution spectra, including fluorescence spectroscopy of uranyl(VI) species.

5.6 URANIUM METAL

Uranium metal was used in earlier reactor systems but is now largely replaced in commercial reactors by ceramic uranium dioxide. Large-scale production of uranium metal requires elevated temperature where the high reactivity of uranium with most common refractory materials and metals makes the selection of reaction vessels a difficult problem. Finely divided uranium reacts even at room temperature with all the components of the atmosphere except the noble gases. However, contrary to the situation with titanium and zirconium, the introduction of small amounts of oxygen or nitrogen does not have an adverse effect on the mechanical properties of the metal. There are three different phases of metallic uranium below the melting point, α-, β-, and γ-uranium, each with its specific structure and physical properties. A detailed discussion of the physical properties is given in Chapter 21 on actinide metals and a short description on uranium metal and alloys in the following section.

5.6.1 Preparation of uranium metal

The element uranium is strongly electropositive, resembling aluminum and magnesium in this respect; consequently uranium metal cannot be prepared by reduction with hydrogen. Uranium metal has been prepared in a number of ways: reduction of uranium oxide with strongly electropositive elements, such as calcium, electro-deposition from molten-salt baths, thermal decomposition, decomposition of uranium halides (van Arkel de Boer ‘hot wire’ method), and reduction of uranium halides (UCl_3, UCl_4, UF_4) with electropositive metals (Li, Na, Mg, Ca, Ba). Only the last method is of current importance. For details, the reader is referred to two comprehensive surveys (Katz and Rabinowitch, 1951; Warner, 1953) and of older work to a review by Wilkinson (1962) and to the *Gmelin Handbook of Inorganic Chemistry* (1981a).

Both uranium tetrafluoride and tetrachloride are reducible with calcium and magnesium, while uranium dioxide can be reduced with calcium and probably magnesium. Finely divided uranium is pyrophoric and a massive metal product is therefore desired; this can be achieved by ensuring that the entire reaction mixture is fluid for a sufficiently long time for uranium metal to collect; this requires a slag with a moderately low melting point. Calcium oxide and magnesium oxide slags have melting points well above 2500°C, and are therefore less useful than calcium fluoride and magnesium fluoride, with melting points 1423°C and 1261°C, respectively. Uranium tetrachloride is very hygroscopic, and subject to oxidation in air and therefore the much more stable uranium tetrafluoride is preferred. Magnesium is the reagent of choice for reduction, since it is available in large quantities with a high degree of purity and can also be handled in air without special precautions. Details of a process based on these considerations are described by Wilhelm (1956) and in the books by Warner (1953) and by Harrington and Ruehle (1959).

For small-scale production of ^{233}U or ^{235}U in metallic state the batch size is limited by their critical mass of these isotopes and calcium is the preferred reductant. Bertino and Kirchner (1945), have described the special procedures for ^{233}U, and Patton *et al.* (1963) and Baker *et al.* (1946) those for ^{235}U.

Uranium ore concentrates are first purified by solvent extraction with TBP in kerosene as the immiscible solvent in the manner described in Section 5.4.4e. The purified uranyl nitrate is then decomposed thermally to UO_3. The trioxide is reduced with hydrogen to the dioxide, which in turn is converted to uranium tetrafluoride, 'green salt', by high-temperature hydrofluorination. The tetrafluoride is then reduced to metallic uranium with magnesium. A flow sheet of the production of uranium from ore concentrates is given in Fig. 5.8.

The temperature reached during the reduction reaction exceeds 1300°C where magnesium metal has a very high vapor pressure; hence, the reaction must be carried out in a sealed container (bomb). Such bombs are made in various sizes from standard seamless pipes. Their lengths range from 91.4 to 114.3 cm (36 to 45 in.), their diameters up to 33 cm (13 in.).

Uranium prepared by the metallothermic processes described above is of sufficient purity for most purposes. However, it may be further purified by molten-salt electrolysis (Slain, 1950; Noland and Marzano, 1953; Niedrach and Glamm, 1954; Blumenthal and Noland, 1956) using alkali or alkaline-earth chloride as electrolytes. UF_4, UCl_4, or UCl_3 are dissolved in these electrolytes. The material to be purified is used as the anode, molybdenum, or tantalum as the cathode; a diaphragm, usually of a sintered, porous ceramic material, separates the anode and the cathode.

Other methods that have been employed in uranium purification include zone melting (Whitman *et al.*, 1955; Antill, *et al.*, 1961) and hot-wire deposition (Fine *et al.*, 1945; Prescott *et al.*, 1946). Because of the low melting point of uranium, the latter method is only of limited value.

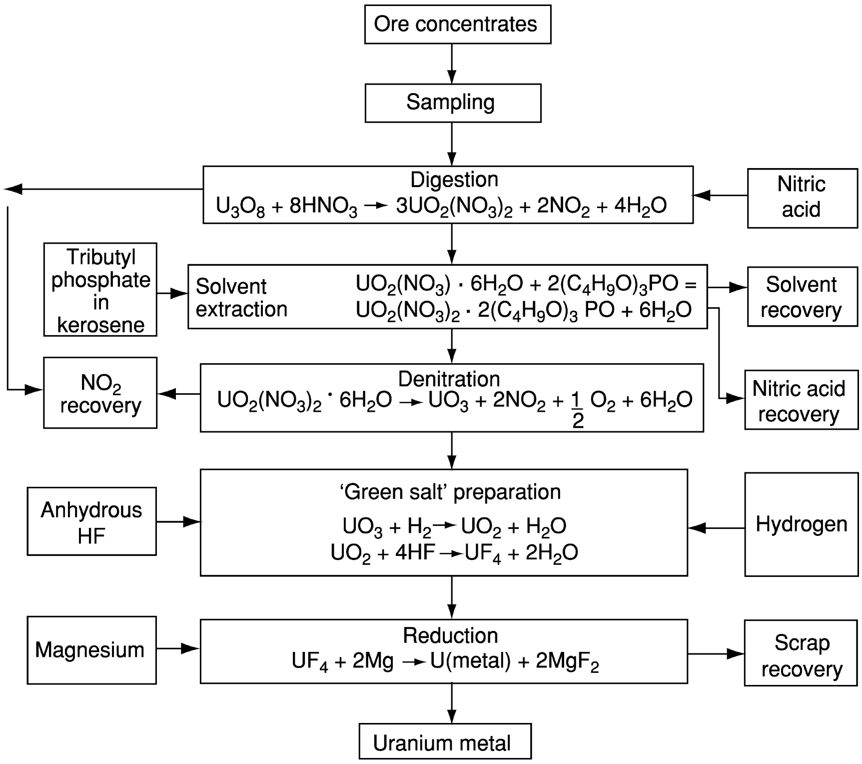

Fig. 5.8 *Flow sheet for the production of uranium metal by reduction of* UF_4 *with magnesium* (*Kelley,* 1955).

(a) Physical properties of uranium metal

(*i*) Crystal structure

Uranium metal has three crystalline phases below the melting point at (1134.8 ± 2.0)°C. The α-phase is the room-temperature modification of uranium; it is orthorhombic with space group No. 63, *Cmcm* and unit cell parameters $a = 2.854$ Å, $b = 5.87$ Å, and $c = 4.955$ Å (Barrett *et al.*, 1963; Lander and Müller, 1970) and one uranium at the site 4c in the space group.

The structure consists of corrugated sheets of atoms, parallel to the *ac*-plane and perpendicular to the *b*-axis. Within the sheets the atoms are tightly bonded, whereas the forces between atoms in adjacent sheets are relatively much weaker (Fig. 5.9). This arrangement is highly anisotropic and resembles the layer structures of arsenic, antimony, and bismuth. In the α-uranium structure, the U–U distances in the layer are (2.80 ± 0.05) Å and between adjacent layers

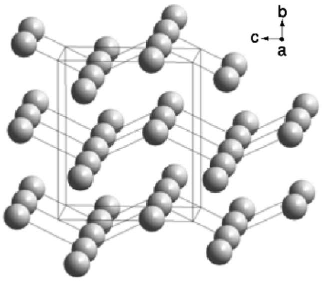

Fig. 5.9 *The structure of α-uranium from Lander and Müller* (1970). *It is a layer structure with puckered ac-layers perpendicular to the b-axis; the uranium–uranium distances in the layer are* (2.80 ± 0.05) Å *and between the layers* 3.26 Å.

3.26 Å. The physical properties of the α-phase are a reflection of its structure, e.g. the strongly anisotropic coefficient of thermal expansion. The average value of the thermal expansion coefficient over the temperature range 25–325°C is 26.5, –2.4, and 23.9 × 10^{-6} °C^{-1}, respectively, along *a*, *b*, and *c*. A chemical consequence of the unique orthorhombic structure of α-uranium is that the formation of solid solutions with metals of the common structure types is severely restricted.

The β-phase of uranium exists between 668 and 775°C; it has a complex structure with six crystallographically independent atoms in the tetragonal unit cell (Donohue and Einspahr, 1971). The space group is $P4_2/mnm$, $P4_2nm$, or $P4n2$, with unit cell parameters $a = 5.656$ Å and $b = c = 10.759$ Å. The lattice parameters were determined in an alloy with 1.4% chromium at 720°C, and in uranium powder in the temperature range where the phase is stable. The tetragonal lattice is a stacked layer structure with layers parallel to the *ab* plane of the unit cell at *c*/4, *c*/2, and 3*c*/4. Additional high-precision measurements are required to solve the structure completely (Donohue and Einspahr, 1971).

The γ-phase of uranium is formed at temperatures above 775°C; it has a body-centered cubic (bcc) structure with the cell parameter $a = 3.524$ Å; the phase stabilized at room temperature by the addition of molybdenum that forms an extensive series of solid solutions with γ-uranium.

(b) General properties

Foote (1956), Holden (1958), and Wilkinson and Murphy (1958) have described the physical metallurgy of uranium and Oetting *et al.* (1976) and Rand and Kubaschewski (1963) the thermodynamic properties of uranium metal.

A number of physical and thermal properties of elemental uranium are collected in Table 5.5. Uranium is not a refractory metal like chromium, molybdenum, or tungsten; it is among the densest of all metals, being exceeded in this respect only by some of the platinum metals and by α-Np and α-Pu.

Table 5.5 *Physical and thermal properties of uranium* (*Oetting* et al., 1976).

melting point	(1408 ± 2) K

The electrical resistivity of uranium is about 16 times higher than that of copper, 1.3 times that of lead and approximates that of hafnium (Gale and Totemeier, 2003).

An important mechanical property (Table 5.6) of uranium is its plastic character, allowing easy extrusion. The mechanical properties are very sensitive

to the pre-history of the sample, and are strongly dependent on crystal orientation, fabrication, and heat treatment. Despite its plastic nature, uranium has a definite yield point with a well-defined, but very low, proportional limit. The ultimate tensile strength of uranium varies between 3.44×10^5 and 13.79×10^5 kPa, depending on the cold working and previous thermal history of the sample. Uranium rapidly loses strength at elevated temperatures, the tensile strength falling from 1.862×10^5 kPa at 150°C to 0.827×10^5 kPa at 600°C.

The Brinell hardness of rolled polycrystalline α-uranium varies between 2350 and 2750 MN m^{-2} at 23°C (Samsonov, 1968). The hardness is strongly affected by impurities. Cold working increases the hardness with up to 50%. Above 200°C, the hardness falls off rapidly. γ-Uranium is so soft as to make fabrication difficult, while the β-phase is harder and considerably more brittle than the α-phase.

(c) Magnetic susceptibility and related properties

The solid-state properties of uranium have been the subject of a relatively recent exhaustive review (Lander *et al.*, 1994). Some pertinent physical properties taken from this review are given here. Although many measurements have been performed on uranium metal, the description and full understanding of its properties is still not complete. Uranium metal is weakly paramagnetic and exhibits almost temperature-independent paramagnetism with a room temperature value of 390×10^{-9} emu mol^{-1}. (Fournier and Troć, 1985). α-Uranium exhibits an anomaly at 43 K apparent in the magnetic susceptibility data and in other measurements. This anomaly and further phase transformations observed at 37 and 23 K have been attributed to charge density waves. α-Uranium exhibits a superconducting transition at low temperatures that can be described by the Bardeen–Cooper–Schreiffer (BCS) theory. The maximal T_c value for

α-uranium is ~2–2.3 K at a pressure of ~1.0–1.1 GPa. The 0.1013 MPa (1 atm) value of T_c is taken as ≤0.1 K.

(d) Electrical and related properties

The temperature dependence of the resistivity of uranium single crystals has been measured by a number of authors and the components of the resistivity tensor are given in Table 5.7. The resistivity–temperature curve for α-uranium along the [010] direction is shown in Fig. 5.10. Many other physical properties of elemental uranium have been determined, such as elastic moduli, heat capacity, de Haas-van Alphen measurements, transport properties and others. The reader is referred to Lander *et al.* (1994) and to Chapter 21 for further discussion.

5.6.3 Uranium intermetallic compounds and alloys

The most noticeable features of the behavior of uranium with other metals are the formation of intermetallic compounds with a wide variety of alloying metals and the extensive ranges of solid solutions in α- and β-uranium. Table 5.8 summarizes the alloying behavior with the metallic elements. Saller and Rough (1955), Pfeil (1956), Rough and Bauer (1958), Hansen and Anderko (1958), Elliott (1965), Shunk (1969), and Wilkinson (1962) have given comprehensive and informative descriptions of the general behavior of the alloying elements, including numerous phase diagrams. The thermodynamics of uranium alloy systems was reviewed by Chiotti *et al.* (1981).

A large number of intermetallic compounds have been characterized by X-ray crystallographic methods and by conventional metallographic techniques. The *Gmelin Handbook of Inorganic Chemistry* gives a comprehensive review of the properties of the uranium alloys with alkali metals, alkaline earths, and elements of main groups III and IV (Gmelin, 1989, vol. B2), with transition metals of groups IB to IVB (Gmelin, 1994, vol. B3), and with transition metals of groups VB to VIIB (Gmelin, 1995a, vol. B4), including the effects of irradiation, which are also discussed in the volume on technology and uses of uranium (Gmelin, 1981a, vol. A3).

Among uranium intermetallic phases of interest may be mentioned the transition-metal compounds U_6Mn, U_6Fe, U_6Co, and U_6Ni, which are distinguished by their hard and brittle nature. Uranium forms intermetallic phases with noble metals and the phase diagrams for U–Ru, U–Rh, U–Pd, U–Os, U–Ir, and U–Pt systems have been assessed by Chiotti *et al.* (1981), a compilation that also provides information on a number other intermetallic phases. The compounds of uranium with the light platinum metals, Ru, Rh, and Pd, are of interest in the pyrometallurgical reprocessing of metallic fuels, because the

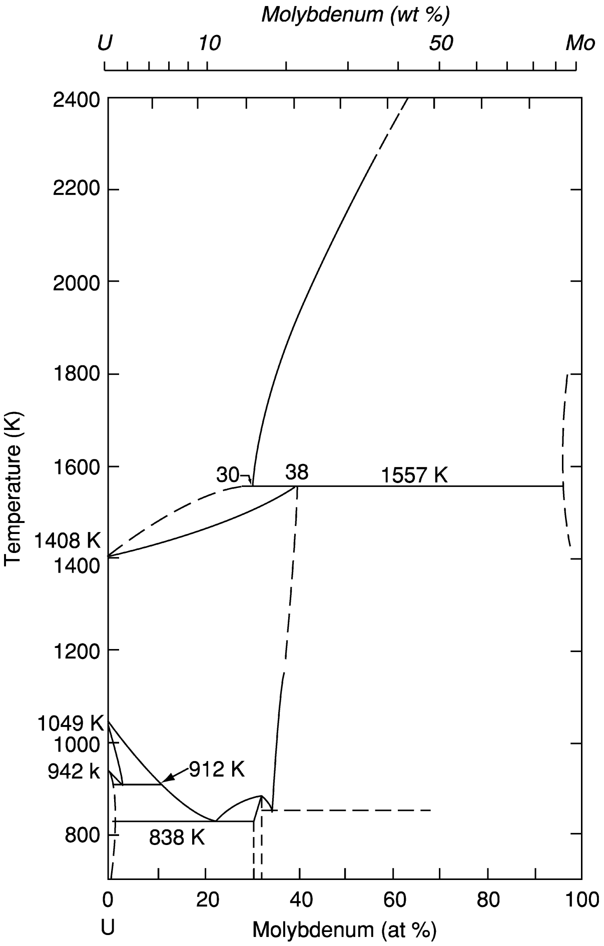

Fig. 5.11 *Phase diagram of the uranium–molybdenum system* (*Chiotti* et al., 1981).

noble metals form alloys that remain with the uranium when the fuel is processed for fission-product removal by oxidative slagging.

Elements of class III in many cases form simple eutectic systems. Molybdenum, titanium, zirconium, niobium, and plutonium form extensive solid solutions with uranium at elevated temperatures. No intermediate phases are detected for the U–Nb system, whereas the U–Mo, U–Pu, U–Ti, and U–Zr systems all show metastable phases. The uranium–molybdenum system is shown in Fig. 5.11 and illustrates the general features of the small but important class of true alloying elements. The uranium alloys have unusual physical properties that are discussed in Chapter 21.

5.6.4 Chemical properties of uranium and its alloys

Uranium metal is a highly reactive substance that can react with practically all of the elements in the periodic table with the exception of the noble gases. Some of the more important chemical reactions of uranium are listed in Table 5.9.

Wilkinson (1962) has discussed in detail the corrosion of massive uranium by various gaseous agents, such as dry oxygen, dry air, water vapor, carbon monoxide, carbon dioxide, and others, as well as the pyrophoricity of this element. Totemeier (1995) has written a more recent review of the corrosion and pyrophoricity behavior of uranium (and plutonium) with oxygen, water vapor, and aqueous solutions in terms of reaction rates, products, and reaction mechanisms.

From a practical point of view, the reactions of uranium with oxygen, nitrogen, and water are probably the most significant. Uranium metal exposed to oxygen, water, or air undergoes reaction even at room temperature. The kinetics of corrosion of uranium by various reagents such as dry and moist oxygen, dry and moist air, water vapor and hydrogen, and the pyrophoricity of uranium, as well as that of plutonium, are discussed in detail in Chapter 29 devoted to handling, storage, and disposal of these elements and their relevant compounds.

Uranium dissolves very rapidly in aqueous hydrochloric acid. The reaction frequently yields considerable amounts of a black solid, presumably a hydrated uranium oxide but very likely containing some hydrogen. The addition of a small amount of fluorosilicate ion prevents the appearance of the black solid during dissolution in hydrochloric acid. Non-oxidizing acids, such as sulfuric, phosphoric, and hydrofluoric, react only very slowly with uranium, whereas nitric acid dissolves massive uranium at a moderate rate. With finely divided uranium, the dissolution in nitric acid may approach explosive violence. Uranium metal is inert to alkalis. Addition of oxidizing agents such as peroxide to sodium hydroxide solution leads to the dissolution of uranium and to the formation of ill-defined water-soluble peroxyuranates.

5.7 COMPOUNDS OF URANIUM

Ever since the discovery of uranium in 1789, its compounds have been synthesized and studied, so that a wealth of information has accumulated over the years. Much of this information may be found in the books by Katz and Rabinowitch (1951, 1958) and in the various volumes of the Supplement Series of the *Gmelin Handbook of Inorganic Chemistry* (1975–1996), which constitute probably the most comprehensive collection of information on uranium compounds.

For obvious reasons, such as lack of space, it is impossible to give a complete account of every uranium compound known to date. Rather, representative examples will be discussed with emphasis on preparation, structure, and chemical properties; information and discussion of thermodynamic properties of uranium and other actinide compounds are found in Chapter 19. In its compounds, uranium exhibits the oxidation states 3+, 4+, 5+, and 6+, with 4+ and 6+ as the predominant ones. Also, mixed valence and non-stoichiometric compounds are known.

While general features of the structures of uranium compounds, both from coordination and chemical points of view, will be discussed in Section 5.9, structures pertaining to each family of compounds will be described in the following subsections.

5.7.1 The uranium–hydrogen system

The uranium–hydrogen system has been reviewed by Katz and Rabinowitch (1951), Mallett *et al.* (1955), Libowitz (1968), Flotow *et al.* (1984), and Ward (1985). An extensive review has been given in the *Gmelin Handbook* (Gmelin, 1977, vol. C1). The kinetics of the reaction of hydrogen on uranium is discussed in detail in Chapter 29, describing the handling, storage, and disposition of plutonium and uranium. This topic will therefore not be developed here.

(a) Preparative methods

β-UH_3 forms rapidly as fine black or dark gray powder when uranium turnings or powder, as well as large massive lumps, are heated to 250°C in a vacuum followed by the introduction of H_2 gas into the reaction system (Spedding *et al.*, 1949; Libowitz and Gibb. Jr, 1957). Crystalline β-UH_3 may be prepared as gray, fibrous crystals at 30 atm H_2 and 600–700°C in an autoclave using a uranium nitride crucible as the primary container inside the pressure vessel.

α-UH_3 can only be prepared by slow reaction at temperatures below about −80°C. The α-phase is unstable, and the products are usually a mixture with more than 50% β-UH_3 (Mulford *et al.*, 1954; Abraham and Flotow, 1955). Purer α-UH_3 has been obtained by the diffusion method: Fine reactive uranium metal powder, formed by thermal decomposition of β-UH_3, was kept below −78°C in an Ar (or He) filled cryostat at a pressure of 0.25–0.40 atm, to which H_2 was introduced with an adequately low rate (reaction period: 20 days). More than 80% of the product was α-UH_3 (Wicke and Otto, 1962).

(b) Crystal structures

α-UH_3 is cubic with space group *Pm*3*n*. Two uranium atoms occupy (0,0,0) and (1/2,1/2,1/2), and six hydrogen atoms ±(1/4,0,1/2), ±(1/2,1/4,0), and ±(0,1/2,1/4) positions. The crystallographic data are listed in Table 5.10.

β-UH_3 also has a cubic structure with space group *Pm*3*n*, the same as in α-UH_3, but with different atom positions, $2U_I$ in (0,0,0) and (1/2,1/2,1/2), and

$6U_{II}$ in ±(1/4,0,1/2) and their equivalent positions. The hydrogen position was determined by neutron diffraction of β-UD_3 (Rundle, 1951). The hydrogen atoms are located in the 24(*k*) position, where each hydrogen atom is equidistant from four uranium neighbors within the experimental error, i.e., $12H_I$ in ±(5/16,0,±5/32) and $12H_{II}$ in ±(11/32,±1/2,3/16).

(c) Phase relations and dissociation pressures

A pressure–composition (isotherm) diagram of the $U–UH_3–H_2$ system is shown in Fig. 5.12; the region of the existence of α-hydride phase is not given because this phase is unstable and transforms irreversibly to β-UH_3 at higher

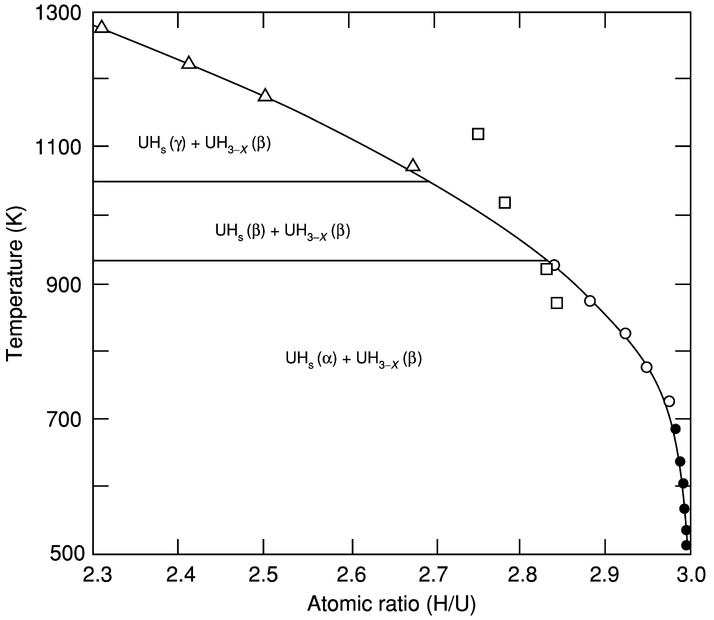

Fig. 5.13 *Phase diagram of the uranium–hydrogen system in the range H/U* = 2.3–3.0 (*from Flotow* et al., 1984). *UH_s (α, β, and γ) represent uranium metal phases (α, β, and γ), respectively, with dissolved hydrogen.* •: *Besson and Chevallier* (1964); ○: *Libowitz and Gibb, Jr.* (1957); □: *Northrup, Jr.* (1975); △: *Lakner* (1978). *Reproduced by the permission of the Atomic Energy Agency, Vienna.*

temperatures. The equilibrium H_2 pressure over α-UH_3 is much higher than that over β-UH_3, but no quantitative data are available. The rate of the α → β transformation is relatively low; α-UH_3 changes to β-UH_3 in a few hours at 250°C (Wicke and Otto, 1962).

The β-hydride phase, β-UH_{3-x}, has a relatively wide range of hydrogen hypostoichiometry at higher temperatures. The slight hyperstoichiometry at 846.2°C shown in Fig. 5.12 is an experimental artefact caused by hydrogen permeation from the sample vessel (Northrup, Jr., 1975).

Fig. 5.13 shows the hypostoichiometric range for uranium trihydride up to 1300 K (Flotow *et al.*, 1984). At 1280 K, the lower limit of the β-hydride phase attains to $UH_{2.3}$.

The solubility of hydrogen in uranium metal increases with increasing temperature (Fig. 5.12). The data determined by Mallett and Trzeciak (1958) obey Sieverts law.

$$\alpha\text{-U: } \log S(\mathrm{H/U}) = 1/2 \log p_{\mathrm{H_2}}(\mathrm{atm}) - 2.874 - 388\,T^{-1}\ (T < 942\,\mathrm{K}),$$
$$\beta\text{-U: } \log S(\mathrm{H/U}) = 1/2 \log p_{\mathrm{H_2}}(\mathrm{atm}) - 1.778 - 892\,T^{-1}(942 < T < 1049\,\mathrm{K}),$$
$$\gamma\text{-U: } \log S(\mathrm{H/U}) = 1/2 \log p_{\mathrm{H_2}}(\mathrm{atm}) - 2.238 - 227\,T^{-1}\ (1049 < T < 1408\,\mathrm{K}),$$
$$\text{Liquid U: } \log S(\mathrm{H/U}) = 1/2 \log p_{\mathrm{H_2}}(\mathrm{atm}) - 1.760 - 587\,T^{-1}\ (T > 1408\,\mathrm{K}),$$

where S is the solubility measured as the atom ratio. It may be noteworthy that finely divided uranium chemisorbs much larger amounts of hydrogen than those given by the previous equations (e.g. about 100 times larger at 295°C and 0.15 mmHg H_2).

Below 400°C the hydrogen pressure for formation of hydrides is not the same as that for the decomposition in the region of two solid phases (plateau region). Spedding *et al.* (1949) reported that the decomposition and formation pressures at 357°C were 0.176 and 0.188 atm, respectively. Wicke and Otto (1962) indicated that this difference is 170% at 369°C as shown in Fig. 5.12. Various explanations of the hysteresis and the dip in the decomposition process have been proposed (Libowitz, 1968; Condon and Larson, 1973); there is a possibility that traces of oxygen play a role. Using very pure uranium samples, no evidence of hysteresis was found and the time to attain equilibrium was quite short (Meusemann and von Erichsen, 1973; Condon, 1980).

The plateau hydrogen pressures are given by the equation

$$\ln p(\text{atm}) = A - BT^{-1}$$

where $A = 14.55$ and $B = 10233$ for UH_3 in the temperature range 298–942 K (Chiotti, 1980). For uranium trideuteride, UD_3, Flotow *et al.* (1984) assessed the measured data by Spedding *et al.* (1949), Wicke and Otto (1962), Destriau and Sériot (1962), and Carlson (1975), and recommended the values $A = 15.046$ and $B = 10362$ (500–800 K), which were obtained by averaging the results of Spedding *et al.* (1949) and Wicke and Otto (1962). The data for uranium tritritide, UT_3, are meager. The recommended A and B values (Flotow *et al.*, 1984) are those obtained by averaging the results of Flotow and Abraham (1951) and of Carlson (1975); they are $A = 14.57$ and $B = 9797$ in the temperature range 600–800 K. The above equilibrium pressures are considerably lower than the pressures derived from calorimetric data for UH_3, UD_3, and UT_3 (Flotow *et al.*, 1984).

(d) Thermodynamic properties

The heat capacity, entropy, and enthalpy of formation of UH_3, UD_3, and UT_3 (β forms) at 298 K are listed in Table 5.11.

Table 5.11 *Heat capacity, entropy, and enthalpy of formation of* β-UH_3, β-UD_3, *and* β-UT_3 *at* 298.15 K (*Flotow* et al., 1984).

Compound	C_p°(298.15 K) (J K^{-1}mol^{-1})	S°(298.15 K) (J K^{-1}mol^{-1})	$\Delta_f H^\circ$ (298.15K) (kJ mol^{-1})
β-UH_3	49.29 ± 0.08	63.68 ± 0.13	– 126.98 ± 0.13
β-UD_3	64.98 ± 0.08	71.76 ± 0.13	– 129.79 ± 0.13
β-UT_3	74.43 ± 0.75	79.08 ± 0.79	–130.29 ± 0.21

Flotow and Osborne (1967) and Flotow *et al.* (1959) have measured the low-temperature heat capacity of $UH_3(\beta)$ from 1.4 to 23 K and from 5 to 350 K, respectively. Abraham *et al.* (1960) have reported the low-temperature heat capacity of UD_3 from 5 to 350 K and Ward *et al.* (1979) that from 4 to 17 K.

Although no experimental heat capacity data have been published for $UT_3(\beta)$, Flotow *et al.* (1984) obtained the estimated C_p values using semiempirical equations to estimate the optical mode contributions of the hydrogen lattice vibrations. Abraham *et al.* (1960) found that the sum of the lattice heat capacity associated with the acoustic modes, the electronic heat capacity, and the magnetic heat capacity, agreed within 0.08 $JK^{-1}mol^{-1}$ for $UH_3(\beta)$ and $UD_3(\beta)$, which means that this part of heat capacity is virtually the same for UH_3, UD_3, and UT_3. Moreover, they showed that this could be represented by a linear function of temperature. On this basis, Flotow *et al.* (1984) calculated the optical mode contributions of UT_3 by using the Einstein heat capacity function to estimate the heat capacity of UT_3.

The heat capacity of UH_3 and UD_3 up to 800 K was also obtained by this method as shown in Fig. 5.14. The sharp anomaly in the vicinity of 170 K is due to the ferromagnetic–paramagnetic transition of the β-hydride phases.

(e) Electrical resistivity

The electrical resistivity, ρ, of β-hydride increases with increasing temperature as in metals. Ward *et al.* (1979) measured the electrical resistivity of β-UD_3 from 2.4 to 300 K. The ρ vs T curve has an anomaly due to a magnetic transition at 166 K. These resistivities are in good agreement with the unpublished data of Flotow for β-UH_3 communicated to Grunzweig-Genossar *et al.* (1970). The resistivity of β-hydride is about ten times higher than that of uranium metal.

(f) Magnetic properties and the nature of bonding

The history of magnetic studies of uranium hydrides is described in the review of Troć and Suski (1995). In the earlier work, α-UH_3 was considered to be ferromagnetic at low temperatures with T_C the same as, or close to that of β-UH_3. However, the neutron diffraction study on α-UD_3 (Lawson *et al.*, 1991) revealed the α-hydride phase to be non-magnetic at least above 15 K, i.e. the apparent ferromagnetism was due to β-hydride impurities in the α-hydride samples.

β-Hydride is ferromagnetic at low temperatures. The magnetic data for β-UH_3 and β-UD_3 are shown in Table 5.12. At the Curie temperature, the λ-type heat capacity anomaly has also been observed at 170.5 and 167.6 K for β-UH_3 and β-UD_3, respectively (Fig. 5.14). The lower Curie temperature in the deuteride is associated with the somewhat shorter U–U distance, resulting in a change of the exchange integrals for the Weiss field (Ward, 1985). The electrical

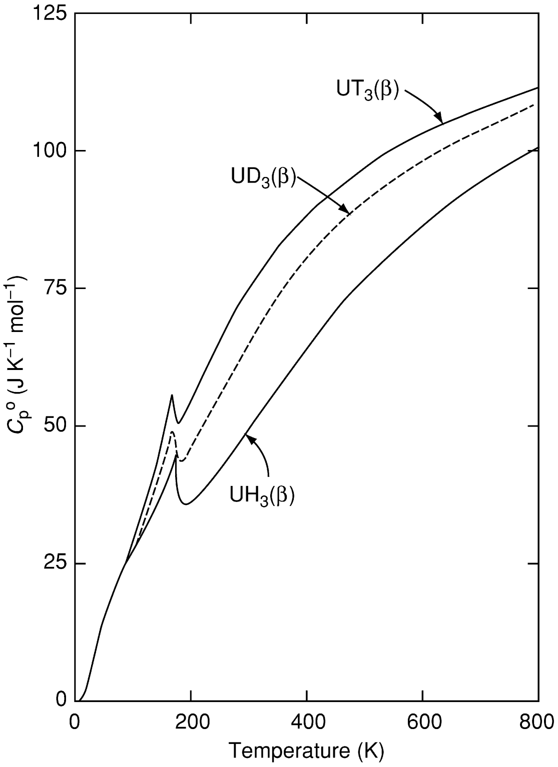

Fig. 5.14 *Heat capacities of $UH_3(\beta)$, $UD_3(\beta)$, and $UT_3(\beta)$* (*Flotow* et al., 1984).

resistivity for β-UD_3 changed at the Curie temperature (166 K) (Ward *et al.*, 1979). Andreev *et al.* (1998) report that the Curie temperature of β-UH_3 decreases with increasing external pressure from 175 K (0 kbar) to 169 K (8 kbar). In Table 5.12, the saturation uranium magnetic moments obtained by neutron diffraction are far larger than those obtained by magnetization measurements, possibly a result of a large magnetic anisotropy in β-UH_3 (Bartscher *et al.*, 1985). The neutron diffraction studies of β-UH_3 carried out at the ferromagnetic temperatures revealed that the two U_I and six U_{II} atoms, which occupy different crystallographic positions in space group *Pm*3*n*, are magnetically equivalent giving the same magnetic moment; no (110) reflection peak was observed in the diffraction patterns (Wilkinson *et al.*, 1955; Bartscher *et al.*, 1985; Lawson *et al.*, 1990). Increased external pressure lowers the saturation magnetic moment of uranium from $1\mu_B$(0 kbar) to $0.985\mu_B$(10 kbar) at 4.2 K (Andreev *et al.*, 1998). The effective uranium moments in Table 5.12 are those obtained from the slope of the Curie–Weiss curves in the paramagnetic range of temperatures.

Grunzweig-Genossar *et al.* (1970) assume that uranium is composed of uranium ions and protons (deuterons) in a high-density interacting electron gas. The magnetic moments arise from 5f electrons. The uranium ions are magnetically coupled through the polarized conduction electrons by the RKKY interaction, which can explain the ferromagnetic ordering below ~180 K and the large Knight shift obtained by their nuclear magnetic resonance (NMR) measurement, i.e. $K = 0.40\chi_{\mathrm{M}}$, where χ_{M} is the molar magnetic susceptibility. The second moment and line-shape data suggest that the 5f electrons ($Z \sim 2.5$ conduction electrons per uranium atom) are localized and do not form a band as in metallic uranium.

Cinader *et al.* (1973) measured the NMR spin-lattice relaxation time in the paramagnetic state at 189–700 K. In addition to the time-dependent dipolar interaction through hydrogen diffusion, the relaxation time was dependent on (1) the direct interaction between the conduction electrons and the protons (deuterons) causing Korringa relaxation, and (2) the indirect RKKY (Ruderman-Kittel-Kasuya-Yosida) interaction. The density of states of the s-type conduction electrons at the Fermi level was 1.65 states per eV. A model with a spherical Fermi surface and free electron behavior in the RKKY interaction, results in U^{3+} and H^{-} as the ionic species.

(g) Chemical properties

Uranium hydride is very reactive and, in most respects its reactions resemble those of the finely divided uranium metal; in fact, reactions that occur at temperatures where the hydrogen decomposition pressures are high may be those of the metal. Uranium hydride ignites spontaneously in air, but gradual oxidation at low oxygen pressures at room temperature results in the formation of a protective film of oxide on the surface of hydride particles, which prevents the hydride from ignition. Adsorption of a variety of electron-pair-donor compounds can reduce the pyrophoric properties.

Uranium hydride is used as a starting material in many reactions, including the preparation of finely divided uranium metal. Hydrogen, deuterium, and tritium may be stored as UH_3, UD_3, and UT_3, respectively. These gases are released when the compounds are heated to the decomposition temperatures. Gram quantities of UH_3 reacts slowly with water, but larger samples react violently and produce high temperatures (Newton *et al.*, 1949). UH_3 reacts slowly with solution of non-oxidizing acids such as HCl and weak acids such as CH_3COOH, but vigorously with HNO_3. UH_3 reacts with H_2SO_4 to form S, SO_2, and H_2S, and with H_3PO_4 to form UPO_4. UH_3 is unstable in strong bases and reduces aqueous solutions of $AgNO_3$ and $HgCl_2$. At elevated temperatures, UH_3 reacts with O_2, hydrogen halides, H_2S, HCN, NH_3, N_2, CO_2, CH_4, and C_2H_2 (acetylene), but not with liquid hydrocarbons and chlorinated solvents, although an explosive reaction occurs with CCl_4. The reactions of UH_3 with most compounds are thermodynamically favored, and many cases where the

reactions do not proceed are a result of kinetic inhibition (Haschke, 1991). Typical reactions of uranium hydride are given in Table 5.13.

(h) Other uranium hydride compounds

(*i*) *Uranium*(IV) *borohydride,* $U(BH_4)_4$

The volatile $U(BH_4)_4$ is obtained as dark green crystals by the reaction

$$UF_4 + 2Al(BH_4)_3 \rightarrow U(BH_4)_4 + 2Al(BH_4)F_2.$$

Purification is made by vacuum sublimation (Schlesinger and Brown, 1953).

$U(BH_4)_4$ is tetragonal with space group $P4_32_12$ having four formula units in the unit cell. The lattice parameters are $a = (7.49 \pm 0.01)$ Å and $c = (13.24 \pm 0.01)$ Å. The positions of U, B, and H have been determined by X-ray and neutron diffraction analyses (Bernstein *et al.*, 1972a,b).

In vacuo and in an inert-gas atmosphere, $U(BH_4)_4$ is fairly stable, but it is immediately decomposed by oxygen or moisture. Bernstein and Keiderling (1973) determined the molecular structure from optical and nuclear magnetic resonance spectra.

The vapor pressure of $U(BH_4)_4$ is given by the equation

$$\log p(\text{mmHg}) = 13.354 - 4265T^{-1}.$$

$U(BH_4)_3$ is a red solid, which has been observed as a by-product in the synthesis of $U(BH_4)_4$. Because of its pyrophoric properties, it has not been well characterized (Schlesinger and Brown, 1953).

(*ii*) *UNiAlH*$_y$ *and related compounds*

The intermetallic compounds UXAl (X = Ni, Co, Mn) absorb hydrogen on heating in the temperature range 20–250°C at high H_2 pressures. The maximum hydrogen content attained at 20°C corresponds to $UNiAlH_{2.74}$ ($p_{H_2} = 55$ atm), $UCoAlH_{1.2}$ (40 atm), and $UMnAlH_{0.15}$ (40 atm) (Drulis *et al.*, 1982). UNiAl absorbs the largest amount of hydrogen in these compounds, though lower maximum hydrogen absorption values have been reported, at room temperature and 70 atm viz. $UNiAlH_{2.5}$ (Jacob *et al.*, 1984), and $UNiAlD_{2.2}$ at 30°C and 50 atm D_2 (Yamamoto *et al.*, 1998). The lower limit of the hydride phase is $y = 0.7$–0.8 (Yamamoto *et al.*, 1994, 1998; Yamanaka *et al.*, 1999). The hydrogen solubility in the UNiAl metal appears to obey Sieverts law in the hydrogen concentration region below 0.02 H per formula unit UNiAl (Yamanaka *et al.*, 1999).

The symmetry and space group of $UNiAlH_y$ are the same as those for UNiAl. The structure consists of alternate planes containing three Al (in 3f) and two Ni (2c) atoms at $z = 0$ and three U (3g) and one Ni (1b) atoms at $z = 1/2$. The hydrogen atoms are located in the center of one of the adjacent U_3Ni tetrahedra, in the bipyramid U_3Al_2, and in the bipyramid Al_3Ni_2 (Kolomiets *et al.*, 2000). The lattice parameter a increases whereas b decreases slightly with increasing value of y (Drulis *et al.*, 1982; Jacob *et al.*, 1984; Yamamoto *et al.*, 1994; Yamanaka *et al.*, 1999; Kolomiets *et al.*, 2000). This variation, expressed in Å, is approximately represented by the equations $a = 6.736 + 0.187y$ and $c = 4.037 - 0.028y$ in the range $0.8 \leq y \leq 2.7$. The hydrogenation of UNiAl is accompanied by a volume change. The quotient $\Delta V/V$ attains a value of 0.124 for both hydride ($y = 2.3$) and deuteride ($y = 2.1$). In addition, the X-ray diffraction peak intensities indicate a positional shift of the U atoms from (0.572, 0, 1/2) in UNiAl to (2/3, 0, 1/2) in $UNiAlH_{2.3}$. These changes are supposed to favor the accommodation of a larger amount of hydrogen (Kolomiets *et al.*, 2000).

The desorption isotherms of $UNiAlH_y$ have two sloping plateaus, which suggests the existence of two hydride phases (Jacob *et al.*, 1984). The partial molar enthalpy and entropy of hydrogen for the non-stoichiometric $UNiAlH_y$ varies with the y value. $\Delta\bar{H}(H_2)$ and $\Delta\bar{S}(H_2)$ were –53 kJ (mol H_2)$^{-1}$ and –88 J K^{-1} (mol H_2)$^{-1}$, respectively, for $UNiAlH_{1.35}$, and –41 kJ (mol H_2)$^{-1}$ and –95 J K^{-1} (mol H_2)$^{-1}$ for $UNiAlH_{2.30}$ (Drulis *et al.*, 1982). The values measured by Jacob *et al.* (1984) are comparable with the above values: $\Delta\bar{H}(H_2)$ and $\Delta\bar{S}(H_2)$ were −64 kJ (mol H_2)$^{-1}$ and –90 J K^{-1} (mol H_2)$^{-1}$, respectively, for $UNiAlH^{1.2}$, and −47 kJ (mol H_2)$^{-1}$ and –94 J K^{-1} (mol H_2)$^{-1}$, respectively, for $UNiAlH_{2.0}$.

The incorporation of hydrogen into UNiAl leads to a large increase in the antiferromagnetic ordering temperature from 19 K to 90–100 K. The transition temperatures for $UNiAlH_{2.3}$ and $UNiAlD_{2.1}$ are 99 and 94 K, respectively (Kolomiets *et al.*, 2000). According to Zogal *et al.* (1984), $UNiAlH_{1.9}$ has magnetic transitions at 122 and 34 K, where the second transition possibly refers to the hydride at the lower phase limit. The magnetic susceptibility in the paramagnetic region is represented by the modified Curie–Weiss equation. The effective moment, μ_{eff}, the paramagnetic Curie temperature, θ_{p}, and the temperature-independent susceptibility, χ_{o}, are 2.42 μ_{B}/f.u., –42 K and 7×10^{-9} $\mathrm{m^3\,mol^{-1}}$, respectively, for $\mathrm{UNiAlH_{2.3}}$. The values are 2.43 μ_{B}/f.u., –50 K and 8×10^{-9} $\mathrm{m^3\,mol^{-1}}$, respectively, for $\mathrm{UNiAlD_{2.1}}$ (Kolomiets *et al.*, 2000).

$\mathrm{U(Fe_{1-x}Ni_x)Al}$ with $x \geq 0.7$ absorbs hydrogen forming $\mathrm{U(Fe_{1-x}Ni_x)AlH_y}$ hydrides. Raj *et al.* (2000) studied the magnetic properties of $\mathrm{U(Fe_{0.3}Ni_{0.7})AlH_y}$, and found that no other hydride phase was formed above or below $y = 0.8$. $\mathrm{U(Fe_{0.3}Ni_{0.7})AlH_y}$ is ferromagnetic with $T_{\mathrm{C}} = 15$ K ($y = 0$) and 90 K ($y = 0.8$). Magnetization of $\mathrm{U(Fe_{0.3}Ni_{0.7})Al}$ at 5.5 T gave a saturation moment of $\cong 0.3\mu_{\mathrm{B}}$/f.u. The value for the hydride ($y = 0.8$) was much higher, $\cong 0.9\mu_{\mathrm{B}}$/f.u., indicating considerable increase in the ferromagnetic correlations. Other intermetallic hydrides, e.g. $\mathrm{U_5Ni_4PdH_{1.0}}$ (Drulis *et al.*, 1982), $\mathrm{UCoH_{2.7}}$ (Andreev *et al.*, 1986; Yamamoto *et al.*, 1991), and $\mathrm{UTi_2D_y}$ (Yamamoto *et al.*, 1995) have also been studied.

5.7.2 The uranium–oxygen system

(a) Binary uranium oxides

(*i*) *Preparative methods*

Comprehensive information on the preparation of actinide oxides including uranium oxides is given in a monograph by Morss (1991).

UO(s)

Although UO gas is one of the main species over $\mathrm{U(l)+UO_{2-x}}$ at high temperatures, solid UO ($Fm\bar{3}m$, $a = 4.92$ Å) with NaCl-type structure is very unstable and its formation has not been definitely established. When $\mathrm{UO_2}$ was heated with uranium metal at high temperatures, a fcc phase was produced only in cases of considerable carbon contamination (Rundle *et al.*, 1948). Carbon is thought to promote the reaction. It is possible that UC or UN must be present for the formation of the UO phase (Rundle *et al.*, 1948; Cordfunke, 1969).

UO_2(s)

$\mathrm{UO_2}$ is prepared by hydrogen reduction of $\mathrm{UO_3}$ or $\mathrm{U_3O_8}$ between 800 and 1100°C (Katz and Rabinowitch, 1951; Belle, 1961; Wedermeyer, 1984). The $\mathrm{H_2}$ gas used for this purpose should not contain impurity of $\mathrm{O_2}$ in order to avoid oxidation to hyperstoichiometric $\mathrm{UO_{2+x}}$, which occurs on cooling at temperatures below 300°C. The $\mathrm{UO_2}$ pellets for reactor fuel are reduced at much higher temperatures around 1700°C in order to approach the theoretical density. For laboratory use, other reductants such as CO, C, $\mathrm{CH_4}$, and $\mathrm{C_2H_5OH}$ may be used, but they offer no advantages over H_2 (Katz and Rabinowitch, 1951; Wedermeyer, 1984; Roberts and Walter, 1966). NH_3 is not suitable (Belle, 1961). Commercial methods of UO_2 synthesis start from the peroxide $UO_4 \cdot 2H_2O$, ammonium diuranate with the approximate composition $(NH_4)_2U_2O_7$ or ammonium uranyl carbonate $(NH_4)_4UO_2(CO_3)_3$ followed by air calcination at 400–500°C. Subsequent H_2 reduction at 650–800°C yields UO_2 with high surface area. The nuclear fuel pellets are produced by cold pressing of these powders, followed by sintering.

$U_4O_9(s)$

U_4O_9 can be prepared from the stoichiometric amounts of UO_2 and U_3O_8 according to the reaction $5UO_2 + U_3O_8 = 2U_4O_9$. The reactants are ground in an agate mortar and the mixture is sealed in an evacuated quartz ampoule, and then heated at 1000°C for about 2 weeks until the sample is completely homogenized. The sample is slowly cooled to room temperature over a period of 2 weeks (Gotoo and Naito, 1965; Westrum, Jr. *et al.*, 1965). U_4O_9 has three phases: α-U_4O_9 that transforms into β-U_4O_9 on heating to ~350 K, and β-U_4O_9 that transforms into γ-U_4O_9 at ~850 K (Labroche *et al.*, 2003b). These transformations are reversible.

$U_3O_7(s)$

Three polymorphs of α, β, and γ are known for U_3O_7; all of them are tetragonal. α-U_3O_7 with *c/a* ratios 0.986–0.991 is prepared by oxidizing UO_2 at temperatures below 160°C (Hoekstra *et al.*, 1961; Westrum, Jr. and Grønvold, 1962). To prepare a single phase with $O/U \approx 2.33$, the use of reactive UO_2, which is obtained by low-temperature reduction of UO_3 by H_2, is recommended (Hoekstra *et al.*, 1961). Oxidation of UO_2 in air at 200°C yields β-U_3O_7 with *c/a* ratios between 1.027 and 1.032 (Garrido *et al.*, 2003). The oxidation of standard uranium dioxide ceases at $UO_{2.33}$ at temperatures below 200°C and no formation of U_3O_8 takes place (Hoekstra *et al.*, 1961). Allen and Tyler (1986) report that well-crystallized single-phase β-U_3O_7 was obtained by oxidation at 230°C for 16 h. The γ-U_3O_7 ($U_{16}O_{37}$) phase, which has *c/a* ratios of 1.015–1.017 and smaller O/U ratios of 2.30–2.31 (Hoekstra *et al.*, 1961; Westrum, Jr. and Grønvold, 1962; Hoekstra *et al.*, 1970; Nowicki *et al.*, 2000), is formed when U_4O_9 is oxidized at 160°C (Hoekstra *et al.*, 1961). This compound has also been prepared as a mixture with monoclinic U_8O_{19} on heating a pellet of mixed UO_2 and UO_3 at $\geq$400°C under high pressures (15–60 kbar) (Hoekstra *et al.*, 1970).

$U_2O_5(s)$

High-pressure syntheses by Hoekstra *et al.* (1970) identified three U_2O_5 phases (α-U_2O_5, β-U_2O_5 and γ-U_2O_5). α-U_2O_5 was prepared by heating a mixture of UO_2 and U_3O_8 at 400°C and 30 kbar for 8 h. At 500°C, a pressure of 15 kbar was enough to prepare α-U_2O_5. Hexagonal β-U_2O_5 is formed at 40–50 kbar pressure at temperatures higher than 800°C. Monoclinic γ-U_2O_5 was sometimes

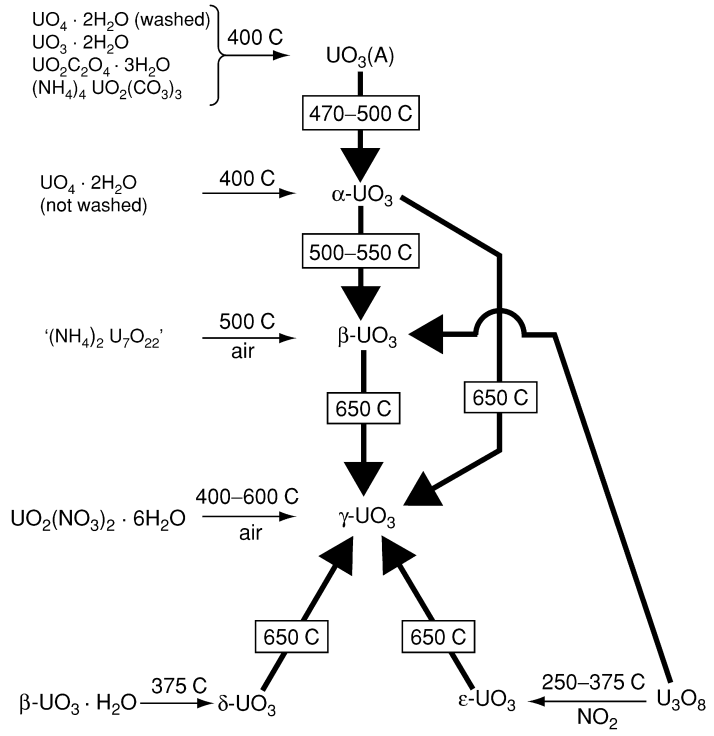

Fig. 5.15 *Flow sheet for the preparation of various UO_3 modifications: Bold lines refer to high O_2 pressure* (*Hoekstra and Siegel*, 1961; *Cordfunke*, 1969).

obtained when the UO_2 and U_3O_8 mixture was heated above 800°C at a pressure of 60 kbar.

$U_3O_8(s)$

α-U_3O_8 is prepared by oxidation of UO_2 in air at 800°C followed by slow cooling (Loopstra, 1970a). β-U_3O_8 is prepared by heating α-U_3O_8 to 1350°C in air or oxygen, followed by slow cooling (cooling rate: 100 K per day) to room temperature (Loopstra, 1970b).

$UO_3(s)$

Seven modifications are known for UO_3: A, α, β, γ, δ, ε, and ζ-UO_3. The methods of their syntheses are outlined in the flow sheet of Fig. 5.15 (Hoekstra and Siegel, 1961; Cordfunke, 1969).

Amorphous UO_3 (A-UO_3) forms when any of the compounds $UO_4 \cdot 2H_2O$ (washed with H_2O), $UO_3 \cdot 2H_2O$, $UO_2C_2O_4 \cdot 3H_2O$ and $(NH_4)_4UO_2(CO_3)_3$ is heated in air at 400°C. Because of the difficulty to remove residual traces of nitrogen and carbon, it is preferable to use either of the first two of the above compounds (Hoekstra and Siegel, 1961). α-UO_3 is prepared by crystallization of A-UO_3 at 485°C for 4 days. The heating time can be shortened at 500°C but a pressure of 40 atm oxygen is then needed (Hoekstra and Siegel, 1961). β-UO_3 is prepared by heating 'ammonium diuranate' or uranyl nitrate rapidly in air at 450–500°C. The crystallinity of β-UO_3 is improved by keeping the sample at 500°C (not higher) for 4–6 weeks (Debets, 1966). This compound is also obtained by heating at 500–550°C under 30–40 atm O_2. γ-UO_3 is formed slowly at 500–550°C in 6–10 atm O_2. At 650°C and 40 atm O_2, all α, β, δ, and ε-UO_3 compounds convert to the γ-phase. γ-UO_3 can be prepared directly in air by heating uranyl nitrate hexahydrate to 400–600°C (Hoekstra and Siegel, 1958; Engmann and de Wolff, 1963). Stoichiometric δ-UO_3 is obtained by heating β-$UO_2(OH)_2$ (= β-$UO_3 \cdot H_2O$) at 375–400°C for more than 24 h (Hoekstra and Siegel, 1961). At 415°C, the oxygen-deficient δ-phase forms (Wait, 1955). ε-UO_3 is prepared by oxidizing U_3O_8 at 350°C in $NO_2(g)$. The reaction goes to completion in a few seconds (Gruen *et al.*, 1951). At a temperature of 400°C, the reaction rate levels off as the stability limit of ε-UO_3 is approached (Hoekstra and Siegel, 1961). The high-pressure modification ζ-UO_3 forms at 30 kbar and 1100°C (Hoekstra *et al.*, 1970).

UO_3 hydrates

The existence of six compounds, i.e. $UO_3 \cdot 2H_2O$, α-$UO_3 \cdot 0.8H_2O$, α-$UO_2(OH)_2$, β-$UO_2(OH)_2$, γ-$UO_2(OH)_2$, and $U_3O_8(OH)_2$, has been confirmed in the UO_3–water system. $UO_3 \cdot 2H_2O$ is prepared by exposure of anhydrous UO_3 to water at 25–75°C. An alternative method is to add 0.65 g $La(OH)_3$ to 50 mL 0.2 M $UO_2(NO_3)_2$ solution. The hydroxide dissolves slowly, accompanied by an increase in solution pH from 2.2 to 4.0. Digestion of the clear solution at 55°C causes a gradual precipitation of a portion of the uranium as bright yellow crystals of $UO_3 \cdot 2H_2O$ (Hoekstra and Siegel, 1973). Water-deficient α-phase monohydrate, α-$UO_3 \cdot 0.8H_2O$, was prepared by heating $UO_3 \cdot 2H_2O$ in air at 100°C or by heating either $UO_3 \cdot 2H_2O$ or UO_3 in water at 80–200°C (Dell and Wheeler, 1963). Stoichiometric α-$UO_2(OH)_2$ (= α-$UO_3 \cdot H_2O$) was prepared in hydrothermal experiments at temperatures approaching 300°C (Harris and Taylor, 1962; Taylor, 1971).

Stoichiometric β-$UO_2(OH)_2$ (or β-$UO_3 \cdot H_2O$) is prepared by the action of water on $UO_3 \cdot 2H_2O$ or UO_3 at 200–290°C in a sealed reactor (Dawson *et al.*, 1956). It is also formed by the hydrolysis of uranyl salt solutions (cf. γ-$UO_2(OH)_2$). γ-$UO_2(OH)_2$ (or γ-$UO_3 \cdot H_2O$) is obtained when 0.65 g $La(OH)_3$ is added to 50 mL of 0.2 M $UO_2(NO_3)_2$ and subsequent heating of the solution to 80–90°C; digestion of the solution leads to slow precipitation of γ-$UO_2(OH)_2$ (Hoekstra and Siegel, 1973). There may be no region of true thermodynamic stability for the γ-phase. Continued digestion for several weeks eventually gives β-$UO_2(OH)_2$ as the sole product. $U_3O_8(OH)_2$ (= $UO_3 \cdot 1/3H_2O$ or $H_2U_3O_{10}$, i.e. hydrogen triuranate) is prepared by hydrothermal reaction of $UO_3 \cdot 2H_2O$ or UO_3 at temperatures between 300 and 400°C. Although no solid solution range has been observed for this compound, appreciable variations in water content from 0.33 to 0.50 have been reported (Siegel *et al.*, 1972).

Uranium peroxide tetrahydrate, $UO_4 \cdot 4H_2O$, is obtained when the precipitate, grown from the uranyl nitrate solution of $pH = 2$ on addition of hydrogen peroxide solution, is dried at room temperature (Silverman and Sallach, 1961); the dihydrate, $UO_4 \cdot 2H_2O$, is prepared by heating $UO_4 \cdot 4H_2O$ at 90°C.

(*ii*) *Preparation of single crystals*

The basic method to prepare single crystals of UO_2 is to melt UO_2 powders. Arc melting (Brit and Anderson, 1962) and solar furnace heating (Sakurai *et al.*, 1968) techniques have been adopted for this purpose. The vapor deposition method has also been used, where an electric current was passed through a hollow cylinder of UO_2. UO_2 sublimed from the hot central part of the inner surface of the cylinder and deposited at the cooler end, forms large hemispherical single crystals of 4–12 mm (van Lierde *et al.*, 1962). Recrystallization also yields single crystals in the central part of UO_2 rod when the current is directly passed through the specimen (Nasu, 1964).

Single crystals of the length 5 cm have been prepared by means of the floating zone technique. In this case, the preheated UO_2 rods were heated by induction eddy-currents (Chapman and Clark, 1965). Robins (1961) obtained single crystals of 3 mm length by electrolysis of uranyl chloride in fused alkali chloride melts.

Formation of single crystals by chemical transport reactions has been studied by a number of researchers. Naito *et al.* (1971) examined the transport of UO_2, U_4O_9, and U_3O_8 from 1000 to 850°C in sealed quartz tubes using the transporting agents HCl, Cl_2, I_2, Br_2, and Br_2+S_2. Although the transport rate was very low in I_2 ($0.002\ \text{mg h}^{-1}$), it was high enough in Cl_2 of 4 mmHg pressure ($23\ \text{mg h}^{-1}$) and in Br_2+S_2 with partial pressures (2.5 ± 0.2) mmHg ($12.5\ \text{mg h}^{-1}$) to obtain single crystals. Single crystals of UO_2 were deposited on UO_2 substrates with (100) and (111) orientations by the chemical transport method using Cl_2 as the transporting agent (Singh and Coble, 1974). At Cl_2 pressures below 10 mmHg and high substrate temperatures (>950°C), good single crystals free from cracking caused by epitaxial growth were obtained.

Faile (1978) reported the formation of large single crystals of UO_2 by the use of $TeCl_4$ as transport agent. UO_2 was transported in a sealed fused quartz tube from the source end at 1050°C over a temperature gradient to the deposition end at 950°C. The maximum weight of the obtained single crystals was 1 g. $TeCl_4$ has also been used successfully for the preparation of single crystals of other actinide dioxides (Spirlet *et al.*, 1979).

(*iii*) *Crystal structures*

The crystal structures of uranium oxides in the composition range $2.00 \leq O/U \leq 2.375$, which includes UO_2 and polymorphs of U_4O_9 and U_3O_7, are closely related to the fluorite structure. On the other hand, the crystal structures of

U_3O_8 and many of the UO_3 polymorphs are based on the layer structures, which are characterized by the existence of UO_2^{2+} uranyl groups arranged normal to the plane of the layers. The lattice parameters of the uranium oxides are shown in Table 5.14.

UO_2, UO_{2+x}

Stoichiometric uranium dioxide crystallizes in a fcc structure (space group $Fm\bar{3}m$), where the uranium atoms occupy the positions 0,0,0; 1/2,1/2,0; 1/2, 0, 1/2 and 0, 1/2, 1/2 and the oxygen atoms occupy the 1/4, 1/4, 1/4 and its equivalent positions. As the temperature is raised, the anisotropic thermal vibration causes the oxygen atoms to move to the $1/4 + \delta$, $1/4 + \delta$, $1/4 + \delta$ positions, where $\delta = (0.016 \pm 0.001)$ at 1000°C (Willis, 1964a).

In the hyperstoichiometric uranium dioxide, UO_{2+x}, the interstitial oxygen atoms occupy two different sites of the UO_2 lattice, which are displaced by about 1 Å along the <110> and <111> directions from the cubic coordinated interstitial position. These oxygen atoms are denoted as O' and O'', respectively. Together with these interstitial atoms, it was observed that vacancies were formed at the normal oxygen sites, although the uranium sublattice remained undisturbed (Willis, 1964b). Willis (1978) later analyzed the neutron diffraction data for $UO_{2.12}$ at 800°C by taking into account the anharmonic contribution to the Debye–Waller factor. The occupancy numbers of O' and O'' and the vacant lattice oxygens were calculated to be equal within one standard deviation, indicating that the defect complex has a 2:2:2 configuration of oxygen defects. The two O'' oxygen atoms displace two normal oxygen atoms forming two O' atoms and two oxygen vacancies.

A model that assumes a chain-like coordination of the 2:2:2 clusters along <110> directions has been proposed (Allen *et al.*, 1982). However, it failed to give a satisfactory agreement between the observed and calculated neutron intensities (Willis, 1987). There may be a similarity between the clusters present in UO_{2+x} and $Fe_{1-x}O$. In the non-stoichiometric $Fe_{1-x}O$, the Roth clusters (Roth, 1960) or Koch–Cohen clusters (Koch and Cohen, 1969) are thought to be statistically distributed. These clusters have different structures but their compositions are close to that of Fe_3O_4 (Anderson, 1970), which is formed as an ordered phase when the concentration of clusters exceeds a certain value. In the case of UO_{2+x}, the possibility of disordered arrangement of cuboctahedral clusters exists, as U_4O_9 might be composed of ordered cuboctahedral clusters.

U_4O_9

The low-temperature phase α-U_4O_9 transforms to β-U_4O_9 at 340–350 K, which is accompanied by an anomaly in the specific heat at 348 K (Westrum, Jr. *et al.*, 1965) or 330 K (Gotoo and Naito, 1965) and of a dilatation at 293–359 K (Grønvold, 1955). The lattice parameter decreases with increasing temperature in this range (Ferguson and Street, 1963), but no anomaly was observed in the

(d): decomposes.
(*): Parameters for these phases refer to a pseudo-cell.

magnetic susceptibility (Gotoo and Naito, 1965). The transition was claimed to be due to disordering of oxygen with U^{4+}–U^{5+} rearrangement (Naito *et al.*, 1967; Fournier and Troć, 1985). Belbeoch *et al.* (1967) reported that α-U_4O_9 has a rhombohedral structure, slightly distorted from a cubic structure with the lattice parameters $a = 5.4438n$ (n: an integer) and $\alpha = 90.078°$ at 20°C. The transition is possibly of order–disorder type coupled with a small change in crystal structure.

Another transition from β-U_4O_9 to γ-U_4O_9 occurs at higher temperatures around 850 K. An X-ray diffraction analysis showed the transition temperature to be 823–973 K (Blank and Ronchi, 1968), while the heat capacity measurement gave 900–950 K (Grønvold *et al.*, 1970). A transition between 813–893 K was observed for the specimens of $2.228 \leq O/U \leq 2.25$ (Naito *et al.*, 1973) using X-ray diffraction and electrical conductivity measurements. This β/γ transition is assumed to be based on the order–disorder mechanism (Blank and Ronchi, 1968; Naito *et al.*, 1973). According to Seta *et al.* (1982), there was no clear anomaly or variation in the heat capacity curves in the above temperature range. Instead they observed two small peaks for hypostoichiometric U_4O_{9-y} ($UO_{2.22}$ and $UO_{2.235}$) at 1000 and 1100 K.

The crystal structure of α-U_4O_9 has not yet been solved, but it is supposed to be closely related to that of strictly cubic β-U_4O_9, with the space group $I\bar{4}3d$. Electron diffraction measurements on α-U_4O_9 showed that the superlattice reflections all obeyed the special extinction rules for the $\bar{4}$ sites of the space group $I\bar{4}3d$ (Blank and Ronchi, 1968). Bevan *et al.* (1986) suggest that α-U_4O_9 consists of cuboctahedral clusters centered on 12(a) or 12(b) sites similar to the crystal structure of β-U_4O_9, although the anion sublattice may be perturbed.

Bevan *et al.* (1986) collected single-crystal neutron diffraction data for β-U_4O_9 at 230 and 500°C. A partial Patterson synthesis obtained using only the superlattice reflections supported the cuboctahedral cluster model. Fig. 5.16 shows a sketch of the cuboctahedral oxygen cluster formed by 12 anions located at the vertices of a cuboctahedron and with a 13th oxygen atom situated in its center. The cube surrounding the cluster has an edge length close to the lattice parameter of the fcc cell of the uranium sublattice (the individual cations are not shown in the figure). In β-U_4O_9, the discrete U_6O_{37} cuboctahedral clusters are arranged on $\bar{4}$ axes with positions 12(b) of $I\bar{4}3d$.The displacement of oxygen in the cluster gives rise to the O′ interstitial atoms of Willis. The cuboctahedral cluster contains the Willis 2:2:2 clusters as a component. The structure contains twelve U_6O_{37} clusters per unit cell. There are 60 extra anions per unit cell, and the composition is then $U_{256}O_{572}$, i.e. the β-U_4O_9 phase has the composition U_4O_{9-y} with $y = 0.062$.

U_3O_7

The U_3O_7 polymorphs all crystallize in the tetragonal system but none of their space groups have been specified. The axial ratio *c/a* is here an important parameter to classify the different polymorphs. α-U_3O_7, which is prepared by

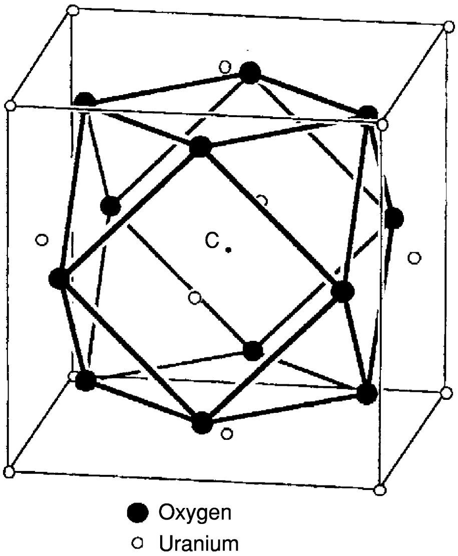

Fig. 5.16 *A schematic diagram of the cuboctahedral cluster. Eight oxygen anions inside the cationic cube are replaced by* 12 *anions located along the* <110> *directions from the center C.* (*from Garrido* et al. (2003), *reproduced by the permission of Elsevier*).

oxidation of UO_2 in air at temperatures of 120–175°C, has *c/a* ratios less than 1 (0.986–0.991) (Pério, 1953b; Westrum, Jr. and Grønvold, 1962). The *c/a* ratios for β-U_3O_7, prepared by oxidizing UO_2 in air at temperatures 160–250°C, are 1.027–1.032 (Hoekstra *et al.*, 1961; Simpson and Wood, 1983; McEachern and Taylor, 1998). In the range of O/U ratios between 2.26 and 2.33, the *c/a* ratio of α-U_3O_7 did not vary in a systematic way between 0.986 and 0.989, while that of β-U_3O_7 seemed to increase very slightly with increasing O/U ratio (Hoekstra *et al.*, 1961). The γ-U_3O_7 ($U_{16}O_{37}$) phase with *c/a* ratios of 1.015–1.016 appears in a range where the O/U ratios are 2.30–2.31 (Westrum, Jr. and Grønvold, 1962; Hoekstra *et al.*, 1970; Tempest *et al.*, 1988), which are significantly smaller than those of α-U_3O_7 and β-U_3O_7.

In the recent studies on β-U_3O_7, it was found that all the uranium atoms and 70% of the oxygen atoms were hardly affected by the oxidation of UO_2 to U_3O_7; however, the remaining 30% of the oxygen atoms changed their location to new sites which are shifted 0.31 Å along $\langle 110 \rangle$ vectors from the holes in the fluorite framework of UO_2. This result, based on a neutron diffraction analysis, is consistent with the assumption that the excess oxygen atoms in β-U_3O_7 are accommodated in the cuboctahedral oxygen clusters (Garrido *et al.*, 2003) as in the case of β-U_4O_9.

According to a theoretical study by Nowicki *et al.* (2000), the crystal structures of U_3O_7 differ from that of UO_2 by the presence of the cuboctahedral

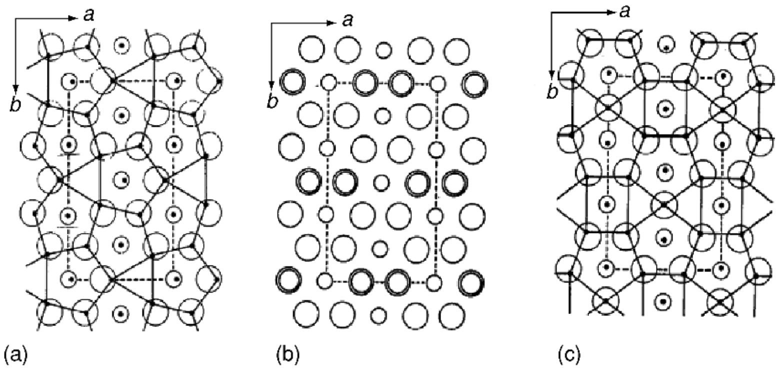

Fig. 5.17 *Atom arrangements on the sections perpendicular to the c-axis (Loopstra, 1970b). (a) α-U_3U_8; (b) hypothetical 'ideal' UO_3; (c) β-U_3O_8. The dots in the figure represent the actual positions. Isolated dots: uranium atoms; dots connected by full-drawn lines denote oxygen atoms. In (a), the section is at $z = 0$, and in (c), the origin is shifted b/3 at $z = 1/4$. Reproduced by permission of the International Union of Crystallography.*

clusters centered at specified ordered positions, and the arrangement of the clusters can be expressed as a stacking of identical polyatomic modules. A single module contains clusters arranged in a square pattern. The square sides have a length approximately equal to $R_1 = \sqrt{2.5}a_{\mathrm{UO_2}} \approx 0.86$ Å. The thickness of the modules is close to $1.5a_{\mathrm{UO_2}} \approx 0.82$ Å. The various polytypes found in U_3O_7 can be rationalized with different stacking order of these modules; the small change in the energy of formation of the crystal reflects the interaction between the clusters.

U_3O_8

α-U_3O_8 is orthorhombic (*C2mm*; $a = 6.716$ Å, $b = 11.96$ Å, $c = 4.1469$ Å; $z = 2$) (Loopstra, 1962). β-U_3O_8 is also orthorhombic (*Cmcm*; $a = 7.069$ Å, $b = 11.445$ Å, $c = 8.303$ Å; $z = 4$) (Loopstra, 1970b), and the crystal structures of these two modifications are very similar. Fig. 5.17 depicts the relation of α- and β-U_3O_8 with the hypothetical 'ideal' UO_3 structure. The idealized α-U_3O_8 structure (Fig. 5.17a) is derived from a layer of the hypothetical 'ideal' UO_3 (Fig. 5.17b) by removing one oxygen atom from every third row. The idealized β-U_3O_8 structure is obtained by replacing two oxygen atoms by a single one, located halfway between them (Fig. 5.17c). Fig. 5.17a and c show that the actual structures are only slightly distorted from the hypothetical ideal positions, which are represented in Fig. 5.17 by small circles (uranium atoms) and large circles (oxygen atoms). In α-U_3O_8, all uranium atoms are coordinated with oxygen atoms forming pentagonal bipyramids. In β-U_3O_8 the layers are stacked along the *c*-axis so that a set of chains of uranium atoms is formed at $x = 0$, $y = 0$ and $x = 1/2$, $y = 1/2$. The other uranium atoms form chains in the *c* direction, in which the oxygen coordination is alternately pentagonal bipyramidal and distorted octahedral.

α-U_3O_8 shows a λ-type anomaly in the specific heat at 208.5°C (Girdhar and Westrum, Jr., 1968). At this first-order phase transformation temperature, the orthorhombic pseudo-hexagonal α-U_3O_8 changes to a hexagonal structure ($P\bar{6}2m$; a = 6.812 Å, c = 4.142 Å; z = 1) (Loopstra, 1970a). Although the high- and low-temperature phases are closely related, there is an essential difference in the atom arrangement. In the high-temperature phase the uranium atoms occupy a single three-fold position, whereas at room temperature (in the low-temperature phase) they are located at two-fold and four-fold positions making it possible for the uranium atoms to have different localized charges.

Allen and Holmes (1995) pointed out the resemblance in the crystal structures of UO_2 and α-U_3O_8. The UO_2 fluorite structure can be transformed to the layer structure of α-U_3O_8 by displacing the (111) planes in UO_2. A displacement of 2.23 Å along the ⟨112⟩ direction in the (111) plane brings the outermost uranium layer directly above the second layer of the structure of α-U_3O_8.

UO_3

The crystal structure of α-UO_3 was first reported as trigonal ($P\bar{3}m1$; a = 3.971 Å, c = 4.170 Å) (Zachariasen, 1948a). However, the later neutron powder diffraction data could not be adequately described in this way. Loopstra and Cordfunke (1966) published a structure assignment using an orthorhombic unit cell ($C2mm$; a = 3.961 Å, b = 6.860 Å, c = 4.166 Å). This structure is close to the former one, since in both cases there are linear chains of O–U–O–U–O with the uranium surrounded by six additional oxygen atoms lying approximately in a plane normal to the chains. The reassignment to the orthorhombic cell reduced the R-value from 0.35 to 0.19, but this is still high. Neither of the structures proposed could explain the abnormally low experimental density and the infrared absorption spectrum; the experimental densities were 7.25 g cm^{-3} (Loopstra and Cordfunke, 1966) or 7.30 g cm^{-3} (Siegel and Hoekstra, 1971a), which are much lower than the X-ray density of 8.39 g cm^{-3}. Strong infrared absorption was observed around 930 cm^{-1} (Hoekstra and Siegel, 1961; Carnall *et al.*, 1966). This is typical of the antisymmetric stretching vibration of the linear uranyl group with the U–O bond distance of about 1.7 Å (Jones, 1959), but isolated uranyl groups do not exist in either of the above crystal structures.

A characteristic feature of a large number of solid uranium(VI) oxides is that they contain uranyl groups (UO_2^{2+}) with collinear atom arrangement (O–U–O) (Zachariasen, 1954b). The U–O bond (primary bond) of the uranyl group is a strong covalent bond (cf. Section 5.8.3c), giving short bond distances of 1.7–1.9 Å. The antisymmetric vibration of O_I–U–O_I, where O_I denotes the oxygen atoms in the uranyl group, gives rise to a strong infrared absorption in the frequency range of 600–950 cm^{-1}. The oxygen atoms (O_{II}), bound to uranium in a plane perpendicular to the linear uranyl group, form secondary bonds which are weaker than the U–O_I bonds. The U–O_{II} bond distances are longer, usually between 2.1 and 2.5 Å. The uranyl groups are often seen in the uranium oxides having layer structures. The collinear axis of the uranyl group is along the c-axis of such crystals with the four to six U–O_{II} bonds formed in the a–b plane.

Greaves and Fender (1972) carried out a structure refinement based on the assumption that α-UO_3 is formed by introducing statistically distributed vacancies into the uranium sublattice of α-U_3O_8 so as to re-establish an O/U ratio of three. For each missing uranium atom there were two displaced oxygen atoms in the z-direction. Refinement of diffraction data using this model for the α-U_3O_8 structure (space group *C*222) of Andresen (1958) decreased the R-value to 0.031 and the theoretical density to 7.44 g cm^{-3}; the U–O distance in the uranyl groups was 1.64 Å. The same refinement based on the *C*2*mm* space group of Loopstra (1962) yielded fairly reasonable values of the uranium occupation number, 0.82, and the U–O distance, 1.58 Å, but the R-value (0.13) and the uranium and oxygen temperature factors were somewhat higher. The superlattice reflections observed in both the neutron and electron diffraction patterns could be indexed on an orthorhombic unit cell with dimensions a = 6.84 Å, b = 43.45 Å, and c = 4.157 Å.

The crystal structure of high-pressure phase, ζ-UO_3, is orthorhombic ($P2_12_12_1$; a = 7.511 Å, b = 5.466 Å, c = 5.224 Å) (Siegel *et al.*, 1966). There are no uranium vacancies in this UO_3 modification as shown by the agreement of the measured density (8.62 g cm^{-3}) with the X-ray density (8.85 g cm^{-3}). In this structure each uranium atom is bonded to seven oxygen atoms, leading to shared [UO_7] configurations with bridging oxygen atoms in the plane perpendicular to the UO_2-axis, identified by two short collinear bonds of 1.80 and 1.85 Å. The other five coordinated oxygen atoms form a puckered pentagonal coordination geometry around the uranyl groups.

(*iv*) *Phase relations*

There have been numerous reports on the phase relations and thermodynamic properties of the uranium–oxygen system. Rand *et al.* (1978) made an assessment of thermodynamic data and presented a phase diagram of this system. Recently, Chevalier *et al.* (2002) and Guéneau *et al.* (2002) published critical reviews. In two recent papers Labroche *et al.* (2003a,b) critically assessed the composition range and oxygen potential of uranium oxides in the UO_2–U_3O_8 region taking into account the uncertainties of the published data.

Uranium–uranium dioxide region

Hypostoichiometric UO_{2-x} exists as a single phase or as a mixture with liquid. Since the formation energy of an oxygen vacancy in UO_2 is much higher than that of interstitial oxygen, the lower phase boundary of single phase UO_{2-x} is very close to O/U = 2.0 up to ~1500 K. In the phase diagram of Rand *et al.* (1978), this phase boundary has been obtained up to 2500 K by using the relation $\ln x = (3.877 \pm 0.094) - (13130 \pm 210)T^{-1}$ proposed by Winslow (1973) based on examination of the relevant experimental data. In the recent critical review on the thermodynamic properties in the uranium–oxygen system, Chevalier *et al.* (2002) presented the phase diagram of the U–UO_2 region by careful selection of the experimental data from Blum *et al.* (1963),

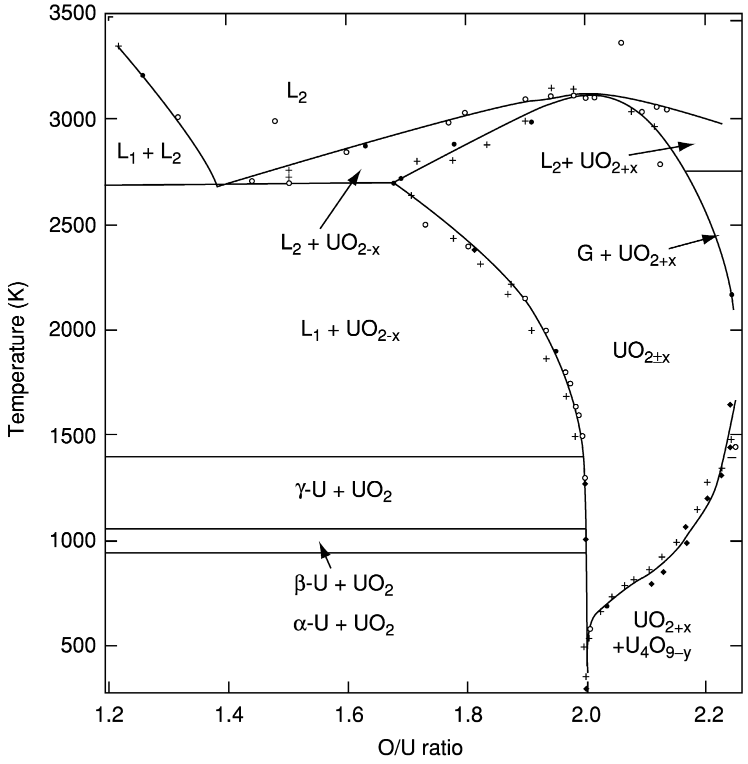

Fig. 5.18 *Partial phase diagram of the U–UO_2 system assembled from values in Rand* et al. (1978), *Chevalier* et al. (2002), *and Guéneau* et al. (2002).

Bates (1964, 1966), Martin and Edwards (1965), Edwards and Martin (1966), Guinet *et al.* (1966), Bannister (1967), Tetenbaum and Hund (1968, 1970), Ackermann *et al.* (1969), Latta and Fryxell (1970), Ackermann and Rauh (1972), Garg and Ackermann (1977, 1980), and Guéneau *et al.* (1998). Guéneau *et al.* (2002) presented the phase diagram of this region using the data from Cleaves *et al.* (1945), Martin and Edwards (1965), Edwards and Martin (1966), Bannister (1967), Hein *et al.* (1968), Ackermann *et al.* (1969), Kjaerheim and Rolstad (1969), Latta and Fryxell (1970), Tachibana *et al.* (1985), and Guéneau *et al.* (1998). Fig. 5.18 shows a phase diagram of the U–UO_2 region ($1.2 \leq$ O/U ≤ 2.0) and the UO_{2+x} region with $x \leq 0.25$ drawn by using the selected values from Rand *et al.* (1978), Chevalier *et al.* (2002), and Guéneau *et al.* (2002).

The monotectic temperatures for the reaction $L_2 = UO_{2-x} + L_1$ are (2773 ± 30) K (Edwards and Martin, 1966), (2743 ± 30) K (Guinet *et al.*, 1966) and (2693 ± 70) K (Bannister, 1967). The reported compositions of the liquid L_2 phase at the monotectic temperature are O/U = (1.3 ± 0.1) (Edwards and Martin, 1966), 1.18 (Guinet *et al.*, 1966), (1.53 ± 0.05) (Bannister, 1967) and

1.46 (Latta and Fryxell, 1970). The measured composition of the liquid L_1 phase at this temperature was O/U = 0.05 (Edwards and Martin, 1966; Latta and Fryxell, 1970). The O/U ratios of solid UO_{2-x} are in reasonable agreement: 1.67 (Latta and Fryxell, 1970; Rand *et al.*, 1978), 1.64 (Edwards and Martin, 1966), 1.60 (Guinet *et al.*, 1966), and (1.62 ± 0.06) (Bannister, 1967). The ratio O/U is decreased to ≈1.67 at the lower phase boundary of single phase UO_{2-x} at the monotectic temperature. Above the monotectic temperature the O/U ratio at the lower phase boundary increases to $UO_{2.00}$, until the maximum melting temperature is reached. At the monotectic temperature, three condensed phases, i.e. oxygen-saturated liquid uranium metal L_1 ($UO_{0.05}$), liquid L_2 of a composition $UO_{1.39}$, and solid UO_{2-x} ($UO_{1.67}$) coexist in equilibrium.

$UO_{2.00}$–$UO_{2.25}$ region

Stoichiometric uranium dioxide, UO_2, shows a first-order transition at 30.8 K. This is a magnetic transition, and below that temperature UO_2 is antiferromagnetic, with a structure of type I (Fournier and Troć, 1985), accompanied by an internal distortion in the oxygen sublattice (Faber, Jr. and Lander, 1976). At the transition temperature, a discontinuity in the lattice parameter vs temperature curve (Marples, 1976) and a sharp anomaly in the heat capacity with an entropy increment of 3.6 $J\,K^{-1}\,mol^{-1}$ (Westrum, Jr. and Grønvold, 1962; Huntzicker and Westrum, Jr., 1971) were observed.

Uranium dioxide is stoichiometric at low temperatures, but exhibits a hyperstoichiometric (UO_{2+x}) homogeneity range above 500 K; this range increases with increasing temperature. The upper phase boundary of single phase UO_{2+x} has been extensively studied at temperatures between 500 and 1950 K. The boundary increases with increasing temperature up to (1398 ± 8) K (Blackburn, 1958; Roberts and Walter, 1961; Anthony *et al.*, 1963; Belbeoch *et al.*, 1967; Blank and Ronchi, 1968; van Lierde *et al.*, 1970; Dodé and Touzelin, 1972; MacLeod, 1972; Matsui and Naito, 1975; Labroche *et al.*, 2003b), at which the U_4O_9 phase decomposes to UO_{2+x} and U_3O_{8-z} ($UO_{2.61}$) peritectoidally. The upper phase boundary of UO_{2+x} above that temperature increases only slightly with increasing temperature up to 1950 K.

The phase diagram in the region $2.0 \leq O/U \leq 3.0$ is shown in Fig. 5.19, where the upper phase boundary of UO_{2+x} was obtained by referring to the literature (Blackburn, 1958; Schaner, 1960; Aronson *et al.*, 1961; Roberts and Walter, 1961; Kiukkola, 1962; Markin and Bones, 1962a; Hagemark and Broli, 1966; Kotlar *et al.*, 1967a; Bannister and Buykx, 1974; Saito, 1974; Picard and Gerdanian, 1981; Labroche *et al.*, 2003b). The U_4O_9 phase has a narrow homogeneity range; the reported lower phase boundary is located between the O/U ratios of 2.228 and 2.235 (Blackburn, 1958; Schaner, 1960; Roberts and Walter, 1961; Kotlar *et al.*, 1968; van Lierde *et al.*, 1970; Inaba and Naito, 1973; Picard and Gerdanian, 1981; Labroche *et al.*, 2003b). This boundary is almost unchanged with temperature from room temperature to the peritectic temperature. The reported upper phase boundaries have the O/U values mostly between

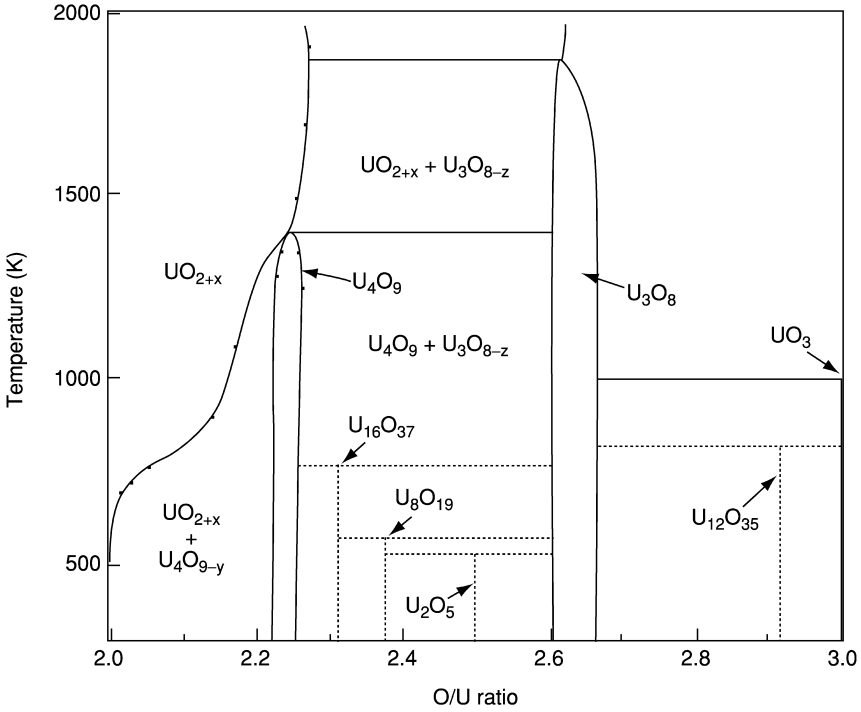

Fig. 5.19 *Phase diagram of the U–O system in the region* 2.0 ≤ *O/U* ≤ 3.0.

2.24 and 2.25 (Blackburn, 1958; Schaner, 1960; Roberts and Walter, 1961; Kotlar *et al.*, 1968; van Lierde *et al.*, 1970; Inaba and Naito, 1973; Picard and Gerdanian, 1981; Labroche *et al.*, 2003b), and many of the papers indicate the uppermost composition to have O/U = 2.242. It is generally assumed that also the upper phase boundary does not change substantially with temperature.

U_4O_9 shows no low-temperature anomaly in the heat capacity due to a magnetic transition observed for UO_2. This is interesting if one considers the close resemblance in the crystal structures between U_4O_9 and UO_2. Instead, the low-temperature modification α-U_4O_9 undergoes a non-magnetic second-order transition to β-U_4O_9 at 340–350 K giving rise to a λ-type specific heat anomaly. The enthalpy and entropy increments of this transition for $U_4O_{9\text{-}y}$ with O/U = 2.246–2.254 are 630–710 J mol^{-1} and 1.9–2.2 J K^{-1} mol^{-1}, respectively (Gotoo and Naito, 1965; Westrum, Jr., *et al.*, 1965; Grønvold *et al.*, 1970; Inaba and Naito, 1973). β-U_4O_9 transforms into γ-U_4O_9 at around 850 K. According to Bevan *et al.* (1986), the maximum O/U atom ratio of the β-U_4O_9 phase should be 2.2345 (cf. section on U_4O_9), which supports the hypostoichiometries at the upper phase boundary observed for U_4O_9. The phase transitions α/β and β/γ are reversible, as described in the crystal structure section.

$UO_{2.25}$–$UO_{2.667}$ region
Most compounds in the composition range of $2.25 \leq O/U \leq 2.5$, i.e. α- and β-U_3O_7, γ-U_3O_7 ($U_{16}O_{37}$), U_8O_{19}, and β- and γ-U_2O_5 have fluorite-type structures. α-, β-, and γ-U_3O_7 have been prepared under ambient atmosphere, but U_8O_{19} and α-, β-, and γ-U_2O_5 were formed only at high pressures (15–60 kbar). On this basis, U_8O_{19} and U_2O_5 are regarded as metastable phases, which are thermodynamically unstable at atmospheric pressure (Hoekstra *et al.*, 1970). The phases for which the stability has not been established are indicated in Fig. 5.19 by broken lines. U_3O_7 decomposes at 700°C in air to U_4O_9 and U_3O_8 (Pério, 1953a; Grønvold, 1955). Although β-U_3O_7 shows no low-temperature transitions, α-U_3O_7 exhibits a small λ-type anomaly at 30.5 K with enthalpy and entropy increments of 11 J mol^{-1} and 0.4 J K^{-1} mol^{-1}, respectively. This transition is assumed to be of magnetic origin (Westrum, Jr. and Grønvold, 1962). The other oxides $U_{13}O_{34}$ ($UO_{2.615}$) and $U_{11}O_{29}$ ($UO_{2.636}$) have been described (Kovba *et al.*, 1972; Spitsyn *et al.*, 1972), but no information is given for their stability at low temperatures and pressures.

Two modifications of U_3O_8, i.e. α- and β-U_3O_8, crystallize both in orthorhombic system and their crystal structures are very similar. These compounds are not based on the fluorite structure but are composed of the layer structures related to the hypostoichiometric ‘ideal’ UO_3 structure (Section 5.7.2a(iii)), which has uranyl bonds perpendicular to the layer planes. The difficulty to rearrange the oxygen atoms in these infinite layer structures is probably the reason for the slow equilibration between U_3O_8 and the gas phase at different temperatures and the oxygen partial pressures. The O/U ratio of the U_3O_8 phase varies with the experimental methods (Gerdanian and Dodé, 1965; Fujino *et al.*, 1981; Srirama Murti *et al.*, 1989). Labroche *et al.* (2003a) suggested that the reason for the scattered data is dissolution of atmospheric nitrogen in the oxides. Although the measured data at the lower phase boundary of U_3O_8 phase are not in good agreement above 1000 K (Labroche *et al.*, 2003b), the ratios O/U are in general between 2.595 and 2.62 (Blackburn, 1958; Hagemark and Broli, 1966; Kotlar *et al.*, 1967b; Ackermann and Chang, 1973; Caneiro and Abriata, 1984). This phase boundary does not change with temperature up to ~1600 K. Above 1000 K, the upper phase boundary was observed to have O/U = 2.667 (stoichiometric U_3O_8) up to ~1400 K (Ackermann and Chang, 1973; Caneiro and Abriata, 1984). At an ambient pressure of 0.21 atm O_2, however, the compound becomes hypostoichiometric above 873 K (Cordfunke and Aling, 1965; Rodriguez de Sastre *et al.*, 1967; Ackermann and Chang, 1973). On the other hand, at lower temperatures of 773–873 K, freshly prepared U_3O_8 samples often show hyperstoichiometry with O/U = 2.670. Moreover, a hysteresis is seen in the O/U ratio in heating and cooling cycles. Repetition of the heating and cooling cycle results in formation of compounds of lower O/U ratios (Dharwadkar *et al.*, 1975; Fujino *et al.*, 1981). Similar hysteresis phenomena for U_3O_{8-z} have also been observed in oxygen partial pressure vs O/U ratio isotherms (Caneiro and Abriata, 1984) and the electrical conductivity (Ishii *et al.*, 1970b;

Dharwadkar *et al.*, 1978). Slow formation of another phase in α-U_3O_8 may take place at temperatures of 1273–1573 K; according to Hoekstra *et al.* (1955); this is possibly the U_8O_{21} phase with a homogeneity range extending between the compositions $UO_{2.60}$ and $UO_{2.65}$. A slightly different composition range, $UO_{2.617}$–$UO_{2.655}$, has also been reported (Caneiro and Abriata, 1984). It is possible that the proper stoichiometry of β-U_3O_8 is U_8O_{21}, since β-U_3O_8 has been prepared by heating α-U_3O_8 to 1623 K followed by slow cooling to room temperature (Loopstra, 1970b). However in the majority of reports, the phase in this region of compositions is considered to be hypostoichiometric U_3O_8 (i.e. U_3O_{8-z}) (Kotlar *et al.*, 1967a; Ackermann and Chang, 1973; Labroche *et al.*, 2003a,b).

α-U_3O_8 shows a λ-type transition in the heat capacity at 25.3 K with associated enthalpy and entropy increments of 50 J mol^{-1} and 2.3 J K^{-1} mol^{-1}, respectively (Westrum, Jr. and Grønvold, 1959, 1962). This is due to a para-antiferromagnetic transition (Leask *et al.*, 1963). α-U_3O_8 shows three other transitions at higher temperatures: 490, 570, and 850 K. The reported temperature for the 490 K transition varies between 480 and 490 K (Girdhar and Westrum, Jr., 1968; Maglic and Herak, 1970; Inaba *et al.*, 1977; Naito *et al.*, 1982). For the 570 K transition, the reported temperatures are between 562 and 576 K (Inaba *et al.*, 1977; Naito *et al.*, 1982, 1983). The 850 K transition has been observed in one study using adiabatic calorimetry (Inaba *et al.*, 1977). Naito *et al.* (1983) proposed an electronic ordering on uranium atoms with displacement of oxygen atoms as the origin of the above transitions.

$UO_{2.667}$–UO_3 region

Hoekstra and Siegel (1961) regard the $UO_{2.9}$ phase ($U_{12}O_{35}$), which is formed by partial decomposition of amorphous UO_3, as a distinct compound because on heating amorphous UO_3 the O/U ratio remains virtually constant over a 100 K temperature interval from 450 to 550°C. The pycnometric density measured for $UO_{2.9}$ is considerably lower than the theoretical density. This is similar to the case of α-UO_3 assigned to a *C2mm* orthorhombic cell with $a = 3.961$ Å, $b = 6.860$ Å, and $c = 4.166$ Å (Loopstra and Cordfunke, 1966). Thus the crystal structure of $UO_{2.9}$ may also have vacant uranium sites as in the α-UO_3 structure.

For UO_3, one amorphous and six crystalline modifications are known. When α-UO_3 is heated in air with a constant heating rate, it decomposes to U_3O_8 passing through a non-stoichiometric range with the O/U ratios between 3.0 and ca. 2.95 (Hoekstra and Siegel, 1961). The δ- and ε-UO_3 compounds convert to U_3O_8 at about 450°C in air with no evidence of a non-stoichiometric oxide range. However, if the heating rate is low, they do not decompose directly, instead re-oxidation of the partially reduced oxides to γ-UO_3 takes place. Also in the γ-UO_3 there is no measurable oxygen non-stoichiometry. The γ-phase is more stable and decomposes to U_3O_8 at higher temperatures of 620–700°C. ζ-UO_3 is formed by heating U_3O_8 at 500°C under high pressures of 15–60 kbar interval produced by a pyrophyllite tetrahedral assembly. This compound is unstable at the ambient pressure (Hoekstra *et al.*, 1970). No magnetic transition has been observed for UO_3 (Jones *et al.*, 1952).

In the uranium trioxide–water system, six compounds have been well established (Dawson *et al.*, 1956; Harris and Taylor, 1962; Debets and Loopstra, 1963; Dell and Wheeler, 1963; Cordfunke and Debets, 1964; Bannister and Taylor, 1970; Taylor, 1971; Siegel *et al.*, 1972; Hoekstra and Siegel, 1973; Vita *et al.*, 1973; Tasker *et al.*, 1988). The physical properties for these compounds are listed in Table 5.15 together with those for uranium peroxide hydrates.

(*v*) *The heat capacity of UO_2*

The low-temperature heat capacity of UO_2 shows a very sharp λ-type anomaly of magnetic origin (Fournier and Troć, 1985) at 30.44 K (Huntzicker and Westrum, Jr., 1971) or 28.7 K (Jones *et al.*, 1952). The entropy increment is 3.6 J K^{-1} mol^{-1} (Westrum, Jr, and Grønvold, 1962). Faber, Jr. and Lander (1976) carried out a neutron diffraction and scattering study on this transition. They showed that the anomaly took place at 30.8 K and that it could be explained as a first-order transition from the low-temperature antiferromagnetic state of type I, associated with an internal distortion of the oxygen sublattice, to the paramagnetic state. The low-temperature (5–346 K) heat capacity data of Huntzicker and Westrum, Jr. (1971) are in good agreement with those of Grønvold *et al.* (1970) (304–1006 K) in the range of overlapping temperatures.

The high-temperature heat capacity of UO_2 has been studied extensively because of the importance of this compound as nuclear fuel; several critical reviews have also been published (Browning, 1981; Browning *et al.*, 1983; Naito, 1989; Ronchi and Hyland, 1994; Fink, 2001; Carbajo *et al.*, 2001). The selected data of heat capacities are shown in Fig. 5.20 together with the correlations calculated by the MATPRO equation (Hagrman, 1995) and by the Fink equations with functional and polynomial forms. In the figure two sets of data of Ronchi *et al.* (1999) are shown for high temperatures, and the data of Huntzicker and Westrum, Jr. (1971) and Grønvold *et al.* (1970) are shown for low and intermediate temperatures. Since the heat capacities of the functional and polynomial equations differ by at most 1%, the latter equation is recommended because of its simplicity (Fink, 2001). This equation, which is based on a combined analysis of the reported data (Moore and Kelley, 1947; Hein and Flagella, 1968; Hein *et al.*, 1968; Ogard and Leary, 1968; Leibowitz *et al.*, 1969; Fredrickson and Chasanov, 1970; Grønvold *et al.*, 1970; Huntzicker and Westrum, Jr., 1971; Ronchi *et al.*, 1999), for $298.15 \leq T \leq 3120$ K is:

$$\begin{aligned} C_\mathrm{p}(T)(\mathrm{J\ K^{-1}\ mol^{-1}}) = {} & 52.1743 + 87.951\,\tau - 84.2411\,\tau^2 + 31.542\,\tau^3 \\ & - 2.6334\,\tau^4 - 0.71391\,\tau^{-2}, \end{aligned}$$

where, $\tau = T(\mathrm{K})/1000$. The MATPRO equation (Hagrman, 1995) gives somewhat lower C_p values at higher temperatures.

The λ-type transition found by Bredig (1972) at 2670 K has been confirmed by other researchers (Hutchings *et al.*, 1984; Ralph and Hyland, 1985; Hiernaut *et al.*, 1993). Hiernaut *et al.* (1993) modeled the transition in $UO_{2.00}$ as

a second-order transition involving oxygen Frenkel disorder. The transition temperature of hypostoichiometric uranium dioxide (UO_{2-x}) increases with increasing x. Their model explains the shift as due to the change from a λ-transition to a first-order phase transition in UO_{2-x}.

The discussion on the heat capacity of UO_2 can be divided into the following four regions (Ronchi and Hyland, 1994):

(1) *Room temperature – 1000* K *region*. The increase in the heat capacity is caused by the harmonic lattice vibrations with a smaller contribution from thermal excitation of localized electrons of U^{4+} in the crystal field.

(2) *1000–1500* K *region*. The heat capacity increases with increasing anharmonicity of the lattice vibrations as shown by thermal expansion.

(3) *1500–2670* K *region*. The heat capacity increase in this region is mainly ascribed to the formation of lattice and electronic defects. The C_p peak at 2670 K is due to the oxygen Frenkel defects as determined by neutron scattering measurements.

(4) *Region above 2670* K. The peak of the heat capacity drops sharply by rapid saturation of the defects. At temperatures from 2700 K to the melting point, the concentration of Schottky defects increases.

(*vi*) *Oxygen potential and other thermodynamic properties*

A large number of reports have been published on the partial molar thermodynamic quantities $\Delta\bar{G}(O_2)$, $\Delta\bar{H}(O_2)$, and $\Delta\bar{S}(O_2)$ for non-stoichiometric uranium oxides. These studies have been carried out mainly by means of thermogravimetric method (Gerdanian, 1964; Gerdanian and Dodé, 1965; Hagemark and Broli, 1966; Kotlar *et al.*, 1967b; Ugajin, 1983; Matsui and Naito, 1985a) and emf method (Aronson and Belle, 1958; Kiukkola, 1962; Markin and Bones, 1962a,b; Marchidan and Matei, 1972; Saito, 1974; Nakamura and Fujino, 1987); however, tensimetric (Roberts and Walter, 1961), quenching (Anthony *et al.*, 1963), and Knudsen effusion (Blackburn, 1958) techniques have also been used.

In the two-phase regions of solid oxides, the equilibrium oxygen pressure over uranium oxides, p_{O_2}(atm), which is related with the oxygen potential of the oxides $\Delta\bar{G}(O_2)$ by the equation $\Delta\bar{G}(O_2) = RT \ln p_{O_2}$, is a function of only temperature. For the UO_{2+x}–U_4O_{9-y} two-phase region, Saito (1974) showed that $\log p_{O_2}$ is:

$$\log p_{O_2}(\text{atm}) = -105.7 - 5136\,T^{-1} + 33.46 \log T \tag{5.1}$$

The previous equation describes the measured data from the literature (Aronson and Belle, 1958; Blackburn, 1958; Roberts and Walter, 1961; Kiukkola, 1962; Markin and Bones, 1962b; Kotlar *et al.*, 1967b; Marchidan and Matei, 1972; Saito, 1974; Nakamura and Fujino, 1987), although it gives gradually too low values at temperatures above 1323 K (Roberts and Walter, 1961; Nakamura and Fujino, 1987).

For the U_4O_9–U_3O_{8-z} two-phase region, $\log p_{O_2}$ is represented by (Saito, 1974)

$$\log p_{O_2}(\text{atm}) = 7.996 - 16\,330\,T^{-1} \tag{5.2}$$

or (Roberts and Walter, 1961)

$$\log p_{O_2}(\text{atm}) = 8.27 - 16\,760\,T^{-1}. \tag{5.3}$$

The difference in $\log p_{O_2}$ of equations (5.2) and (5.3) is 0.20 at $T = 900$ K, which decreases to 0.033 at $T = 1400$ K.

The oxygen potential of UO_{2+x} in the single-phase region is a function of the composition x and temperature. A number of experimental $\Delta\bar{G}(O_2)$ isotherms plotted against O/U ratio of UO_{2+x} for various temperatures in the range 1173–1773 K have been reported (Aukrust *et al.*, 1962; Markin and Bones, 1962a,b; Hagemark and Broli, 1966; Ugajin, 1983; Matsui and Naito, 1985a). The scatter in the experimental $\Delta\bar{G}(O_2)$ data seems to increase as the O/U ratio decreases in the composition range below 2.01, where $\Delta\bar{G}(O_2)$ rapidly decreases with decreasing O/U ratio.

Fig. 5.21 shows $\Delta\bar{G}(O_2)$ for UO_{2+x} as a function of the O/U ratio expressed by an equation which consists of component equations giving experimental values in polynomial forms (Nakamura and Fujino, 1987) with small modifications for

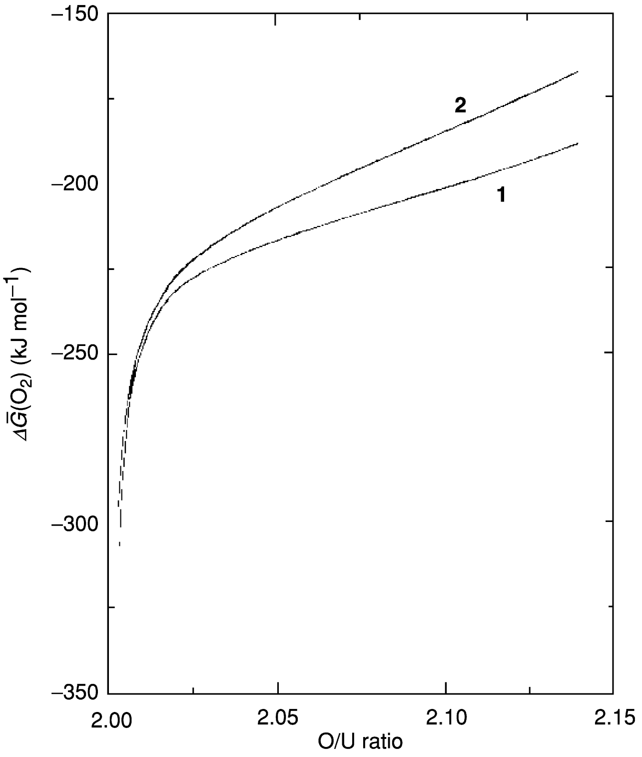

Fig. 5.21 *Oxygen potential as a function of O/U ratio. Curve* 1, 1173 K; *curve* 2, 1373 K.

$\Delta\bar{G}(O_2)$ below O/U = 2.02. The lowest O/U ratio shown in the figure is 2.003, below which the $\Delta\bar{G}(O_2)$ values approach those at $x = 0$, i.e. –633.3 and –588.4 kJ mol^{-1} for 1173 and 1373 K, respectively. These values are obtained from the equation $\Delta\bar{G}(O_2) = -897\,000 + 224.8\ T$ J mol^{-1} at $x = 0$ assessed by Lindemer and Besmann (1985) for temperatures between 873 and 1673 K.

The partial molar entropy of oxygen, $\Delta\bar{S}(O_2) = -\mathrm{d}\Delta\bar{G}(O_2)/\mathrm{d}T$, was in most papers regarded as temperature independent and on this basis differentiation of $\Delta\bar{G}(O_2)$ was made without specifying temperature. There have been rather wide scattering in the reported values of the partial molar enthalpy of oxygen, $\Delta\bar{H}(O_2)$, and the entropy, $\Delta\bar{S}(O_2)$. This is significantly reduced when $\Delta\bar{S}(O_2)$ is treated as a temperature-dependent quantity: $\mathrm{d}\Delta\bar{S}(O_2) = \bar{C}_p(O_2)\mathrm{d}T/T$ where $\bar{C}_p(O_2)$ is the partial molar heat capacity of oxygen expressed as a polynomial of $\log x$ (Nakamura and Fujino, 1987). In this case, $\Delta\bar{H}(O_2)$ also becomes temperature-dependent because of the relation $\Delta\bar{H}(O_2) = \Delta\bar{G}(O_2) + T\Delta\bar{S}(O_2)$.

Fig. 5.22a compares the calculated $\Delta\bar{H}(O_2)$ vs x curves obtained by using the above $\bar{C}_p(O_2)$ values with the literature data. Fig. 5.22b compares the $\Delta\bar{S}(O_2)$ vs x curves. The derived $\Delta\bar{H}(O_2)$ curve at 1323 K is in good agreement

with the measured curve of Picard and Gerdanian (1981). Most reported values of the temperature-independent $\Delta\bar{H}(O_2)$ and $\Delta\bar{S}(O_2)$ are within the curves derived using temperature-dependent $\Delta\bar{H}(O_2)$ and $\Delta\bar{S}(O_2)$ in the range 1073–1323 K.

Labroche *et al.* (2003a) made a critical assessment of the thermodynamic data for UO_{2+x} taking into account the uncertainties in the measurements. The result showed that $\log p_{O_2}$ could be represented by equations of the form $\log p_{O_2} = A - BT^{-1}$ with A and B varying with the O/U ratio in the range 2.01–2.23. On the other hand, this treatment revealed that the x dependence of $\log p_{O_2}$ could not be given with adequate accuracy by the above simple formulas if the temperature range is larger.

Gerdanian and Dodé (1968) determined $\Delta\bar{H}(O_2)$ by measuring the evolved heat when a small amount of oxygen was passed over UO_{2+x} in a Calvet-type microcalorimeter. This technique made it possible to measure $\Delta\bar{H}(O_2)$ close to the stoichiometric composition as shown in Fig. 5.23.

In this figure, $\Delta\bar{H}(O_2)$ increased very sharply with increasing O/U ratio from <–800 kJ mol^{-1} at $UO_{2.0003}$, and then attained a maximum of about

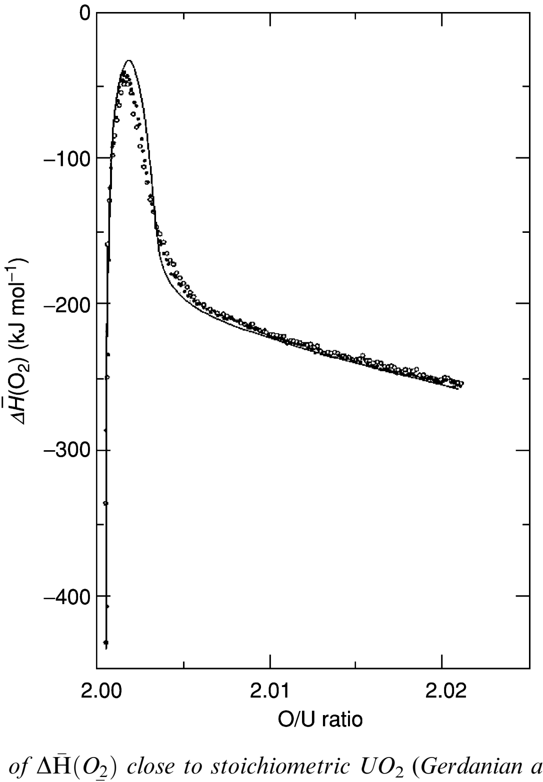

Fig. 5.23 *Change of* $\Delta\bar{H}(O_2)$ *close to stoichiometric* UO_2 (*Gerdanian and Dodé*, 1968). •: run 1; ○: *run* 2;———: $\Delta\bar{H}(O_2)$ *corrected for systematic experimental errors.*

–29 kJ mol^{-1} at $UO_{2.0018}$. The curve afterwards decreased and became progressively linear above O/U = 2.01.

No significant anomaly has been observed for $\Delta\bar{G}(O_2)$ in the above composition range (Markin and Bones, 1962a), though precise determination could not be made at small O/U ratios near stoichiometric UO_2 due to rapid change of $\Delta\bar{G}(O_2)$. When there is no anomaly in $\Delta\bar{G}(O_2)$, $\Delta\bar{S}(O_2)$ should have the sharp peak at the same composition as $\Delta\bar{H}(O_2)$. Gerdanian (1974) showed that the $\Delta\bar{H}(O_2)$ anomaly could be well described by assuming that the formation of the Willis (2:2:2) cluster is the predominant reaction. At the same time he commented that the choice of cluster structures and ionic charges was not crucial and it could be changed if another appropriate and consistent set of $\Delta\bar{H}(O_2)$ and $\Delta\bar{S}(O_2)$ was selected. Actually, the $\Delta\bar{H}(O_2)$ anomaly can also be interpreted by the oxygen Frenkel disorder and Willis (2:1:2) cluster formation reactions coupled with the intrinsic hole–electron formation reaction (Nakamura and Fujino, 1986).

(*vii*) *Vaporization of* UO_2

The vaporization of uranium oxides has been studied mainly on stoichiometric and hypostoichiometric uranium dioxides. The vaporization data concerning U_3O_8 and U_4O_9 phases (Ackermann *et al.*, 1960; Ackermann and Chang, 1973) have attracted only little attention (Naito and Kamegashira, 1976). The vaporization behavior of uranium dioxide may be discussed for the temperature regions below and above the melting point. In the region below the melting point, vaporization has been studied using a variety of techniques such as Knudsen mass effusion, Langmuir surface evaporation, mass spectrometry, and transpiration. The important gaseous species are U(g), UO(g), UO_2(g), UO_3(g), O(g), and O_2(g). The transpiration method can only give total pressures. The partial pressures of each of the uranium-bearing species are measured by means of the Knudsen cell - mass spectrometer technique. In the temperature range 1890–2420 K, the partial pressure of UO_2(g) measured by the latter method (Pattoret *et al.*, 1968) was $\log p_{UO_2}(\text{atm}) = 8.60 - 30850\,T^{-1}$.

In order to obtain the total pressure, it is necessary to measure the pressures of the other gaseous species. However, since the partial pressure p_{UO_2} over uranium dioxide near the stoichiometric composition is (94 ± 3)% of the total pressure at 2150 K (Pattoret *et al.*, 1968; Ackermann *et al.*, 1979), the total pressure is very close to p_{UO_2}. Ackermann *et al.* (1979) compared, at 2150 K, the reported values of the total pressure (10^{-6} atm), the apparent heat of sublimation (kJ mol^{-1}) obtained from a plot of log p_{total} versus $1/T$, and the apparent entropy of sublimation for UO_2(s) (J K^{-1} mol^{-1}). The values are 1.21, 596.2, and 164 (Ackermann *et al.*, 1956); 1.91, 627.6, and 182 (Ivanov *et al.*, 1962); 0.577, 587.9, and 154 (Voronov *et al.*, 1962); 1.32, 635.1, and 183 (Ohse, 1966); 0.914, 589.5, and 159 (Alexander *et al.*, 1967); 1.97, 617.1, and 178 (Gorban, *et al.*, 1967); 1.81, 590.8, and 165 (Pattoret *et al.*, 1968) and 1.16, 598.7, and 165 (Tetenbaum and Hunt, 1970), respectively. The ΔH_V values spread in a range from 585 to 635 kJ mol^{-1}. The Langmuir method (Voronov *et al.*, 1962) yields low total pressures. The pressure data obtained by the transpiration method (Alexander *et al.*, 1967; Tetenbaum and Hunt, 1970) also tend to be low, which is supposed to be caused by more rapid loss of material giving rise to composition gradient in uranium dioxide during transpiration evaporation. The transpiration total pressures in the form of $\log p_{\text{total}} = A - BT^{-1}$, measured at temperatures between 2500 and 2900 K for $UO_{1.88}$(s) (Szwarc and Latta, 1968), were in good agreement with those of Tetenbaum and Hunt (1970) measured over the temperature range 2080–2705 K, but the total pressures for $UO_{1.92}$ (s) and $UO_{1.94}$ (s) were low; approximately two-third to half of the values of Tetenbaum and Hunt (1970).

For hypostoichiometric uranium dioxide, the pressure of UO(g) becomes comparable to p_{UO_2}or, depending on the composition of the solid, higher than p_{UO_2}. Storms (1985) measured p_{UO} as a function of composition between U(l) + UO_{2-x}(s), and $UO_{2.0}$(s) in the temperature range 1667–2175 K using a mass spectrometer equipped with a tungsten Knudsen cell. The gas-phase reaction $2UO_2(g) = UO(g) + U(g)$ was assumed to be in equilibrium in the cell and its equilibrium constant should be independent of the solid composition. Thus, the uranium activity, a_U, and the partial enthalpy of vaporization of U(g), $\Delta\bar{H}_U$, were obtained by adopting the two-phase mixture U(l) + UO_{2-x}(s) as the reference in which a_U was measured to be unity below 2100 K. The partial pressures of U(g), UO(g), and UO_2(g) were expressed as a function of temperature and a_U. From the gas-phase equilibrium $UO_3(g) + UO(g) = 2UO_2(g)$, p_{UO_3} was also given as a (T, a_U) function using the $\Delta_f G^o(UO_3, g)$ data. The pressures p_U and p_{UO_2} were then obtained in terms of temperature, a_U, and $\Delta_f G^o(UO_2, s)$. The partial pressures and the total pressures over various compositions of UO_{2-x}(s) at 2000 K are shown in Fig. 5.24.

The sum of the partial pressures of U(g), UO(g), and UO_2(g) over U(l) + UO_2(s) at 2300 K was in good agreement with that of Ackermann *et al.* (1969), but it was about one-third that of Pattoret *et al.* (1968). The partial pressures of O_2 over U(l) + UO_{2-x} measured recently by Baïchi *et al.* (2002) using the twin-cell method are, for example, $\sim 1 \times 10^{-19}$, $\sim 1 \times 10^{-18}$, and $\sim 1 \times 10^{-17}$ atm for 2000, 2100, and 2200 K, respectively. The above O_2 pressure at 2000 K is in accord with that of Fig. 5.24.

The congruently vaporizing composition (CVC) changes with temperature as reported in the literature (Ackermann *et al.*, 1960, 1969; Pattoret *et al.*, 1968; Edwards *et al.*, 1969). The calculated relation between temperature and the O/U ratio for CVC by Storms (1985) is in reasonable accord with these data: Up to 2100–2200 K, CVC is O/U = 2.00. As the temperature rises above these temperatures, CVC decreases nearly linearly with increasing temperature to O/U = 1.95–1.96 at 2700 K.

The total vapor pressures over uranium dioxide above its melting point measured by the transpiration technique (Reedy and Chasanov, 1972), pulsed

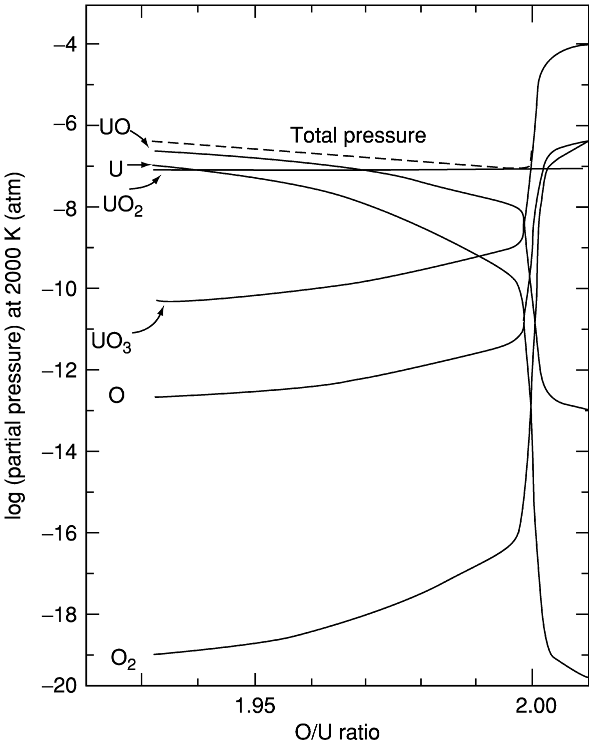

Fig. 5.24 *Partial pressures and total pressure over UO_{2-x} of various compositions at* 2000 K (*from Storms*, 1985, *reproduced by the permission of Elsevier*).

laser surface heating (Asami *et al.*, 1975; Bober *et al.*, 1975; Tsai *et al.*, 1975; Babelot *et al.*, 1977), and electron beam heating (Benson, 1977) have been compared by Ohse *et al.* (1979). In the latter monograph, a discussion was made of the methods to measure the equilibrium pressure from the evaporation rate of the gaseous species generated by dynamic, non-equilibrium pulse heating techniques. The upper temperature limit of the transpiration measurements was 3400 K for hypostoichiometric uranium dioxide of O/U = 1.94 (Reedy and Chasanov, 1972). The total pressure data above 4200 K showed a small curvature toward high pressures due to the composition change of liquid uranium dioxide to hypostoichiometry (Babelot *et al.*, 1977). In the case where the correction was made for this deviation by normalizing to O/U = 2.00 in forced congruency evaporation mode, a straight line was obtained in the $\log p_{\text{total}}$ vs. $1/T$ plot. The scattering of the corrected data (Asami *et al.*, 1975; Bober *et al.*, 1975; Tsai *et al.*, 1975; Babelot *et al.*, 1977; Benson, 1977) around the straight line is reasonable in the temperature range 3120–5000 K.

The suggested total pressure up to 5000 K by the IAEA Specialists' Meeting (1978) is

$$\log p_{\text{total}}(\text{MPa}) = 28.65 - 34\,930\,T^{-1} - 5.64 \log T.$$

The data of the equation of state for UO_2 were obtained using the principle of corresponding states (Browning *et al.*, 1978), the method of rectilinear diameters (Partington, 1949; Ohse *et al.*, 1979), and significant structure theory (Vilcu and Misdolea, 1967; Lu *et al.*, 1968). The values of critical temperature, T_c(K), critical pressure, p_c(atm), and critical density, ρ_c(g cm^{-3}) calculated by means of the principle of corresponding states are: 7300, 1915, and 3.16 (Meyer and Wolfe, 1964); 7300, 1900, and 3.16 (Menzies, 1966). The values obtained by the method of rectilinear diameters are 9110, 1230, and 1.59 (Miller, 1965). Gillan (1975) obtained the critical values on the basis of the significant structure theory. The values changed greatly when using the vapor pressures measured over UO_2(s) at lower temperatures from 6960, 1070, and 1.64 (Ohse, 1966) to 9330, 1450, and 1.63 (Tetenbaum and Hunt, 1970), respectively. Fischer *et al.* (1976), obtained the values 7560, 1210, and 1.66 using the experimental data of Ohse (1966).

(*viii*) *Diffusion*

Oxygen self-diffusion in hypostoichiometric uranium dioxide takes place by the vacancy mechanism. The self-diffusion coefficient, D^*, is expressed as

$$D^* \cong D_V^O = A_V \theta_V (1 - \theta_V) \exp(-\Delta H_V^O / RT),$$

where D_V^O, A_V, θ_V and ΔH_V^O are the oxygen self-diffusion coefficient of vacancy, pre-exponential factor, oxygen vacancy concentration (site fraction), and migration enthalpy of vacancy motion, respectively. Most of the observed values for ΔH_V^O are between 48 and 58 kJ mol^{-1} (Matzke, 1981, 1987; Bayovlu and Lorenzelli, 1984). Kim and Olander (1981) report 48.9 kJ mol^{-1}. The theoretically calculated enthalpy is 52 kJ mol^{-1} (Jackson *et al.*, 1986).

For stoichiometric UO_2, the oxygen diffusion mechanism changes with temperature: At low temperatures, thermal oxygen vacancies are the primary species contributing to oxygen mobility, whereas thermal interstitial oxygens predominate at high temperatures. In the range of 800–1800°C, both defects have significant mobility. Calculation suggests $D_i \approx D_V$ at 1400°C (Kim and Olander, 1981). The activation enthalpy of oxygen migration for stoichiometric UO_2, Q, has been determined to be 247 kJ mol^{-1} (Marin and Contamin, 1969), which is related to the enthalpy of oxygen Frenkel defect formation, H_F, by $Q = \Delta H_V^O + H_F/2$. This equation gives $H_F = 396$ kJ mol^{-1} for $\Delta H_V^O = 50$ kJ mol^{-1} (Murch and Catlow, 1987).

For hyperstoichiometric uranium dioxide, UO_{2+x}, the oxygen self-diffusion is considered to occur via the structural interstitial oxygen ions. By plotting D^* against $1/T$, the migration enthalpy of interstitial oxygens, ΔH_i^O, has been measured to be ca. 96 kJ mol^{-1} (Belle, 1969; Contamin *et al.*, 1972; Murch and Catlow, 1987) or 99.6 kJ mol^{-1} (Breitung, 1978) for x values between 0.01 and 0.1. The calculated $\Delta H_{\mathrm{i}}^{\mathrm{O}}$ value is 62 kJ mol^{-1} (Jackson *et al.*, 1986).

The chemical diffusion coefficient of oxygen, $\tilde{D}^{\mathrm{O}}$, describes the movement of oxygen ions under the oxygen concentration gradient of hyperstoichiometric UO_{2+x}; it is expressed as (Lay, 1970; Breitung, 1978):

$$\tilde{D}^{\mathrm{O}} = D^{*}\,\frac{(2+x)}{2RT}\,\frac{\mathrm{d}[\Delta\overline{G}(\mathrm{O}_2)]}{\mathrm{d}x}$$

The $\tilde{D}^{\mathrm{O}}$ values are higher than the oxygen self-diffusion coefficient, D^{*}, by several orders of magnitude. The $\tilde{D}^{\mathrm{O}}$ values calculated by the above equation are comparable with the experimental values for the x values up to 2.14 (Marin, 1968; Bittel *et al.*, 1969; Carter and Lay, 1970; Lay, 1970).

Uranium self-diffusion in uranium dioxide also depends on oxygen non-stoichiometry. For $x \geq 0$, the uranium vacancies are mainly responsible for uranium diffusion, while in the range of significant hypostoichiometry the interstitial uranium atoms become predominant. The activation enthalpies of uranium migration, Q_{U}, were measured to be 540 and 250 kJ mol^{-1} for UO_2 and UO_{2+x}, respectively (Matzke, 1987).

The calculated Q_{U} values are 1200 and 750 kJ mol^{-1} for UO_2 and UO_{2+x}, respectively (Jackson *et al.*, 1986). The uranium self-diffusion coefficient, D_{U}^{*}, is smaller than oxygen diffusion coefficient, D^{*}, by a factor of 10^5 at 1400°C. Another feature is the pronounced dependence of D_{U}^{*} on non-stoichiometry. D_{U}^{*} increases approximately proportionally with increasing x^2 from UO_2 to $\mathrm{UO}_{2.20}$ at 1400–1600°C by about five orders of magnitude (Marin and Contamin, 1969).

(*ix*) *Electrical conductivity*

UO_2, UO_{2+x}

The electrical conductivity of hyperstoichiometric uranium dioxide is caused by positive holes (Tagawa *et al.*, 1975). Although the measured values of mobility of the holes are scattered over a rather wide range, viz. from 0.0015 cm^2 V^{-1} s^{-1} at room temperature (Nagels *et al.*, 1964) to 0.021 cm^2 V^{-1} s^{-1} at 600°C or 0.055 cm^2 V^{-1} s^{-1} at 1100°C (Aronson *et al.*, 1961), these mobilities are much lower than those for usual band-type semiconductors for which the mobility is larger than 1 cm^2 V^{-1} s^{-1} (Tuller, 1981).

To explain the above conduction behavior of uranium dioxide, the small polaron model is used, where the holes are assumed to move in the oxide structure dragging the local distortion of the lattice caused by the electrical interaction. de Coninck and Devreese (1969) measured the electrical conductivity and thermoelectric power of UO_{2+x} having $x = 0.001$ and reported that the small polaron model could be applied with a nearly linear dependence of $\ln(\sigma T^{3/2})$ against $1/T$, where σ is the electrical conductivity. The holes and electrons are localized on individual atoms, giving the species of U^{5+} and U^{3+}, respectively; the electrical conduction occurs as a result of their hopping in the crystal (Catlow and Pyper, 1979). For wider range of x values of UO_{2+x}, the electrical conductivity follows (Aronson *et al.*, 1961; Winter, 1989)

$$\sigma T = 3.8 \times 10^6 (n+p)(1-n-p)e^{-0.3/kT},$$

where n and p are the electron and hole concentrations, respectively. The activation energy of conduction was measured to be 0.3 eV.

Based on Seebeck data, Winter (1989) claims the same mobility for electrons and holes in UO_{2+x}. The ratio σ_p/σ_n is larger than 1 for $x > 0$, and smaller than 1 for $x < 0$. Since one of the electronic defects always has a concentration higher than that of the ionic defects and the electronic mobilities are much higher, the ionic conductivity is insignificant. The conductivities for nominally stoichiometric UO_2 with $x \sim 10^{-3}$ can be represented by the above equation (Bates *et al.*, 1967; Winter, 1989). At $x = 0$, the intrinsic conductivity by the U^{5+} and U^{3+} charge carriers produced by a disproportionation reaction $2U^{4+} = U^{5+} + U^{3+}$ becomes important. The above reaction parameters were given by a band gap of 2 eV and a vibrational entropy of $2k$ (Winter, 1989).

For UO_{2+x} at 500–1400°C, the electrical conductivities plotted against x decrease nearly linearly with decreasing x below $x = 0.1$ in the direction $\sigma \rightarrow 0$. The conductivity changes in the different measurements, but there is a fairly good consistency in the σ values of the samples having larger x values: For $x = 0.1$ at 1000°C, for example, $\sigma \approx 30\ \Omega^{-1}\ \mathrm{cm}^{-1}$ (Aronson *et al.*, 1961), which is close to the conductivity obtained by Dudney *et al.* (1981). The other reported values are $\approx 10\ \Omega^{-1}\ \mathrm{cm}^{-1}$ (Matsui and Naito, 1985b) and $\approx 1.5\ \Omega^{-1}\ \mathrm{cm}^{-1}$ (Ishii *et al.*, 1970c), while the measured values of Lee (1974) are much lower.

U_3O_{8-z}

There are no large differences in the electrical conductivity between U_3O_{8-z} and UO_{2+x}. The conductivities for U_3O_{8-z} are $\sigma \approx 10^{-1}$ and $10^{-3}\ \Omega^{-1}\mathrm{cm}^{-1}$ at 730 and 230°C, respectively, when the oxygen partial pressure is 150 mmHg. Contrary to the conduction behavior of UO_{2+x}, however, σ for U_3O_{8-z} increases with decreasing p_{O_2} (in the range 10^2 to 10^{-2} mmHg O_2), suggesting that the main carriers are electrons (George and Karkhanavala, 1963). A change of slope in the $\log \sigma$ vs $1/T$ plots, resulting from a phase transition, was observed at 723 K. The activation energies of conduction were 0.64 and 1.10 eV below and above the transition, respectively. The transition temperature varies with non-stoichiometry from 658 K ($UO_{2.667}$, i.e. stoichiometric U_3O_8) to 923 K ($UO_{2.558}$ to $UO_{2.650}$) (Ishii *et al.*, 1970b). At higher temperatures of 1111–1190 K, another σ anomaly has been measured, presumably due to the formation of U_8O_{21+x} (Dharwadkar *et al.*, 1978).

(x) *Chemical properties*

UO_2 is oxidized to U_3O_8 on heating in air at temperatures of 600–1300°C. When UO_3 is heated in air above 600°C, the compound is reduced to U_3O_8. U_3O_8 has been used as a standard material for chemical analysis of uranium oxides

Table 5.16 *Reactions of uranium oxides.*

		Products of the following oxides		
Reagent	*Temperature* (°C)	*UO_2*	*U_3O_8*	*UO_3*
H_2(g)	>750	—	UO_2	UO_2
CO(g)	>750	—	UO_2	UO_2
HF(g)	550	UF_4	$UO_2F_2 + UF_4$	UO_2F_2
F_2(g)	400	UF_6 (>500°C)	UF_6	UF_6
CCl_4(g)	400	UCl_4	$UCl_4 + UCl_5$	$UCl_4 + UCl_5$
$SOCl_2$(g)	450	UCl_4	UCl_4	UCl_4
H_2S(g)	1000	UOS	UOS	UOS
C(s)	1500–1700	UC (UC_2)	UC (UC_2)	UC (UC_2)
C(s) + Cl_2(g)	1000	UCl_4	UCl_4	UCl_4
C(s) + CS_2(g)	1000	US_2	US_2	US_2
C(s) + N_2(g)	1700–1900	UN	UN	UN

because of its high stability in air. However, U_3O_8 is now recognized as a compound that is rather difficult to obtain in strictly stoichiometric composition; the O/U ratio deviates significantly from 8/3 depending on the heating temperature, time, and thermal history.

Stoichiometric UO_2 can be obtained by heating uranium oxides in H_2 or CO gas streams at temperatures 750–1700°C (Table 5.16). However, if the H_2 gas contains an O_2 impurity, the formed UO_2 is oxidized to non-stoichiometric UO_{2+x} during the cooling process at temperatures below 300°C. The reaction of UO_2 with air at room temperature deserves special attention, as the reaction is dependent on particle size and reactivity. Very fine UO_2 powder formed by the hydrogen reduction at lower temperatures below 800°C may be pyrophoric. Even though large particles are usually not pyrophoric, the O/U ratio increases steadily with time of exposure to air. UO_2 can take up appreciable quantities of oxygen for particle diameters of about 0.05–0.08 μm. When the particle size is 0.2–0.3 μm or larger, UO_2 is fairly stable to oxidation (Belle, 1961). UO_2 pellets sintered at around 1700°C are not oxidized for years due to protection by slightly oxidized thin surface films.

Some reactions of uranium oxides with chemical reagents are shown in Table 5.16. For the reaction with C(graphite), the product is UC if the mixing mole ratio of carbon and UO_2 is $C/UO_2 = 3$, and UC_2 if $C/UO_2 = 4$.

An interesting reaction between uranium oxides and liquid N_2O_4 has been observed (Gibson and Katz, 1951). Anhydrous uranium oxides react with liquid N_2O_4 to yield $UO_2(NO_3)_2 \cdot N_2O_4$. A similar reaction with N_2O_5 (Gibson *et al.*, 1960) may be used to prepare anhydrous $UO_2(NO_3)_2$. It was found that the reaction between metal and liquid N_2O_4 also gives $UO_2(NO_3)_2 \cdot N_2O_4$ (Addison and Hodge, 1961).

Uranium oxides dissolve in mineral acids such as HNO_3, $HClO_4$, HCl, and H_2SO_4. In HCl, H_2SO_4, and strong phosphoric acid, the mean valence of uranium does not change from that in the solid state before dissolution. Sintered UO_2 pellets dissolve in HNO_3 with a slow rate, but the dissolution can be accelerated if a small amount of NH_4F is added, due to the formation of fluoro-complexes of uranium. The addition of a small amount of H_2O_2 to HNO_3 is also effective to enhance the dissolution rate of UO_2 in laboratory experiments; in this way no contamination of the solution takes place.

The mechanism of dissolution of UO_2 in H_2O_2 aqueous solution has been studied by a number of researchers. It is regarded as a second-order reaction with a rate constant 8×10^{-7} m min^{-1} (based on the surface-to-solution volume ratio) (Ekeroth and Jonsson, 2003). The plausible mechanism is a slow electron transfer step producing $UO^{+}_{2(\mathrm{surface})} + OH^{\bullet}$ followed by a rapid reduction of the radical $OH^{\bullet}$ to OH^{-}. The $UO^{+}_{2(\mathrm{surface})}$ ions are oxidized to $UO^{2+}_{2(\mathrm{surface})}$ by $OH^{\bullet}$ or by disproportionation (Shoesmith and Sunder, 1994; Ekeroth and Jonsson, 2003). Carbonate ions increase the solubility of $UO^{2+}_{2(\mathrm{surface})}$ (Grenthe *et al.*, 1984). The above mechanism is consistent with the results by other oxidants, viz. $IrCl_6^{2-}$, MnO_4^{-}, $Fe(EDTA)^{-}$, $CO_3^{\bullet -}$, $HO_2^{\bullet}$, and O_2 (Bard and Parsons, 1985; Wardman, 1989; Huie *et al.*, 1991).

(b) Alkali metal uranates and alkaline-earth metal uranates

In Table 5.17, some physico-chemical properties and crystal structures are shown for ternary alkali metal uranates and alkaline-earth metal uranates.

(*i*) *Uranates*(*VI*)

The most frequently encountered uranates(VI) are a series of compounds of types $M_2^{+}U_nO_{3n+1}$ (M^{+}: alkali metals) and $M^{2+}U_nO_{3n+1}$ (M^{2+}: alkaline-earth metals), but other compounds such as $M_4^{+}UO_5$, $M_2^{2+}UO_5$, $M_3^{2+}UO_6$, and $M_2^{2+}U_3O_{11}$ are also well known.

Preparation

Carbonates, nitrates, or chlorides of alkali or alkaline-earth elements are mixed with the calculated amounts of U_3O_8 or UO_3. Uranates(VI) are obtained by heating the mixtures in air or oxygen at temperatures 500–1000°C. Because of higher volatility of rubidium and cesium oxides, the uranates of these elements are prepared by heating at lower temperatures of 600–700°C (Hoekstra, 1965). The alkaline-earth oxides are also used as starting materials. Reaction temperatures above 1000°C can be used for the preparation of alkaline-earth uranates on account of very low vapor pressures of alkaline-earth oxides.

A number of stoichiometric sodium uranates (α- and β-Na_2UO_4, $Na_2U_2O_7$, α-Na_4UO_5, etc.) have been prepared following a procedure described by Jayadevan *et al.* (1974) by calcining well-characterized thermally labile double sodium uranium salts such as carbonates, oxalates, and acetates. This technique avoids high-temperature treatment and decreases losses by vaporization. This is

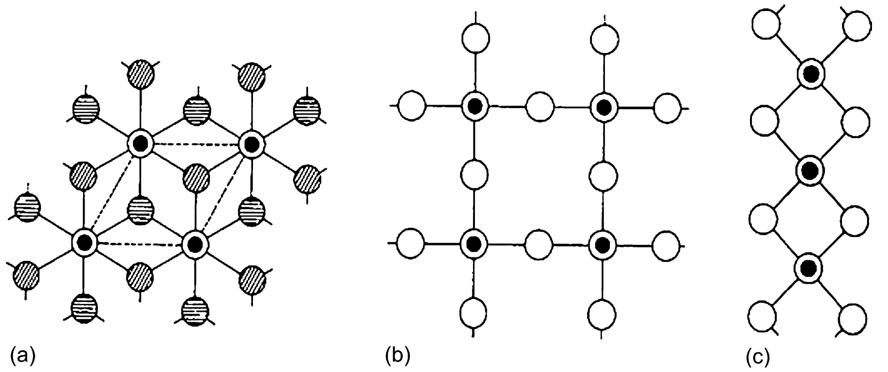

Fig. 5.25 *Schematic atom arrangement around a uranyl group (Zachariasen, 1954b); the notation is as follows: ◉: the inner filled circles show U in the plane of the page; the outer empty circles denote O_I, one above and the other below the plane of the page; ○: denotes O_{II} in the plane of the page; ◍: denotes O_{II} slightly above the plane of the page and ⊜: denotes O_{II} slightly below the plane. (a) Hexagonal coordination by six O_{II} atoms (β-Li_2UO_4, $CaUO_4$, α-$SrUO_4$). Each uranium atom is coordinated with six oxygen atoms in an approximately planar arrangement. The axis of the collinear U_I–U–O_I group is normal to the plane of the page. (b) Tetragonal coordination by four O_{II} atoms forming an infinite plane ($BaUO_4$). Uranium is octahedrally coordinated by four O_{II} atoms and two O_I atoms. Each octahedron shares four corners with adjacent octahedra forming a layer structure extended in the bc plane. The Ba atoms are located between the layers and link them by electrostatic force. (c) Tetragonal coordination by four O_{II} atoms forming an infinite chain ($MgUO_4$). The octahedra share two opposite edges, resulting in formation of chains along the a-axis. Reproduced by the permission of the International Union of Crystallography.*

discussed in Tso *et al.* (1985). Note that the technique is also discussed by Keller (1972) for BaU_2O_7 and $Ba_2U_3O_{11}$.

Crystal structures

An important feature of $M_2^+U_nO_{3n+1}$ and $M^{2+}U_nO_{3n+1}$ type uranates(VI) is their layer structure and the existence of the uranyl groups, UO_2^{2+}, in the crystals.

The structure of monouranates ($n = 1$) is characterized by the layer planes; the oxygen atoms on this plane are coordinated to uranium atoms forming secondary bonds. The primary bonds between the uranium and oxygen atoms of the uranyl group, O_I–U–O_I, are collinear and perpendicular to the layer plane. The atom arrangements around the uranyl groups are schematically drawn in Fig. 5.25 (Zachariasen, 1954b).

For β-Li_2UO_4 (Zachariasen, 1945), $CaUO_4$ and α-$SrUO_4$ (Zachariasen, 1948b), each uranium atom is coordinated to six oxygen atoms (cf. Fig. 5.25a, viewed from the *c*-axis). The axis of the UO_2^{2+} group in the figure is normal to the page, while three of six O_{II} atoms are located about 0.5 Å above and remaining three O_{II} atoms about 0.5 Å below the plane through uranium and perpendicular to the UO_2^{2+} axis. The oxygen atoms coordinated to uranium in

$BaUO_4$ and $MgUO_4$ form a deformed octahedron, where each O_{II} oxygen atom acts as a bridge between two adjacent uranium atoms. In $BaUO_4$ the octahedra share corners (Fig. 5.25b), but in $MgUO_4$ they share edges (Fig. 5.25c). As a consequence, infinite layers are formed in $BaUO_4$ and infinite chains in $MgUO_4$. The alkali or alkaline-earth metals occupy the positions between the layers and bind them together by electrostatic force (Zachariasen, 1954b).

There are no uranyl groups in Li_4UO_5 and Na_4UO_5, and the structure instead contains four orthogonal planar U–O_I bonds (with the distance 1.99 Å in both Li_4UO_5 and Na_4UO_5), yielding UO_4^{2-}; in addition, there are also two collinear U–O_{II} bonds (Li_4UO_5: 2.23 Å; Na_4UO_5: 2.32 Å) (Hoekstra and Siegel, 1964). The octahedra produced in this way are linked to bridges through the diagonally located O_{II} atoms, resulting in formation of a structure containing octahedral chains running along the *c*-axis. $M_3^{2+}UO_6$-type compounds (M = Ca, Sr, Ba) crystallize into distorted perovskite structures ($2[M_{1/4}U_{1/4}][M_{5/4}U_{1/4}]O_3$), where the alkaline-earth atoms and uranium atoms corresponding to $[M_{1/4}U_{1/4}]$ occupy the octahedral sites in an ordered manner (Keller, 1964; Morss, 1982; Williams *et al.*, 1984).

Physicochemical properties

Alkali metal monouranates(VI) are hygroscopic except for Li_2UO_4, and mostly yellow colored; some diuranates are orange or red-orange. The uranates(VI) of the heavy alkali metals are volatile on heating in air. The antisymmetric stretching vibration of UO_2^{2+} in uranates(VI) gives a strong absorption in the IR range of 600–900 cm^{-1}. The frequency changes depending on the bonding strength of the coordinated oxygen atoms. Since the U–O_I bonds of the uranyl group are much stronger, this vibration can be treated approximately as an isolated linear three-atom system of CO_2-type (Jones, 1958). The U–O_I distances calculated from the infrared frequencies using the empirical Badger equation are mostly in good agreement with those obtained by diffraction experiments (Hoekstra and Siegel, 1964; Allpress, 1965; Hoekstra, 1965; Carnall *et al.*, 1966).

A phase transformation coupled with oxygen non-stoichiometry has been observed for $SrUO_4$ and $CdUO_4$ (Tagawa and Fujino, 1978, 1980). α-$SrUO_4$ can be reduced to non-stoichiometric $SrUO_{4-x}$ with the maximum x value of 0.2–0.3. On heating α-$SrUO_4$ at different oxygen partial pressures from 10 to 600 mmHg and heating rates of 1–5 K min^{-1}, the compound is rapidly reduced to $SrUO_{3.8-3.9}$ at about 800°C. The solid is then immediately re-oxidized to stoichiometric composition by absorbing oxygen from the gaseous phase. At the same time, it transforms into β-$SrUO_4$. The atom rearrangement in the phase transformation may be accelerated by the formation of vacancies in the oxygen sublattice of α-$SrUO_4$.

Magnetic susceptibilities have been measured for $MgUO_4$, $SrUO_4$, $BaUO_4$, CaU_2O_7, SrU_2O_7, and BaU_2O_7 (Brochu and Lucas, 1967). In these compounds U(VI) is expected to be diamagnetic, but a weak paramagnetism was observed; this is ascribed to covalency in the uranyl group (Bell, 1969).

(*ii*) *Uranates* (*v*) *and* (*iv*)

Uranates(v) of $M^{+}UO_3$ (M = Li, Na, K, Rb), $M_3^{+}UO_4$ (M = Li, Na), and $M^{2+}U_2O_6$ (M = Mg, Ca, Sr, Ba) types are the most well known, as are the uranates(iv) of $M^{2+}UO_3$ (M = Ca, Sr, Ba) type.

Preparation

To prepare uranates(v), a symproportionation reaction is widely used, where the uranates(iv) and (vi) are first mixed in 1:1 uranium atom ratio, after which the mixture is heated in an evacuated sealed quartz ampoule. An example is the reaction $Li_2UO_4 + UO_2 = 2LiUO_3$, which takes place at 650–750°C. Another method is to reduce uranates(vi) by H_2 at elevated temperatures; the reaction condition should be carefully defined in order to form uranates(v). Since the uranates of alkaline-earth metals are not volatile, the high-temperature reduction method by H_2 can be used to prepare the corresponding uranates(iv).

For some uranates(vi) having high equilibrium oxygen pressures, uranates(v) can be prepared by heating the uranate(vi) in a vacuum at high temperature. The $M^{2+}U_2O_6$ compounds are prepared by the reaction

$$M^{2+}U_2O_7 = M^{2+}U_2O_6 + 1/2O_2$$

at 1100°C (M = Mg, Ca, Sr, Ba). It is, however, rather difficult to obtain stoichiometric uranates(v) by this method.

Crystal structures

Uranates(v) and (iv) do not contain uranyl groups and as a result, their crystal structures are in general not of the layer type and in many cases simpler. The compounds of $M^{+}UO_3$ and $M^{2+}UO_3$, with the exception of $CaUO_3$ (cubic Mn_2O_3-type structure), have perovskite or deformed perovskite-type structures. $LiUO_3$ crystallizes into a rhombohedrally distorted $LiNbO_3$ structure, as a result of the small ionic radius of Li^{+}. $NaUO_3$ has an orthorhombic $GdFeO_3$ structure with small distortions from cubic perovskite structure. KUO_3 and $RbUO_3$ have cubic perovskite structures, and $BaUO_3$ a cubic or pseudo-cubic perovskite structure.

In the uranates(v) of $M_3^{+}UO_4$-type, Li_3UO_4 crystallizes in a tetragonally distorted NaCl-type structure, in which the lithium and uranium atoms are located in the cation sites in an ordered manner with an atom ratio of 3:1. All $M^{2+}U_2O_6$ compounds have cubic fluorite-type structures, where the alkaline-earth metal atoms and uranium atoms are statistically distributed with an atom ratio of 1:2 over the cation sites.

Physico-chemical properties

Most uranates(v) and (iv) are brown to black. An exception is the pale green Li_7UO_6. Uranates(v) and (iv) dissolve in dilute mineral acids. The dissolution rate in HNO_3 is higher than those in HCl and H_2SO_4 (Trzebiatowski and

Jabłoński, 1960; Scholder and Gläser, 1964; Brochu and Lucas, 1967). Li_3UO_4 is oxidized to Li_2UO_4 in air even at room temperature. Na_3UO_4 absorbs significant amounts of oxygen, water, and CO_2 at room temperature. On heating the uranates(V) or uranates(IV) in air, they are readily oxidized to uranates(VI).

Electronic spectra have been measured for $LiUO_3$, $NaUO_3$, KUO_3, $RbUO_3$, MgU_2O_6, CdU_2O_6, Li_3UO_4, Li_7UO_6, $Ba_2U_2O_7$, etc. in the range 4000–40000 cm^{-1} (Kemmler-Sack *et al.*, 1967). The crystal field parameters were determined for $LiUO_3$ and Li_3UO_4 from the optical absorption electronic spectra (Lewis *et al.*, 1973; Kanellakopulos *et al.*, 1980; Hinatsu *et al.*, 1992a,b). For KUO_3 and $RbUO_3$, the octahedral crystal field around a U^{5+} atom was consistently calculated with a spin–orbit coupling constant of 1770 cm^{-1} (Kemmler-Sack *et al.*, 1967; Selbin *et al.*, 1972a).

Magnetic susceptibilities have been measured for $LiUO_3$, $NaUO_3$, KUO_3, $RbUO_3$, Li_3UO_4, Li_7UO_6, MgU_2O_6, CdU_2O_6, and $Ba_2U_2O_7$ at temperatures 85–473 K (Rüdorff and Menzer, 1957; Kemmler-Sack, 1968a). In the paramagnetic temperature range, the Curie constant changed with the coordination number. The magnetic susceptibilities for M^+UO_3 (M = Li, Na, K, Rb) were measured in a wider temperature range from 4.2 K to room temperature (Keller, 1972; Miyake *et al.*, 1979, 1982; Kanellakopulos *et al.*, 1980). The electron paramagnetic resonance (EPR) spectra for U^{5+} ions doped in $LiNbO_3$, which has the same crystal structure as $LiUO_3$, gave a signal at $g = 0.727$ (Lewis *et al.*, 1973). The EPR signals were also observed for pure M^+UO_3 but they were very broad (Miyake *et al.*, 1979, 1982). $LiUO_3$ showed a ferromagnetic transition at 16–17 K (Miyake *et al.*, 1979, 1982; Hinatsu *et al.*, 1992b).

Li_3UO_4 has a distorted NaCl-type structure and its magnetic properties have been studied by measuring the EPR spectra and magnetic susceptibility in an extended temperature range down to 4.2 K (Keller, 1972; Lewis *et al.*, 1973; Kanellakopulos *et al.*, 1980; Miyake *et al.*, 1982; Hinatsu *et al.*, 1992a). The experimental magnetic susceptibility can be well described by assuming the $5f^1$ electron of U^{5+} in an octahedral crystal field with a small tetragonal distortion with the crystal field parameters obtained from the electronic spectra (Hinatsu *et al.*, 1992a). $NaUO_3$ gives a magnetic transition at 32 K (Miyake *et al.*, 1977) or 35 K (Keller, 1972), for which a λ-type anomaly has also been observed in the heat capacity (Lyon *et al.*, 1977). The EPR and magnetic susceptibility studies for $M^{2+}U_2O_6$ (M = Mg, Ca, Cd, Sr) have been carried out (Brochu and Lucas, 1967; Miyake *et al.*, 1993; Miyake and Fujino, 1998). The anomalies of magnetic origin have been observed at 4–7 K.

(*iii*) *Non-stoichiometry*

The non-stoichiometry in uranates can be classified into three types. The first type occurs when part of the alkali metal in the uranate is lost as an oxide by vaporization on heating, viz. $Na_{2-2x}U_2O_{7-x}$ is formed from $Na_2U_2O_7$ by the loss of $x Na_2O$ ($0 \leq x \leq 0.07$) (Carnall *et al.*, 1966; Anderson, 1969). The second type is caused by non-stoichiometric dissolution of alkali metal in a uranium oxide. An example is Na_xUO_3 ($0 \leq x \leq 0.14$) (Greaves *et al.*, 1973). The third type is the most common non-stoichiometry, i.e. the oxygen non-stoichiometry. Examples of such uranates are $Na_2U_2O_{7-x}$ ($0 \leq x \leq 0.5$) (Anderson, 1969), $K_2U_2O_{7-x}$ (Spitsyn *et al.*, 1961b), $Cs_2U_4O_{13-x}$ (Cordfunke *et al.*, 1975), $CaUO_{4-x}$ ($0 \leq x \leq 0.5$) (Anderson and Barraclough, 1963), α-$SrUO_{4-x}$ ($0 \leq x \leq 0.5$) (Tagawa and Fujino, 1977), CaU_2O_{7-x} ($0 \leq x \leq 0.13$) and SrU_2O_{7-x} ($0 \leq x \leq 0.4$) (Hoekstra and Katz, 1952), SrU_4O_{13-x} (Cordfunke and Loopstra, 1967; Tagawa *et al.*, 1977). Rhombohedral $CaUO_4$ and α-$SrUO_4$, which crystallographically are very similar to ionic UO_2, show a wide range of non-stoichiometries, while β-$SrUO_4$ and $BaUO_4$ with increased covalency have virtually no non-stoichiometry. Examples of the third type of non-stoichiometric compounds derived from uranate(v) are MgU_2O_{6+x} ($-0.16 \leq x \leq 0.03$), CaU_2O_{6+x} ($-0.05 \leq x \leq 0.05$), SrU_2O_{6+x} ($-0.05 \leq x \leq 0.4\sim0.6$), and BaU_2O_{6+x} ($x \leq 0.86$) (Hoekstra and Katz, 1952).

The non-stoichiometric uranates are produced by heating in reducing atmospheres, but generally the U(VI) state is more stable in ternary uranates than in binary uranium oxides. This trend is more pronounced for the uranates with higher M/U ratios (M = alkali metals or alkaline-earth metals). The experimental fact that alkali and alkaline-earth metal uranates(VI) strictly without U(V) and U(IV) are formed under certain conditions when heated in air was utilized for the determination of oxygen in uranium oxides (Fujino *et al.*, 1978b).

(c) Transition metal uranates

Table 5.18 shows the crystallographic properties of ternary transition metal uranates. In this section the uranates of some non-transition metals such as Sb, Tl, Pb, and Bi are included because of the resemblance of their properties. Here we present an overview of preparation methods and crystal structures. For more detailed information, the reader is referred to the following review articles (Hoekstra and Marshall, 1967; Keller, 1972, 1975).

(*i*) *Preparative methods*

The most general 'dry' method for preparation is to heat thoroughly ground mixtures of transition metal oxides and UO_3 (or U_3O_8) in air. $CrUO_4$, $MnUO_4$, and $CoUO_4$ can be synthesized by heating the mixed oxides for 1 day at 1000–1100°C (Hoekstra and Marshall, 1967). $CuUO_4$ is obtained by heating below 875°C. Triuranates, MU_3O_{10} (M = Mn, Co, Ni, Cu, Zn), are prepared by heating the mixtures of M/U = 1/3 at 875°C. Although Ni, Cu, and Zn triuranates are readily obtained as stoichiometric compounds, Mn and Co triuranates tend to remain oxygen-deficient.

Nitrates, viz. $M(NO_3)_2 + UO_2(NO_3)_2$ (Weigel and Neufeldt, 1961), can also be used as starting materials for preparing MUO_4 (M = Cu, Zn, Cd, Hg),

because of their high reactivity. In this case, reaction temperatures not higher than 600°C are recommended for M = Cu, Zn, and Cd to avoid the formation of U_3O_8. $HgUO_4$ forms at 400°C. Ag_2UO_4 has been synthesized by heating a mixture of $AgNO_3$ and UO_2 to 500°C and maintaining this temperature for a period of 15 min. Above 500°C, Ag_2UO_4 begins to decompose with precipitation of metallic silver.

For preparing $FeUO_4$ and FeU_3O_{10}, the symproportionation reaction method in a sealed tube gives a good result. $FeUO_4$ is synthesized by heating either a mixture of $FeO + UO_3$ or $2Fe_2O_3 + U_3O_8 + UO_2$ at 1050°C in evacuated sealed quartz tubes. When a mixture of $Fe_2O_3 + U_3O_8 + 3UO_3$ is heated at 880°C, FeU_3O_{10} forms (Hoekstra and Marshall, 1967). $BiUO_4$ is prepared by heating a mixture of $2Bi_2O_3 + U_3O_8 + UO_2$ at 900–1000°C (Rüdorff *et al.*, 1967). The compounds MU_2O_6 (M = Co, Ni, Cd) have been prepared by heating the mixtures of $MUO_4 + UO_2$ at 800°C (Kemmler-Sack and Rüdorff, 1967). Single crystals of CuU_3O_8 and NiU_3O_{10} were grown by the reaction of UO_3 with the molten anhydrous transition metal chlorides in evacuated sealed silica tubes at 600–650°C for several weeks (Hoekstra and Marshall, 1967).

MU_3O_{10} with M = Mn, Co, and Zn were prepared by hydrothermal reactions using a platinum-lined Morey bomb in which the transition metal oxides and γ-UO_3 were heated in 0.06 M H_2SO_4 solution for 5 days at 350°C (Hoekstra and Marshall, 1967).

MUO_4 (M = Ni, Zn, Co, Mn) was successfully synthesized in experiments where a mixture of oxides was heated for 30 min at 1000°C under high pressures of 30–40 kbar using a tetrahedral anvil. However, the triuranates of these transition metals and $FeUO_4$ did not form by this method (Hoekstra and Marshall, 1967).

(*ii*) *Crystal structures*

$MnUO_4$ and $CoUO_4$ have the infinite chains of edge-sharing oxygen octahedra in the direction normal to the *c*-axis, characteristic of the $MgUO_4$ structure; these compounds crystallize in the same space group. The space group of $CrUO_4$, $FeUO_4$, and α-$NiUO_4$ is different from that of the above two compounds, and the lengths of the uranium–oxygen bonds that are expected to belong to uranyl groups are longer (2.05–2.06 Å) than those in $MnUO_4$ and $CoUO_4$. In these three compounds, the distorted UO_6 octahedra form infinite chains along the *c*-axis and less deformed MO_6 (M = Cr, Fe, Ni) octahedra are running parallel in the direction of the *c*-axis. Similar chain structures are also observed in the crystals of $USbO_5$, $UTiO_5$, and $UMoO_5$ (Dickens *et al.*, 1993). These structures are built from parallel layers of edge-sharing UO_m and MO_n polygons, linked together by metal–oxygen–metal chains or pillars running perpendicularly to the layers. In Pb_3UO_6, the infinite chains are formed by sharing the corners of distorted UO_6 octahedra in the direction of the *c*-axis.

The crystal structure of Pb_3UO_6 is wholly different from those of Ca_3UO_6 and Sr_3UO_6 (Sterns, 1967).

In the system PbO–U_2O_5, cubic $Pb_{1.5}U_2O_{6.5}$ (a = 11.16 Å) accommodates PbO until the $Pb_{2.5}U_2O_{7.5}$ composition is attained, resulting in a slight distortion to a rhombohedral structure (a = 11.23 Å, $\alpha = 90.25°$). This homogeneity range is regarded as derived from pyrochlore-type $Pb_2U_2O_7$ by addition or subtraction of PbO (Kemmler-Sack and Rüdorff, 1966).

$CuUO_4$ comprises a third group of crystal structures among the transition metal monouranates (Siegel and Hoekstra, 1968). The compound is monoclinic with space group $P2_1/n$. The coordination geometry is distorted octahedral with short collinear uranyl bonds, each of length 1.90 Å. The uranyl groups are in the direction nearly normal to a planar and almost square array of secondary uranium–oxygen bonds of lengths 2.15 and 2.24 Å.

Rare-earth oxides form solid solutions with UO_2 in an extended composition range. At the high atom ratio of RE/U = 6 (RE = rare-earth metals), however, the compounds of the composition RE_6UO_{12} crystallize in rhombohedral systems. In RE_6UO_{12} the uranium atom is surrounded by six oxygen atoms that form a distorted octahedron. All the U–O bond distances in the octahedron are 2.34 Å (La_6UO_{12}), and no uranyl groups exist in the crystal (Hinatsu *et al.*, 1988). $Y_5U_2O_{12}$ is produced along with Y_6UO_{12} giving a very similar crystal structure with similar lattice parameters. In $Y_5U_2O_{12}$, half the uranium atoms occupy the Y position (18f) in a disordered manner (Bartram, 1966).

(d) Solid solutions with UO_2

Uranium dioxide forms solid solutions with the oxides of alkaline-earth elements, rare-earth elements, some transition elements (Mn, Zr, Nb, Cd), and actinide elements (Th, Np, Pu, Am, Cm, etc.). The solid solution with PuO_2 (MOX) is important as nuclear fuel. Description on mixed oxide fuel, MOX, is given in Chapter 7.

The solid solutions are prepared by heating intimate mixtures of metal (M) oxides and uranium oxides usually in reducing atmosphere at temperatures between 1000 and 2000°C. The oxide powders are in most cases mechanically mixed, but other techniques such as coprecipitation (Keller *et al.*, 1972; Miyake *et al.*, 1986) and evaporation from aqueous solutions (Markin *et al.*, 1970; Lindemer and Sutton, Jr., 1988) have also been adopted. In the solid solutions, the dissolved foreign metal atoms and host uranium atoms are statistically distributed on the metal sites of the fluorite-type cubic crystals of UO_2 (Rüdorff *et al.*, 1967; Keller *et al.*, 1969; Hutchings *et al.*, 1985; Martin *et al.*, 2003). The solid solution can be written as $M_yU_{1-y}O_{2+x}$, where x is defined (in this section) to take on both positive and negative values. A considerable number of publications on the magnetic properties are available since the magnetic properties of uranium and metals, M, of varying oxidation state can be studied in the same fluorite-type fcc crystal field in these solid solutions; detailed description is given in Chapter 20. Recent progress on this subject is written in a review (Fujino and Miyake, 1991).

(*i*) *Lattice parameter change with composition*

The lattice parameter of cubic solid solution changes nearly linearly with the increase of y and x in $M_yU_{1-y}O_{2+x}$. The differential coefficient, $\partial a/\partial y$, where a is the lattice parameter in Å, can have both negative and positive values depending on the metal ion M^{n+}. Table 5.19 shows the observed $\partial a/\partial y$ and $\partial a/\partial x$ for various solid solutions (Fujino and Miyake, 1991). The underlined values in the table are those obtained from the lattice parameters of the stoichiometric solid solutions at the upper limit of the y-values, i.e. $M^{3+}_{0.5}U_{0.5}O_{2.00}$ and $M^{2+}_{0.33}U_{0.67}O_{2.00}$.

As seen in the table, the coefficient $\partial a/\partial y$ is large for the metals with large ionic radii, although correction for valence state of the metals is required for a more detailed discussion. Investigations to determine the functional relation between these quantities have been performed (Ohmichi *et al.*, 1981; Fujino and Miyake, 1991). The differential coefficient of the oxygen non-stoichiometry, $\partial a/\partial x$, in Table 5.19 have in general the values $-0.3 \leq \partial a/\partial x \leq -0.24$ for $x < 0$ and $-0.13 \leq \partial a/\partial x \leq -0.11$ for $x > 0$ regardless of the M metal.

(*ii*) *The solid solution regions*

$M^{4+}_yU_{1-y}O_{2+x}$

Zr SOLID SOLUTIONS The solubility data on this system are diverse. The Zr solid solution with $y = 0.15$ was obtained by heating at 1500°C (Une and Oguma, 1983a); at 1750°C, solid solutions with y values up to 0.3 were obtained (Aronson and Clayton, 1961). The solid solution with the highest y value, 0.35, has been obtained by heating the mixture of $UO_2(NO_3)_2 \cdot 6H_2O$ and $ZrOCl_2 \cdot 8H_2O$ in H_2 at 1650°C (Hinatsu and Fujino, 1985). The Zr solid solution is regarded as metastable at lower temperatures.

Th SOLID SOLUTIONS Th solid solutions are formed continuously from $y = 0$ to 1 for $x = 0$. However, for $x > 0$, there is an upper limit in the solubility. According to Paul and Keller (1971), the single-phase solid solutions under 1 atm O_2 exist below $y = 0.45$, 0.40, and 0.36 at 1100, 1400, and 1550°C, respectively. The lower limits at $p_{O_2} = 0.2$ atm are $y = 0.383$, 0.359, 0.253, and 0.068 for 700, 1200, 1400, and 1500°C, respectively (Gilpatrick *et al.*, 1964), which is in agreement with the value of $y = 0.22$ below 1400°C reported by Anderson *et al.* (1954). The maximum x value is 0.25 at temperatures between 1250 and 1550°C for $y \leq 0.5$. At lower temperatures of 600–1100°C, the upper limit of x decreases to 0.12–0.14 for y values below 0.4 (Cohen and Berman, 1966; Paul and Keller, 1971).

$M_y^{4+\sim3+}U_{1-y}O_{2+x}$

Ce SOLID SOLUTIONS Ce solid solutions are formed continuously from $y = 0$ to 1 for $x = 0$. For $x < 0$, the region of the single-phase solid solution is restricted to $y \leq 0.35$ (Markin *et al.*, 1970) or $y \leq 0.2$ (Lorenzelli and Touzelin, 1980). Above this value up to $y = 0.7$, the products are two phases $(Ce,U)O_{2.00}$ and $(Ce,U)O_{2-x}$ at room temperature. Further reduction results in formation of single-phase solid solutions. The x values for the single-phase solid solutions are $x < -0.04$, –0.12, –0.19, and –0.24 for $y = 0.1$, 0.3, 0.5, and 0.7, respectively (Lorenzelli and Touzelin, 1980).

In the hyperstoichiometric range of $0 \leq x \leq 0.18$, the solid solutions with $y < 0.5$ are a single phase at room temperature. Air-oxidized hyperstoichiometric solid solutions crystallize in a fluorite-type single phase in the region of high Ce concentrations (Hoch and Furman, 1966). Single-phase regions exist in $y = 0.56$–1.0 (1100°C), 0.43–1.0 (1250 °C), and 0.26–1.0 (1550°C) (Paul, 1970). Single phases with $y = 0.6$–1.0 at 1100°C have also been reported (Tagawa *et al.*, 1981a).

$M_y^{n+}U_{1-y}O_{2+x}$ ($n = 3$ and 2)

SOLID SOLUTIONS IN REDUCING ATMOSPHERE The solid solutions obtained by heating in reducing atmospheres are generally hypostoichiometric. The x values are highly negative when strong reductants such as H_2 or CO are used. The single-phase regions of fcc solid solutions with M metals (M = rare-earth elements, alkaline-earth metals, and Cd) are shown in Table 5.20. In reducing atmosphere, the single-phase solid solution forms essentially in a range starting from $y = 0$. For M^{2+} metals, the maximum y values are around 1/3. If the monoxides of Mg and Ba are heated with UO_2 in a vacuum, the solubility is very low even at high temperatures due to shortage of oxygen (cf. Table 5.20).

SOLID SOLUTIONS IN OXIDIZING ATMOSPHERE The single-phase regions of fcc solid solutions prepared in oxidizing atmospheres are shown in Table 5.21. UO_2 is oxidized to U_3O_8 when heated in oxidizing atmospheres unless mixed with the M elements. Hence, the lower limit of the fcc single phase is not $y = 0$ but at higher values. The x value changes with y value in a rather simple way for rare-earth solid solutions: For Nd solid solutions heated under $p_{O_2} = 1$ atm at 1100°C for example, the mean uranium valence remains constant (+5) when the y value is in a region between ~0.3 and 0.5, i.e. x changes as $x=1/2-y$. The uranium valence then increases linearly from +5 to +6 when y increases from 0.5 to 0.67, during which $x = 0$. For the solid solutions in a higher y range, 0.67–0.75, the uranium valence is U(VI). Here, the x value decreases linearly from 0 to –0.125 ($x=1-3y/2$) with increasing y value in order to satisfy the charge neutrality condition (Keller and Boroujerdi, 1972).

(*iii*) *Oxygen potentials*

$M^{4+}_{y}U_{1-y}O_{2+x}$

Zr SOLID SOLUTIONS The oxygen potential of $Zr_yU_{1-y}O_{2+x}$ solid solution is lower than that of UO_{2+x}. At 1250 K, the $\Delta\bar{G}(O_2)$ value for Zr solid solution with $y = 0.3$ is –270 kJ mol^{-1} at $x = 0.05$ (Aronson and Clayton, 1961), while that for UO_{2+x} at $x = 0.05$ is ca. –210 kJ mol^{-1}. The low $\Delta\bar{H}(O_2)$ of $Zr_yU_{1-y}O_{2+x}$ has been suggested to explain the low $\Delta\bar{G}(O_2)$ of this solid solution. The $\Delta\bar{H}(O_2)$ values vary between –480 and –355 kJ mol^{-1} for $Zr_yU_{1-y}O_{2+x}$, which are significantly lower than those between –355 and –270 kJ mol^{-1} for $Th_yU_{1-y}O_{2+x}$ (Aronson and Clayton, 1960, 1961; Une and Oguma, 1983a).

Th SOLID SOLUTIONS Dissolution of Th causes an increase in $\Delta\bar{G}(O_2)$ with increasing value of y. The difference in $\Delta\bar{G}(O_2)$ between Th solid solution and UO_{2+x} is small if the concentration of Th is low (viz., $y = 0.1$). However, at high Th concentration with $y = 0.71$ ($x = 0.05$), $\Delta\bar{G}(O_2)$ of the solid solution at 1250 K is as high as –150 kJ mol^{-1} (Aronson and Clayton, 1960). This value is 60 kJ mol^{-1} higher than $\Delta\bar{G}(O_2)$ of $UO_{2.05}$ at the same temperature. There have been other thermodynamic studies on this solid solution (Tanaka *et al.*, 1972; Ugajin, 1982; Ugajin *et al.*, 1983; Matsui and Naito, 1985a).

$M^{4+\sim 3+}_{y}U_{1-y}O_{2+x}$

Ce SOLID SOLUTIONS Because two oxidation states, Ce^{3+} and Ce^{4+}, are possible for Ce in oxides, the oxygen potential of Ce solid solution changes over a wide range of x-values from negative to positive values, giving rise to a rapid ('vertical') change of $\Delta\bar{G}(O_2)$ at $x = 0$. The shape of the $\Delta\bar{G}(O_2)$ curve is very similar to that of $Pu_yU_{1-y}O_{2+x}$, but the $\Delta\bar{G}(O_2)$ values of $Ce_yU_{1-y}O_{2+x}$ are markedly higher. Namely, $\Delta\bar{G}(O_2)$ for $Ce_{0.25}U_{0.75}O_{1.95}$ is as high as –460 kJ mol^{-1} at 1200°C, compared to the value of –570 kJ mol^{-1} for $Pu_{0.25}U_{0.75}O_{1.95}$.

This difference has been attributed to the higher $\Delta\bar{G}(O_2)$ value of CeO_{2-x} (Panlener *et al.*, 1975) compared with that of PuO_{2-x} (Woodley, 1981). The $\Delta\bar{G}(O_2)$ measurements of the Ce solid solutions have been carried out by a number of researchers (Hoch and Furman, 1966; Markin and Crough, 1970; Ducroux and Baptiste, 1981; Norris and Kay, 1983; Nagarajan *et al.*, 1985).

Pr AND Am SOLID SOLUTIONS The Pr solid solutions have lower values of $\Delta\bar{G}(O_2)$ than the solid solutions with solely M^{3+} rare-earth ions, because of the two possible oxidation states, Pr^{3+} and Pr^{4+} (Jocher, 1978; Fujino and Miyake, 1991). The situation is the same for Am solid solutions, although their $\Delta\bar{G}(O_2)$ values are markedly higher than those of Pu and Ce solid solutions (Bartscher and Sari, 1983).

$M^{3+}_{y}U_{1-y}O_{2+x}$

A large number of oxygen potential measurements for the M^{3+} solid solutions have been carried out. These comprise solid solutions of Y (Aitken and Joseph, 1966; Hagemark and Broli, 1967; Nakajima *et al.*, 2002), La (Hagemark and Broli, 1967; Stadlbauer *et al.*, 1974; Matsui and Naito, 1986), Pr (Jocher, 1978; Fujino and Miyake, 1991), Nd (Wadier, 1973; Une and Oguma, 1983c), Eu (Tanamas, 1974; Lindemer and Brynestad, 1986; Fujino *et al.*, 1990, 1999), and Gd (Une and Oguma, 1982, 1983b; Lindemer and Sutton, Jr. 1988).

$\Delta\bar{G}(O_2)$ for $M^{3+}_{y}U_{1-y}O_{2+x}$ can be defined from $x = -y/2$ to positive x values; the measured oxygen potential increases with increasing x value, passing through an inflection point at $x = 0$, where $\Delta\bar{G}(O_2)$ increases very rapidly. The dissolution of M^{3+} metals enhances $\Delta\bar{G}(O_2)$ more than do the M^{4+} metals. The $\Delta\bar{G}(O_2)$ value increases with increasing y, but the $\Delta\bar{G}(O_2)$ curve gradually levels off at high M^{3+} concentrations. In a series of rare-earth solid solutions, the La solid solution shows the highest $\Delta\bar{G}(O_2)$ values, which is assumed to be associated with the fact that La^{3+} has the largest ionic radius of these M^{3+} ions. With increasing atomic number of the lanthanides, $\Delta\bar{G}(O_2)$ is lowered, although the $\Delta\bar{G}(O_2)$ difference between the Nd and Gd solid solutions is small. Fig. 5.26 shows the oxygen potential of $Gd_yU_{1-y}O_{2+x}$ as a function of O/(Gd+U) ratio ($=2 + x$).

The Eu solid solutions show a much higher value of $\Delta\bar{G}(O_2)$ than the other M^{3+} solid solutions (Lindemer and Brynestad, 1986). This is possibly due to the coexistence of Eu^{2+} and Eu^{3+} in the solid solutions (Fujino *et al.*, 1990). It is noteworthy that the inflection point of $\Delta\bar{G}(O_2)$ for Eu solid solutions is shifted to a range of $x < 0$ values. This is also observed for $M^{2+}_{y}U_{1-y}O_{2+x}$, supporting the presence of Eu^{2+} in the Eu solid solutions.

$M^{2+}_{y}U_{1-y}O_{2+x}$

The oxygen potential of $Mg_yU_{1-y}O_{2+x}$ (Fujino and Naito, 1970; Fujino *et al.*, 1978a; Tateno *et al.*, 1979) is significantly higher than those of $M^{3+}_{y}U_{1-y}O_{2+x}$. Moreover, the x values at which the 'vertical' change of $\Delta\bar{G}(O_2)$ takes place,

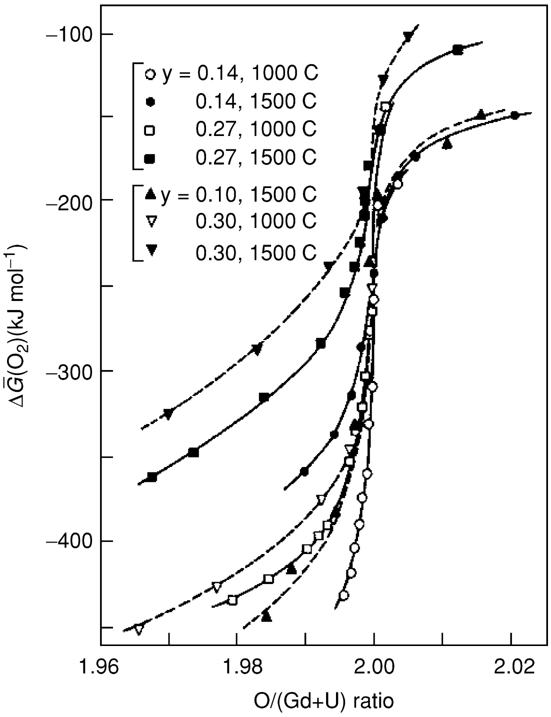

Fig. 5.26 *Oxygen potential of* $Gd_yU_{1-y}O_{2+x}$ *as a function of O/(Gd+U) ratio (Fujino and Miyake,* 1991*). Solid lines: Une and Oguma* (1983*b*)*; Broken lines: Lindemer and Sutton, Jr.* (1988)*. Reproduced by the permission of Elsevier.*

which are also the inflection points, are negative in contrast to the M^{4+} and M^{3+} solid solutions, where the value of x at the inflection is zero. This negative shift for $Mg_yU_{1-y}O_{2+x}$ becomes more pronounced at higher values of y, viz., $x = -0.07$ at $y = 0.3$ (1200–1500°C) (Sugisaki and Sueyoshi, 1978).

The high $\Delta\bar{G}(O_2)$ values are supposed to be rationalized by a configurational entropy change. Dissolution of M^{2+} metals in UO_2 results in formation of a larger number of U^{5+} ions in the solid solution crystals, which increases the number of ways, W, of arranging the cations on the cation sites. The entropy, $\Delta\bar{S}(O_2)$, described by the relation $\Delta\bar{S}(O_2) = 2R\,\partial \ln W/\partial(xN)$, where N is the Avogadro's number (Aronson and Clayton, 1960; Hagemark and Broli, 1967; Fujino and Miyake, 1991), shows therefore a significant decrease. For the Mg solid solutions Fujino *et al.* (1992, 1995, 1997b) claim that the $\Delta\bar{G}(O_2)$ shift is explained if the charge complexes of the form, ($M^{2+}2U^{5+}$), in which the corresponding cations have their normal sites, are formed together with ($M^{2+}U^{5+}$) complexes. In the oxygen potential curves for (Mg,Gd,U)O_{2+x} (Fujino *et al.*, 2001a) and (Mg,Ce,U)O_{2+x} (Fujino *et al.*, 2001b), the shift to negative x values is even larger than in the Mg solid solution.

When the oxygen partial pressure is very low, high concentrations of Mg cannot dissolve in UO_2. The solubility of Mg is in a range $0.1 < y < 0.15$ for $p_{O_2} = 10^{-15}$–10^{-19} atm at 1200°C (Fujino *et al.*, 1997a).

5.7.3 Uranium borides, carbides, silicides, and related compounds

Non-oxide p-block compounds of uranium represent a large family that share certain similarities with oxides in that non-stoichiometric compounds exist; these are especially well noted for the heavy p-block elements of a semi-metallic nature (e.g. Sb and Te). Oxidation state assignment for uranium in some of these compounds can be very tedious, owing to the presence of homoatomic bonding between main group elements where the $E\cdots E$ ($E =$ main group element) contacts between main group elements is intermediate in length between a full single bond and a van der Waals contact. This phenomenon is particularly common in antimonides and tellurides. Full descriptions of all known binaries and especially of ternary and quaternary phases are not possible in the present context. Further historical details can be found in Waber *et al.* (1964), Eding and Carr (1961), Freeman and Darby (1974), and in a series of IAEA bibliographies (Maximov, 1963, 1965, 1967).

(a) Uranium–boron system

The only known binary uranium borides are UB_2, UB_4, and UB_{12}. The crystal structure data for these compounds are given in Table 5.22. The former compounds have been prepared by direct reaction of the elements at high temperatures (Wedekind and Jochem, 1913). Mixtures of UB_{12} and UB_4 have also been deposited by fused-salt electrolysis (Andrieux, 1948; Andrieux and Blum, 1949). It has recently been demonstrated that UB_4 can be prepared by the solid-state metathesis reaction of UCl_4 with MgB_2 at 850°C (Lupinetti *et al.*, 2002).

$$UCl_4 + 2MgB_2 \rightarrow UB_4 + 2MgCl_2$$

A view of the structure of UB_4 is shown in Fig. 5.27.

The phase diagram of the U–B system is shown in Fig. 5.28 (Howlett, 1959, 1960; Elliott, 1965; Chiotti *et al.*, 1981).

In addition, there is mass spectroscopic evidence that supports the existence of UB and UB_2 in the gas phase (Gingerich, 1970). The dissociation energies D_0° were reported as (318 ± 33) kJ mol^{-1} for UB and (949 ± 42) kJ mol^{-1} for UB_2.

Uranium borides are remarkably inert, and borides have been proposed as a potential form for storing transuranium waste generated from the nuclear fuel cycle (Lupinetti *et al.*, 2002). There are some differences in reactivity of the uranium borides with respect to one another. UB_4 is generally more reactive

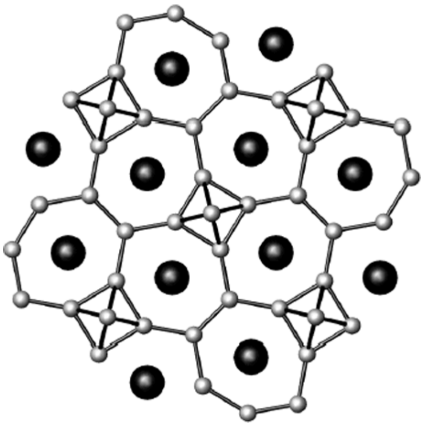

Fig. 5.27 *A view down the c-axis of the structure of UB_4. U–B bonds have been omitted for clarity.*

than UB_{12}. For example, boiling HF, HCl, and H_2SO_4 attack UB_{12} very slowly, but react more rapidly with UB_4, allowing for the separation of the two compounds. Both UB_4 and UB_{12} can be dissolved in HNO_3–H_2O_2 mixtures.

Ternary uranium borides have been extensively investigated for their rich variation in bonding and their complex physical properties. Compounds in this class include $U_5Mo_{10}B_{24}$, which contains three different kinds of B polyanions: two-dimensional puckered sheets formed from six- and eight-membered rings, planar ribbons composed of six-membered B rings, and chains of condensed eight-membered rings (Konrad and Jeitschko, 1996). UNi_4B has been extensively investigated and is a geometrically frustrated antiferromagnetic compound that partially orders below $T_N = 20$ K (Mentink *et al.*, 1998).

(b) Uranium–carbon system

The uranium–carbon system has been studied by a number of teams including Rundle *et al.* (1948), Esch and Schneider (1948), Litz *et al.* (1948), Wilhelm *et al.* (1949), and Mallett *et al.* (1952). The uranium–carbon system bear some similarities with that of uranium with other first-row p-block elements in that in addition to discrete, stoichiometric compounds, there are three known phases, UC, UC_2, and U_2C_3 that can be of variable composition. The complex phase diagram of the uranium–carbon system is shown in Fig. 5.29.

Among other things this diagram demonstrates that UC and UC_2 are completely miscible with one another at elevated temperatures and under these conditions the entire range UC–UC_2 is homogeneous. At lower temperatures, miscibility is much more limited and the exact extent of variability in composition for each of the carbides is still to be determined.

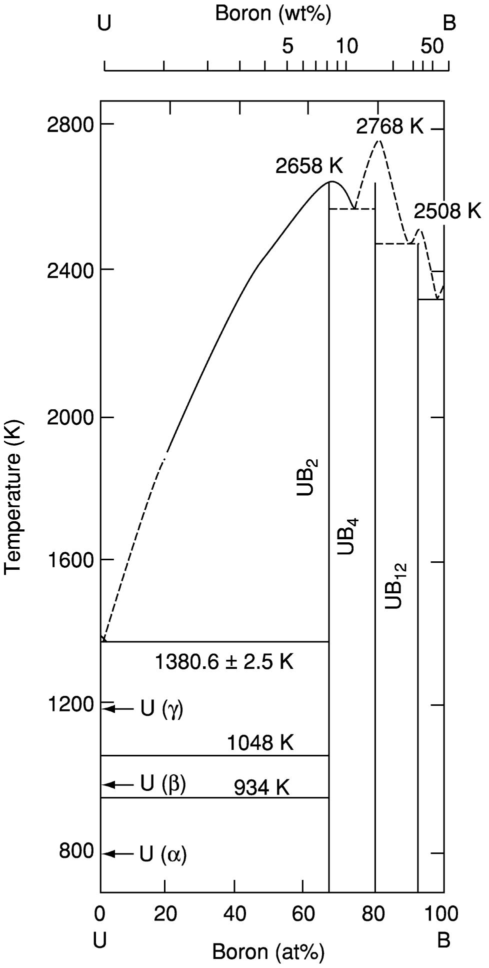

Fig. 5.28 *Phase diagram of the uranium–boron system* (*Chiotti* et al., 1981).

Litz *et al.* (1948) were the first to study the preparation of UC and UC_2. U_2C_3 is an unusual compound in that it has not been prepared by the direct reaction of the elements at high temperatures; this reaction invariably yields UC and UC_2 (Mallet *et al.*, 1952). However, U_2C_3 is obtained when a mixture of UC and UC_2 is heated in the range 1250–1800°C *in vacuo*. It is essential that the fused mixture be given a certain amount of stressing and cold working to initiate the nucleation necessary for the formation of the U_2C_3 phase; once formed it is stable at room temperature. Table 5.22 lists some of the crystallographic data for the uranium carbides. An illustration of the structure of UC_2 is shown in Fig. 5.30.

[d] $USi_{1.88}$ is also referred to as α-USi_2.

[e] U_3Si_5 is also referred to as β-USi_2.

[f] According to Laugier *et al.* (1971), USi is tetragonal. The orthorhombic structure is due to oxygen.

[g] Boulet *et al.*, (1997a).

[h] Existence of these compounds deduced from vapor pressure data taken by Alcock and Grieveson (1962, 1963).

[i] The different lattice constants are due to different interpretations of powder patterns.

[j] Boulet *et al.* (1997b).

[k] Boulet *et al.* (1997c).

[l] Marakov and Bykov (1959). May be the same phase as U_5Ge_4.

[m] The existence of U_5Ge_3 and U_7Ge has been called into question (Boulet *et al.*, 1997c), and they are likely mixture of U_5Ge_4 and U metal dissolving 3% of germanium.

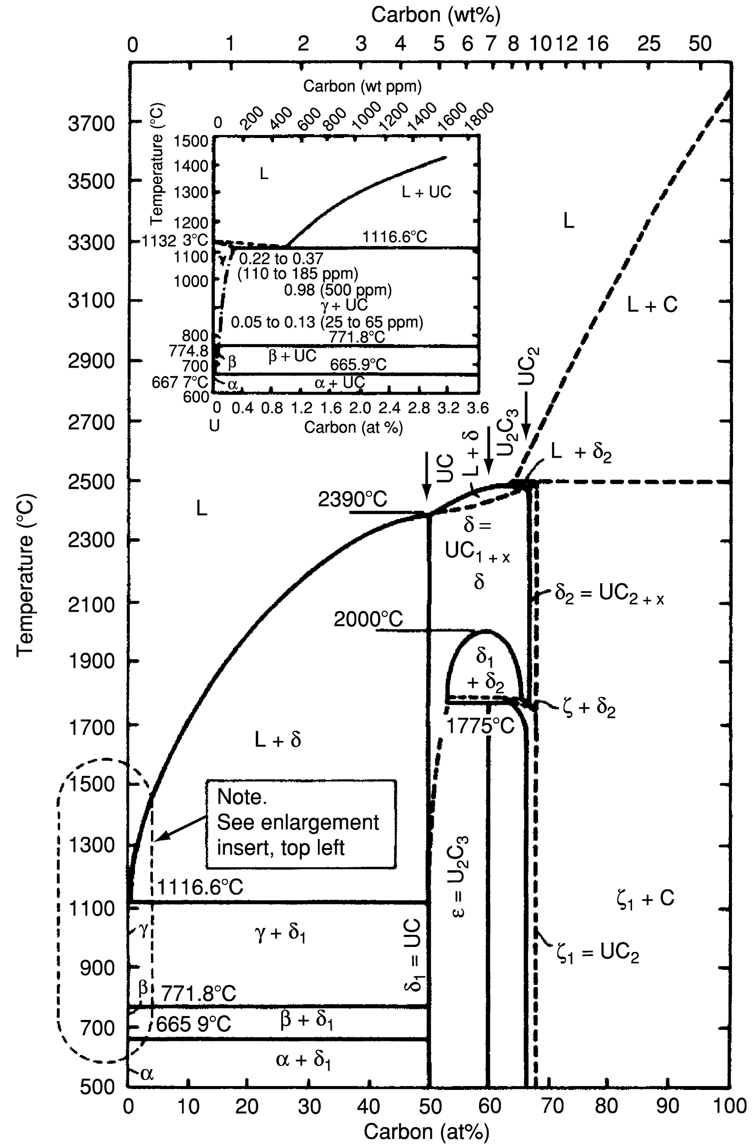

Fig. 5.29 *Phase diagram of the uranium–carbon system* (*Wilkinson,* 1962).

The uranium carbides can undergo a number of hydrolysis reactions; finely divided UC_2 is pyrophoric. The carbides react with water to yield a variety of products. Lebeau and Damien (1913) found that upon hydrolysis of UC_2, in addition to hydrogen, methane, and ethane, significant amounts of liquid and

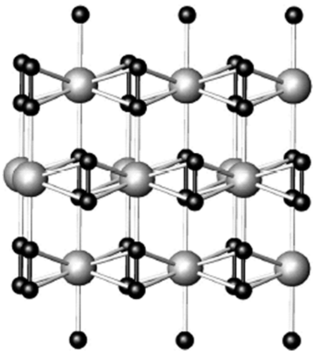

Fig. 5.30 *A view down the a-axis of the structure of UC_2.*

solid hydrocarbons are produced. Litz (1948) made an exhaustive study of the hydrolysis of UC and UC_2, the value of which is limited by the fact that he worked only at temperatures above 83°C and did not measure the quantity of gas evolved or analyze the solid residue for carbon compounds. Bradley and Ferris (1962, 1964) made a very careful study of the hydrolysis of arc-melted UC (1962) and of UC_2, U–UC mixtures, and UC–UC_2 mixtures (1964) at temperatures between 25 and 99°C. In the case of UC, the hydrolysis yielded a gelatinous, hydrous uranium(IV) oxide and a gaseous mixture (93 mL (STP) per gram UC), which consisted of 86 vol% methane, 11 vol% hydrogen, 1.8 vol% ethane, and small quantities of saturated C_3–C_6 hydrocarbons. The gaseous products contained all the carbon originally present in the carbide.

The total amount of carbon originally present in the carbide was also recovered in the hydrocarbon hydrolysis products of UC_2, U–UC, and UC–UC_2 mixtures. In the case of arc-melted $UC_{(1.85 \pm 0.03)}$, 36 different hydrocarbons were identified. The reaction product contained 15 vol% methane, 28 vol% ethane, 7 vol% C_3–C_6 alkanes, 8 vol% alkenes, 0.6 vol% alkynes, 1 vol% unidentified un-saturates, and 40 vol% hydrogen. Approximately 25% of the total carbon was found as a water-insoluble wax. In the hydrolysis of UC–UC_2 mixtures, a linear decrease of the volume percentage of CH_4 and linear increases of the percentages of hydrogen and the C_2–C_8 hydrocarbons were observed as the combined C/U atom ratio increased from 1.0 to 1.85. For UC–UC_2 mixtures, less methane than expected was evolved. This indicates that some polymerization of C units had occurred.

Bunnell *et al.* (1975) studied the hydrolysis of bare and defect-coated UC_2 fuel bead cores by water vapor at $p_{H_2O} = 24$–76 mmHg. They studied the reaction products by optical and scanning electron microscopies, identified hydrogen, methane, and ethane as the major reaction products, and measured the activation energy to be (25.4 ± 2.9) kJ mol^{-1}.

In air, UC_2 decomposes completely in a week, presumably as a result of hydrolysis. According to Mallet *et al.* (1952), U_2C_3 does not react appreciably with water even at 75°C. UC_2 appears to be stable in air at 300°C, but is completely converted to oxide in air within 4 h at 400–500°C. UC_2 reacts at 1100°C with nitrogen to form uranium nitride. Since the reactions of the carbides are greatly affected by the particle size of the solid and the previous thermal history of the sample, no far-reaching conclusions should be drawn regarding the relative reactivity of the uranium carbides.

The uranium carbides have found an important application as nuclear fuels in fast reactors. This type of application and related properties has been discussed in a number of uranium carbide conferences (see Proceedings, 1960a,b, 1961, 1963). One of the problems with reprocessing the spent fuels from these reactors is that oxalic acid is also produced in the dissolution of mixed uranium and plutonium carbides in HNO_3. Complexation of UO_2^{2+} by oxalate can account for the problems of incomplete uranium and plutonium extraction in the PUREX process for fuel reprocessing (Choppin *et al.*, 1983).

Ternary carbides, such as $U_2Al_3C_4$, can be prepared by melting the elements in a carbon crucible in a high-frequency radiofrequency (RF) furnace (Gesing and Jeitschko, 1995). The structure of $U_2Al_3C_4$ is closely related to that of Al_4C_3. Much like binary uranium carbides, $U_2Al_3C_4$ undergoes hydrolysis reactions in dilute HCl resulting in the formation of 74 (wt.)% methane, 8% ethane and ethylene, and 18% saturated and unsaturated higher hydrocarbons.

Laser-ablated U atoms react with CO in a noble gas matrix to form CUO (Li *et al.*, 2002). This molecule exhibits different stretching frequencies in a solid Ar matrix from those in a solid Ne matrix. Further experiments suggest that Ar atoms interact directly with CUO molecules to form an actinide–noble gas compound. The combination of experimental and theoretical methods suggests that multiple Ar atoms interact with a single CUO molecule.

(c) Uranium–silicon system

The uranium–silicon system is remarkably rich and a large number of uranium silicides including U_3Si, U_3Si_2, USi, U_3Si_5, $USi_{1.88}$, and USi_3 have been prepared and crystallographically characterized (Zachariasen, 1949a; Kaufman *et al.*, 1957). The phase diagram, shown in Fig. 5.31, is based on earlier work reported in the compilations by Hansen and Anderko (1958), Elliott (1965), and Shunk (1969), and in the paper by Vaugoyeau *et al.* (1971), which has been assessed and discussed by Chiotti *et al.* (1981).

Further details on the composition ranges of the two phases U_3Si_5 and $USi_{1.88}$ are given by Vaugoyeau *et al.* (1971). U_3Si_5 melts congruently at 2043 K (1770°C) and has a composition range $USi_{1.71}$ to $USi_{1.78}$ (63–64 at % Si) in the temperature range 1000–1300°C. The phase $USi_{1.88}$, in the same temperature range, has a composition span $USi_{1.79}$ to $USi_{1.84}$ (64–64.8 at % Si).

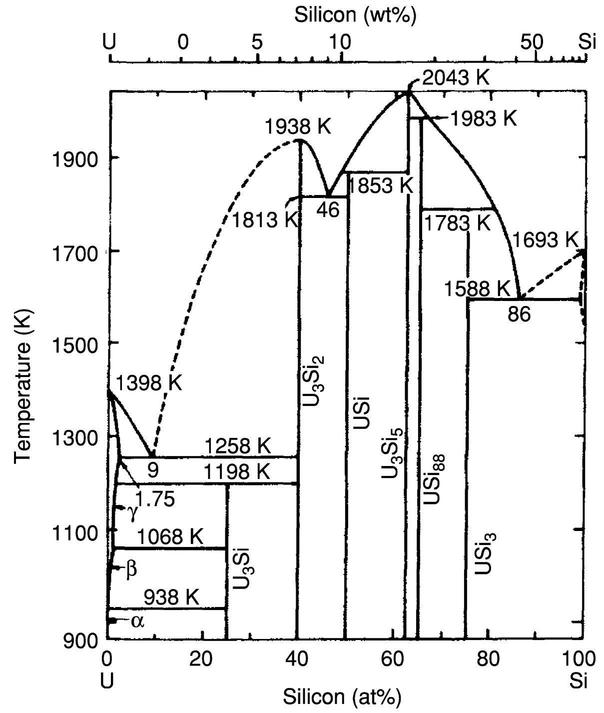

Fig. 5.31 *Phase diagram of the U–Si system* (*Chiotti* et al., 1981).

The two-phase region between the two compounds is very narrow. The compound USi was shown to decompose peritectically at 1580°C and has a narrow homogeneity range. The eutectic between U_3Si_2 and USi occurs at 1540°C and 46 at % Si.

As can be inferred from this information and from the data in Table 5.22, the U–Si phase diagram is very complicated. However, the uranium silicides are of technical importance. For instance, compounds such as $U(Al,Si)_3$ are formed in the layer between the uranium metal and the aluminum can in natural uranium fuel elements (Cunningham and Adams, 1957). Because of the chemical inertness of some of the uranium silicides, these compounds promise more applications. Crystal structures of the U–Si compounds are also summarized in Table 5.22.

Ternary uranium silicides are well established from compounds such as UCu_2Si_2 (Fisk *et al.*, 2003), $U_2Nb_3Si_4$ (Le Bihan *et al.*, 2000), and URu_2Si_2 (Sugiyama and Onuki, 2003). Single crystals of UCu_2Si_2 prepared from a Cu flux undergo a 50 K antiferromagnetic transition below the 100 K ferromagnetic transition (Fisk *et al.*, 2003).

$U_2Nb_3Si_4$ is weakly ferromagnetic below 35 K (Le Bihan *et al.*, 2000). Finally, URu_2Si_2 is one of the most studied heavy fermion materials (Sugiyama and Onuki, 2003).

(d) Uranium–germanium, uranium–tin, and uranium–lead systems

The uranium–germanium system is as complex as that of uranium silicides. U_7Ge (*vide infra*), U_5Ge_3 (*vide infra*), U_5Ge_4, UGe_2, and UGe have all been characterized and subjected to extensive physical property measurements (Onuki *et al.*, 1992). The compound originally formulated as U_3Ge_4 has been shown to be a mixture of UGe and U_3Ge_5. Detailed studies including magnetic structure determination via neutron diffraction have been performed on UGe_2, which is an unusual example of a ferromagnetic superconductor (Saxena, 2000; Sheikin *et al.*, 2000; Nishioka *et al.*, 2002).

This compound was originally reported to crystallize in the $ZrSi_2$ (*Cmcm*) structure type, but in fact crystallizes in the $ZrGa_2$ (*Cmmm*) type (Oikawa *et al.*, 1996; Boulet *et al.*, 1997a). U_5Ge_3 and U_7Ge both undergo a transition to a superconducting phase below 2 K (Onuki *et al.*, 1990). However, the existence of both of these compounds has been called into question (Boulet *et al.*, 1997c), and they are likely mixture of U_5Ge_4 and U metal dissolving 3% of germanium.

The uranium–tin phase diagram has been described by Palenzona and Manfrinetti (1995). U_5Sn_4 (Ti_5Ga_4-type), USn (ThIn-type), USn_2 ($ZrGa_2$-type), U_3Sn_7 (Ce_3Sn_7-type), and USn_3 ($AuCu_3$-type) were identified from this work. Dhar *et al.* (1998) have assessed the magnetic properties of these compounds. U_5Sn_4 and USn are ferromagnetically ordered below 62 and 49 K, respectively; USn_2 and U_3Sn_7 attain an antiferromagnetic state near 80 K. Shunk (1969) and Chiotti *et al.* (1981) have reported the phase diagram for the uranium–lead system.

5.7.4 Uranium pnictides

The systems U–N, U–P, U–As, U–Sb, and U–Bi have been studied in great detail. In particular, the monopnictides UN, UP, and UAs have found major interest because of their solid-state properties, which are relatively easy to study because of their cubic (NaCl) structure. Physical and crystallographic data of the pnictides are summarized in Table 5.23.

The thermodynamic properties of uranium and other actinide nitrides are briefly summarized in Chapter 19. Additional information on uranium nitrides and heavier pnictides is available in Gmelin (1981b, vol. C7; 1981d, vol. C14).

(a) Uranium–nitrogen system

Rundle *et al.* (1948) established the existence of the following uranium nitride phases: UN, U_2N_3, and $UN_{1.75}$, while the phase UN_2 could not be confirmed. Berthold *et al.* (1957) and Berthold and Delliehausen (1966) succeeded, however, in preparing a phase $UN_{1.90}$ by reacting uranium hydride with ammonia at

Table 5.23 *Crystallographic data of uranium pnictides* (*Rough and Bauer,* 1958; *Hansen and Anderko,* 1958; *Waber* et al., *1964; Elliot,* 1965; *Shunk,* 1969).[a]

elevated temperatures. Bugl and Bauer (1964) have studied the U–N system in detail.

The nitrides can be prepared by reaction of very pure uranium metal (or uranium hydride prepared from such metal) with nitriding agents. The surface of the uranium metal has to be pickled with nearly concentrated HNO_3, and then washed with organic solvents to remove even traces of oxide and oil films, which might lead to the formation of oxide or carbide contaminants. The nitriding agents also have to be of high purity. Uranium mononitride can be prepared (i) by reaction of uranium metal (or uranium hydride) with nitrogen or ammonia, (ii) by the thermal decomposition of higher nitrides at or above 1300°C, or (iii) by the reduction of higher nitrides with uranium metal. U_2N_3 can be prepared by reacting UC with NH_3 or a N_2/H_2 gas mixture (Nakagawa *et al.*, 1997). The reaction with ammonia is advantageous because NH_3 acts as both a nitriding agent and as a carbon-clearing agent. Fitzmaurice and Parkin (1994) report that various uranium nitrides could be prepared from the self-propagating reaction of UCl_4 with Li_3N.

Mallett and Gerds (1955) made a kinetic study of the reaction of uranium metal with nitrogen in the temperature range 550–900°C and at atmospheric pressure. Surface reaction products were identified by X-ray diffraction methods. At 775–900°C it was found that all three nitride phases were present. The intermediate nitride U_2N_3 is prepared by similar methods or by reduction of $UN_{1.75}$ with hydrogen. Since U_2N_3 loses nitrogen above 700°C *in vacuo*, the preparative procedure must take this into account. The nitride $UN_{1.75}$ cannot be prepared at all by reaction of the metal with nitrogen, unless a high pressure of nitrogen is used. There appears to be a two-phase region between UN and U_2N_3, but the region between U_2N_3 and $UN_{1.75}$ appears to be homogeneous. A tentative phase diagram of the system is shown in Fig. 5.32.

All of the higher uranium nitrides are thermally unstable relative to UN. UN is easily oxidized by air and is decomposed by water vapor; it is not attacked by either hot or cold hydrochloric or sulfuric acids, but is attacked by molten alkali. U_2N_3 can be used for the catalytic cracking of ammonia (Rizzo da Rocha *et al.*, 1995). Schmitz-Dumont *et al.* (1954) described the interesting uranium compound uranyl amide, $UO_2(NH_2)_2$. This compound can be prepared by the reaction of potassium uranyl nitrate, $KUO_2(NO_3)_3$, with potassium amide in liquid ammonia. Uranyl amide is a brown, amorphous substance that is unaffected by dry oxygen at room temperature. Moisture, however, converts the amide to ammonium diuranate. The uranium amido chlorides, UNH_2Cl_2 and $U(NH_2)_2Cl$, can be obtained by reacting UCl_3 with ammonia at 450 to 500°C. Increased heating of these compounds results in their conversion to U(NH)Cl and then $UN_{1.73-1.75}$ (Berthold and Knecht, 1965a).

The reaction of Li_3N with UH_3 at 900°C results in the formation of $LiUN_2$ (Jacobs *et al.*, 2003). The structure is related to the anatase type with the octahedral sites occupied by Li. Ca_3UN_4 can be prepared by reacting Ca $(NH_2)_2$ and UH_3 between 600 and 1000°C (Heckers *et al.*, 2003). X-ray and

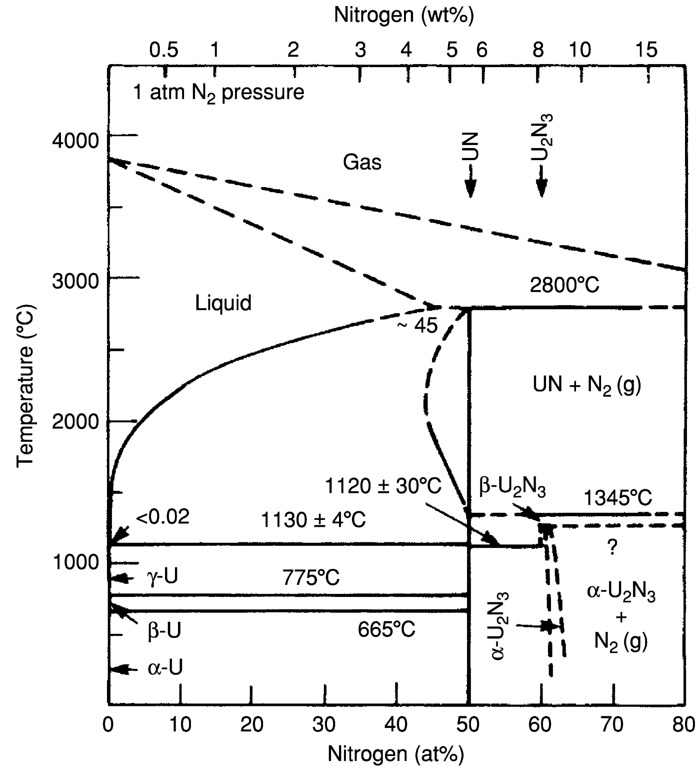

Fig. 5.32 *Phase diagram of the U–N system* (*Shunk*, 1969).

neutron diffraction studies on this phase show that it crystallizes in the NaCl structure type with statistical occupation of the cation site by three Ca atoms and one U atom.

(b) Uranium–phosphorus, uranium–arsenic, and uranium–antimony, and uranium–bismuth systems

In the systems U–P, U–As, U–Sb, and U–Bi, the compounds UX, U_3X_4, and UX_2 (where X = P, As, Sb, or Bi) have been reported. Compounds UX have the cubic NaCl structure for all X, with the exception of β-UBi, which is tetragonal body-centered. U_3X_4 is body-centered cubic and UX_2 tetragonal for all X.

At least four methods have been applied for preparation of the pnictides: direct synthesis from the elements in an autoclave (Albutt *et al.*, 1964) or in a sealed tube, for instance (Iandelli, 1952).

$$2U + P_4 \rightarrow 2UP_2$$

the reaction of uranium hydride with phosphine or arsine, for instance

$$UH_3 + PH_3 \rightarrow UP + 3H_2$$

and finally by circulating gaseous phosphine or arsine over slightly heated hydride (Baskin and Shalek, 1964; Baskin, 1969). For the preparation of the phosphides, a PH_3-loaded stream of argon is passed over the hydride, which is heated at 400–500°C. For the preparation of the arsenides, AsH_3 is reacted with UH_3 at 300°C. The reaction products are annealed at 1200–1400°C. Single crystals of UAs_2 have been grown by reacting uranium metal with a Cs_3As_7 flux (Albrecht-Schmitt *et al.*, 2000). Finally, uranium phosphides, arsenides, and antimonides can be prepared from the reaction of UCl_4 with sodium pnictides (Fitzmaurice and Parkin, 1994).

Buhrer (1969), Spirlet (1979), and Vogt (1982) succeeded in growing single crystals of most uranium pnictides by gas-phase transport, using $TeCl_4$, I_2, and other transporting agents. The crystals grown in this manner allow the determination of physical properties such as magnetic susceptibilities, magnetic phase diagrams (Busch *et al.*, 1979a), or the measurement of the de Haas–van Alphen effect (Henkie *et al.*, 1981); the uranium pnictides are particularly well suited for such measurements. Normally, they should exhibit isotropic behavior because of their structure, but the presence of anisotropy in the cubic crystals suggests the formation of magnetic domains. U_3P_4 and U_3As_4 are both metallic ferromagnets with itinerant 5f electrons (Inada *et al.*, 2001).

The binary compounds of the systems U–Sb and U–Bi may be prepared directly from the elements, or by reacting uranium with alkali metal antimonide and bismuthide fluxes. The binary phase diagram of U–Sb was originally investigated by Beaudry and Daane (1959). Among the binary compounds discovered in this system was a uranium-rich phase (δ) that forms a eutectic with USb at 1770°C. This compound was originally formulated as U_4Sb_3. Magnetic susceptibility measurements on a compound with this nominal composition show ferromagnetic behavior below 86 K (Troć, 1992). However, later microprobe analysis, neutron scattering, and single crystal X-ray diffraction data were utilized to establish that the actual composition of this phase is U_5Sb_4 (Paixão *et al.*, 1994); this compound crystallizes in the Ti_5Ga_4 structure type. Paixão *et al.* (1994) have demonstrated that U_5Sb_4 shows highly anisotropic ferromagnetic behavior below 86 K.

5.7.5 Uranium chalcogenides

The binary, ternary, and quaternary uranium sulfides, selenides, and tellurides have been the subject of intense investigation for more than 160 years. U–Po compounds are currently unknown owing to the high radioactivity and rarity of polonium. A significant number of the chalcogenide phases deduced before 1980 were reinvestigated over the past two decades, primarily by single-crystal X-ray diffraction, as a number of previously known compounds were assigned incorrect space groups, unit cells, and compositions.

(a) Uranium–sulfur system

Uranium sulfide in the form of US_2 was first prepared in the mid-1800s (Péligot, 1842; Herrmann, 1861). This compound was followed by the preparation of US and U_2S_3, which were identified by Alibegoff (1886); these studies pre-date the discovery of X-rays. Systematic X-ray powder diffraction investigations did not take place until 1943 (Strotzer *et al.* 1943), when seven distinct phases were identified from their powder patterns, but these were not indexed. The phase diagram of the uranium–sulfur system is shown in Fig. 5.33.

Based on later systematic studies of the uranium–sulfur system by Eastman *et al.* (1950), Zachariasen (1949b) was able to elucidate the crystal structures of many of the previously synthesized phases. Mills (1974) has compiled thermodynamic data for these phases. Crystal structure data for the uranium chalcogenides and oxychalcogenides are given in Table 5.24.

The uranium sulfides can be prepared by heating uranium or uranium hydride with H_2S, or by heating the elements together in a sealed tube. Lower sulfides may be obtained by thermal decomposition of the higher sulfides *in vacuo* at high temperatures. γ-US_2 can be prepared from what is thought to be a topotactic reaction of U_3S_5 with sulfur (Kohlmann and Beck, 1997).

α-UX_2 compounds (X = S, Se) were previously reported to crystallize in *I*4/*mcm*, but based on single crystal X-ray data they are now known to crystallize in *P*4/*ncc* (Noël and Le Marouille, 1984). U_3S_5 has been the subject of a large number of studies that have concluded that the compound is mixed-valent, containing both U^{3+} and U^{4+}; it can be formulated as $(U^{3+})_2(U^{4+})(S^{2-})_5$ (Noël and Prigent, 1980; Kohlmann and Beck, 2000). A view of the structure of U_3S_5 is shown in Fig. 5.34.

[a] Compiled from Gmelin (1981, vol. C11, 1984, vol. C10) and from original literature.

[b] Old sources listing α-US_2 refer to $US_{1.80}$-$US_{1.93}$. The single crystal structure of α-US_2 is known.

[c] Most of the selenides and tellurides, if prepared in sealed tubes, are obtained as free-running black powders. In some cases, single crystals have been prepared by gas-phase transport.

[d] Peritectic decomposition temperature of the solid-state phase.

[e] α-USe_2 can refer to the phase $USe_{1.88}$ and has variable lattice parameters.

[f] Obtained as black crystals with metallic luster.

[g] This compound has been previously reported in the literature as $UTe_{3.38}$. Powder diffraction data suggests that the uranium content may equal $U_{0.724}Te_3$ (Boehme *et al.*, 1992).

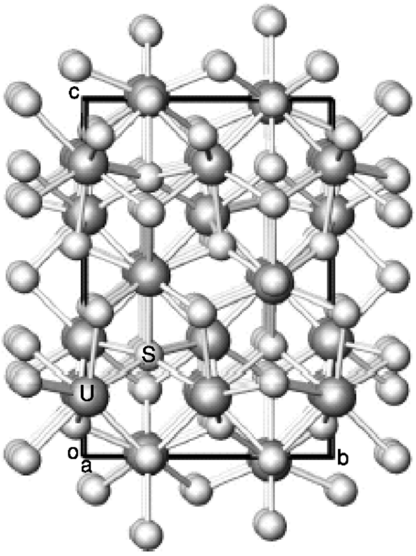

Fig. 5.34 *A view down the a-axis of the structure of U_3S_5. This is a mixed valence compound and should be formulated as $(U^{3+})_2(U^{4+})(S^{2-})_5$.*

(b) Uranium–selenium and uranium-tellurium systems

The selenides and tellurides of uranium have also been studied extensively. A large number of individual phases have been identified and characterized by their X-ray patterns. The crystallographic data of the individual phases have also been summarized in Table 5.24. The phase diagrams of the systems U–Se and U–Te are shown in Figs. 5.35 and 5.36, respectively.

The β modification of UTe_3, which was originally thought to adopt the $NdTe_3$ structure type, has been shown to be non-stoichiometric with uranium defects, giving rise to a formulation of $U_{0.9}Te_3$ (Stoewe, 1997a). This compound is identical to the previously known binary uranium telluride, formulated as $UTe_{3.38}$, and shows variable composition with U content ranging from 0.87 to 0.93. X-ray powder diffraction data suggest even a larger defect concentration consistent with a formula of $U_{0.724}Te_3$ (Boehme *et al.*, 1992). Te–Te bonding exists in a number of uranium telluride phases, making oxidation state assignment difficult. For example, one-dimensional tellurium chains exist in UTe_2. Therefore the compound is not $(U^{4+})(Te^{2-})_2$ but rather $(U^{3+})(Te^{2-})(Te^{1-})$ (Stoewe, 1997b). A view of the structure of UTe_2 is shown in Fig. 5.37.

The selenides and tellurides can be prepared by similar methods as the sulfides, i.e. reaction of uranium powder prepared from the hydride with H_2Se or H_2Te, synthesis from the elements at controlled temperatures in sealed tubes, or thermal decomposition of the higher selenides or tellurides. For a more detailed description of the solid-state properties of USe and UTe,

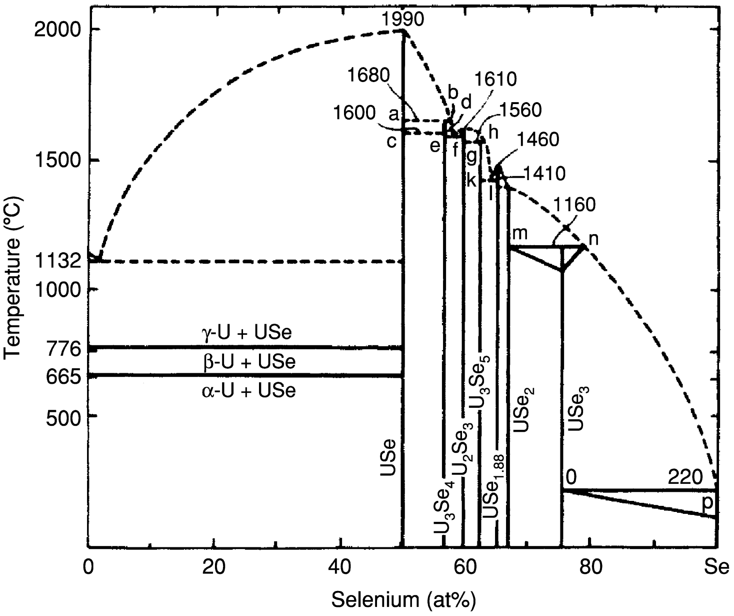

Fig. 5.35 *Phase diagram of the U–Se system* (*Klein-Haneveld and Jellinek*, 1964).

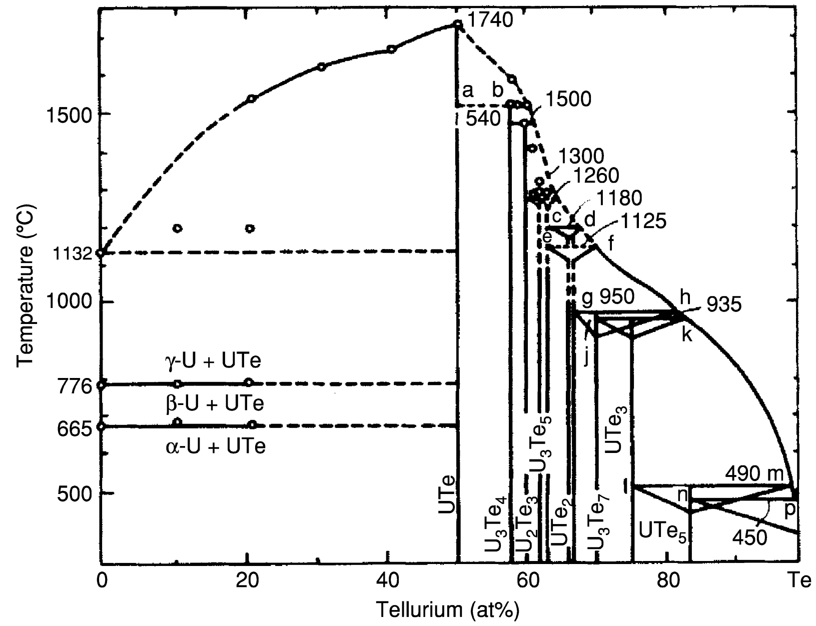

Fig. 5.36 *Phase diagram of the U–Te system* (*Slovyanskikh* et al., 1977).

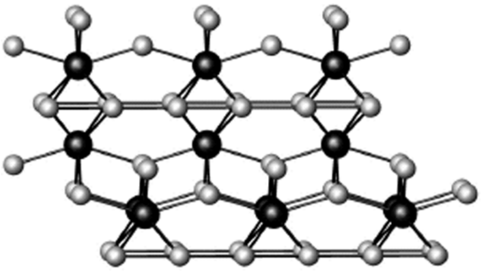

Fig. 5.37 *A view down the a-axis of the structure UTe_2. There are one-dimensional chains formed from Te–Te bonding, leading to the composition* $(U^{3+})(Te^{-})(Te^{2-})$.

see *Gmelin* (1981c, vol. C11) and the Proceedings of the International Conference on the Physics of Actinides and Related 4f Materials (Wachter, 1980). U_2Te_5 has been prepared from the direct reaction of the elements, and single crystals grown by using $TeBr_4$ as a chemical transport reagent (Stoewe, 1996b). Uranium chalcogenides can also be prepared by reacting UCl_4 with Li_2X (X = S, Se, Te) (Fitzmaurice and Parkin, 1994). Narducci and Ibers (1998) have reviewed the ternary and quaternary uranium chalcogenides. These compounds range from simple perovskite-type compounds with ABX_3 (X = S, Se, Te) formula to complex, tellurium-deficient compounds such as one-dimensional $Cs_8Hf_5UTe_{30.6}$ (Cody *et al.*, 1995; Cody and Ibers, 1995). The oxidation state of uranium in these compounds is often called into question due to the presence of Te ··· Te contacts on the order of 3 Å, which are considerably shorter than the van der Waals distance (4.10 Å), but longer than a full Te–Te single bond (2.76 Å). This results in a formal oxidation state for the tellurium with a non-integral value; hence, the oxidation state of uranium is ambiguous.

5.7.6 Uranium halides and related compounds

The halides and complex halides are one of the most thoroughly studied classes of uranium compounds. They have found use in many industrial applications, uranium hexafluoride, tetrachloride, and trichloride in large-scale isotope separation of ^{235}U and uranium tetrafluoride as a component of molten-salt reactor fuels as well as for the preparation of uranium metal. The most stable halides are formed with uranium in the 6+ and 4+ oxidation states. Experimental investigations gave evidence for increasing U 5f participation in the chemical bonds in the more covalent compounds. Ionicity is largest for halides with uranium in higher oxidation states and with the more electronegative halogens. An exception to this rule is UF_3, which is reported to be more covalent than UCl_3 (Thibaut *et al.*, 1982). Uranium in oxidation states 5+ and 6+ forms linear uranyl groups UO_2^+ and UO_2^{2+}. These possess covalent, substitution inert bonds and act like single species with respect to the halogen atoms. Lau and Hildenbrand (1982, 1984) have presented thermochemical data for gaseous

U–F_n and U–Cl_n species (where $n = 1, 2, 3, 4,$ or 5), obtained from mass spectrometric investigations of high-temperature reaction equilibria.

The chemistry of uranium halides has been reviewed in numerous papers and books, e.g. Katz and Sheft (1960), Hodge (1960), Pascal (1962–1970), Bagnall (1967, 1987), Caillat (1961), Chatalet (1967), Brown (1968, 1972, 1973, 1979), Johnson *et al.* (1974), Manes (1985), and Eick (1994). Several reviews were devoted to particular aspects of the halides: the crystallographic data of actinide halides have been reported by Taylor (1976a) and of their binary compounds with non-metallic elements by Benedict (1987); the results of spectroscopic investigations were presented by Carnall (1982), Carnall and Crosswhite (1985), Baer (1984), and Wilmarth and Peterson (1981); the magnetism of actinide compounds by Santini *et al.* (1999); EPR by Kanellakopulos (1983); the thermodynamic data by Kubaschewski and Alcock (1979), Fuger *et al.* (1983), Grenthe *et al.* (1992), and Guillaumont *et al.*, (2003); the industrial production of uranium hexafluoride by Hellberg and Schneider (1981), and the properties of uranium in molten salts and metals by Martinot (1984, 1991). A number of review papers have been also devoted to a particular oxidation state or group of uranium halides, e.g. *Structural systematics in actinide fluoride complexes* (Penneman *et al.*, 1973), *Verbindungen mit Fluor* (Bacher and Jacob, 1980), *Actinide fluorides* (Freestone and Holloway, 1991), *Uranium hexafluoride. Its chemistry related to its major application* (Bacher and Jacob, 1986), *Compounds of uranium with chlorine, bromine, iodine* (Brown, 1979), *Heptavalent actinides* (Keller, 1985), *Complex compounds of uranium* (Bagnall, 1979), *Comprehensive coordination chemistry II – The Actinides* (Burns *et al.*, 2004), *Magnetochemistry of uranium*(V) *complexes and compounds* (Miyake, 1991), *Chemistry of tervalent uranium* (Drożdżyński, 1991). In order to keep the reference number at a reasonable limit these review articles will be frequently cited as the source of chemical and physical properties of the compounds. In each of the following subsections the uranium halides and related compounds are discussed in order of increasing valence state and some of their physical properties summarized in subsequent tables. Although references to original literature data have been kept in these tables, the citation of thermodynamic data have been limited to the most important binary compounds as Chapter 19 of this work is devoted to thermodynamic properties of the actinides.

(a) Tervalent halides and complex halides

The first tervalent uranium compound, UCl_3, was prepared by Péligot (1842), and until the end of the 1960s the binary trihalides have been almost the only ones investigated. The crucial reason was the large sensitivity to oxidation and very poor solubility in aprotic organic solvents of all at that time known uranium(III) compounds. During the last 30 years the development of new experimental methods made it possible to prepare almost 150 uranium(III) compounds (Drożdżyński, 1991). However, the uranium trihalides and complex halides still remain the only relatively well-investigated group.

The stability of the trihalides decreases with increase in the atomic number of the halide. Apart from UF_3, all the halides are more or less hygroscopic and easily oxidized in air. In aqueous solutions they are rapidly oxidized but in pure, thoroughly deoxygenated solvents the U^{3+} ions are fairly stable. Concentrated hydrochloric acid gives intensely deep-red solutions, characteristic of the $[UCl_n]^{3-n}$ complex anions. With the exception of UF_3, UCl_3 and uranium(III) fluoro complexes, the halides are also readily soluble in some more polar solvents. The compounds exhibit a variety of colors (see Table 5.25). The preparation of somewhat more stable hydrated uranium(III) complexes have also been reported. Since all of them are readily soluble in water they are efflorescent in a humid atmosphere. For binary halides the following anion polyhedra have been identified: five capped trigonal prism (UF_3), tricapped trigonal prism (UCl_3, UBr_3), and bicapped trigonal prism (UI_3).

The synthesis of uranium(III) halides and complex halides requires a rather complex equipment and strictly oxygen-free conditions. At temperatures higher than 600°C the syntheses ought to be carried out in tantalum or molybdenum tubes in order to avoid side reactions with silica; Drożdżyński (1991) has reported a survey of the preparation methods.

Trivalent uranium has a [Rn] $5f^3$ electronic configuration with the $^4I_{9/2}$ ground state. A number of crystal-field analyses of high-resolution low-temperature absorption spectra have been reported for U^{3+}-doped single crystals of $LiYF_4$ (S_4) (Simoni *et al.*, 1995), $LaCl_3$ (C_{3h}) (Crosswhite *et al.*, 1980; Carnall, 1989; Karbowiak *et al.*, 2002a), $LaBr_3$ (C_{3h}) (Sobczyk *et al.*, 2005), RbY_2Cl_7 (C_{2v}) (Karbowiak *et al.*, 1997), K_2UX_5 (C_s) ($X = Cl$, Br or I) (Karbowiak *et al.* 1998a), Cs_2NaYCl_6 (O_h) and Cs_2LiYCl_6 (O_h) (Karbowiak *et al.*, 1998b), Ba_2YCl_7 (C_1) Karbowiak *et al.*, 2002b, Cs_2NaYBr_6 (Karbowiak *et al.*, 2003a), $CsCdBr_3$ (Karbowiak *et al.*, 2003b), $Cs_3Lu_2Cl_9$(C_{3v}) and $Cs_3Y_2I_9$ (C_{3v}) (Karbowiak *et al.* 2005a). Such analyses have been also performed for polycrystalline samples of UCl_3 and UBr_3 (C_{3h}) (Sobczyk *et al.*, 2003), $UCl_3 \cdot 7H_2O$ (C_i) (Karbowiak *et al.*, 2001), $CsUCl_4 \cdot 3H_2O$ (C_s), $NH_4UCl_4 \cdot 4H_2O$ (C_2) (Karbowiak *et al.*, 2000), and $ZnCl_2$-based glass (Dereń *et al.*, 1998). However, only the U^{3+}-doped single crystals of $LaCl_3$ and $LiYF_4$ exhibit suitable site symmetry for precise energy-level investigations, using selection rules for electric and magnetic dipole transitions. The energy levels of the U^{3+} ion in the different site symmetries were assigned and fitted to a semiempirical Hamiltonian representing the combined atomic and crystal-field interactions. *Ab initio* calculations made it possible to use a simplified parametrization and the determination of the starting values in the angular overlap model in cases where the U^{3+} ion had the lowest site symmetry (Karbowiak *et al.*, 2000). The free ion and crystal-field parameters obtained from an analysis of low-temperature absorption spectra of thin films of UF_3, UCl_3, and UBr_3 are presented in Table 5.25. In addition, an analysis of low-temperature absorption, luminescence, and excitation

[*] Estimated values.

[†] Values recommended by the Nuclear Energy Agency (Guillaumont *et al.*, 2003).

[a] Values have been selected in part from review articles (Brown, 1979; Bacher and Jacob, 1980; Freestone and Holloway, 1991; Grenthe *et al.*,1992; Guillaumont *et al.*, 2003).

[b] m.p. = melting point (°C); b.p.. = boiling point (°C); (cr) = crystalline; (g) = gaseous; thermodynamic values in kJ mol^{-1}, or J K^{-1} mol^{-1} at 298.15 K, unless otherwise mentioned; $\Delta_f G^o_m$, standard molar Gibbs energy of formation; $\Delta_f H^o_m$, standard molar enthalpy of formation; S^o_m, standard molar entropy; $C^o_{p,m}$(J K^{-1} mol^{-1}), standard molar heat capacity; log p (mmHg) = $-AT^{-1} + B - C \log T$: vapor pressure equation for indicated temperature range; IR = infrared active; lat. = lattice vibrations; val. = valence vibrations; def. = deformation vibrations; all values in cm^{-1}; vs: very strong; s: strong; m: medium; ms: medium strong; w: weak; sh: shoulder; b: broad; C, Θ, paramagnetic constants from the Curie Weiss law $C = \chi'_M(T\text{-}\Theta)$; $\mu_{eff} = 2.84\sqrt{C}$ - effective magnetic moment; T_N, ordering temperature; atomic and crystal-field parameters; F^k and ζ_{5f} = electrostatic and spin–orbit interaction; α, β, γ; = two-body correction terms; $T^i t_i$ (i = 2,3,4,6,7,8) = three-particle configuration interaction; M^j (j = 0, 2 and 4) = spin–spin and spin–other–orbit relativistic corrections; P^k (k = 2, 4 and 6) = electrostatically correlated spin-orbit perturbation; B^k_q, crystal-field parameters; values in brackets indicate parameter errors; parameters in square brackets were kept constant during the final fitting procedure; standard deviation: $rms = \sum_i \left[(\Delta_i)^2/(n-p)\right]^{1/2}$ [cm^{-1}], where Δ_i is the difference between the observed and calculated energies, n is the number of levels fitted and p is the number of parameters freely varied.

[c] All values are in Å and angles are in degrees; d, density [g cm^{-3}]; CN, coordination number, V = molar volume [cm^3 mol^{-1}].

[d] Temperature range with linear relationship of χ_M^{-1} against T.

spectra of co-doped (U^{4+},U^{3+}):Ba_2YCl_7 single crystals has been also reported (Karbowiak *et al.*, 2003c) Efficient luminescence was observed at 7 K from both the $^4G_{7/2}$ and $^4F_{9/2}$ levels of the U^{3+} ions and from the $^1D_2$ and $^1I_6$ levels of U^{4+}. For the U^{4+}ions a very strong anti-Stokes emission was noticed due to energy transfer processes. Contrary to U^{4+} for which emission was observed even at room temperature the emission of U^{3+} ions is strongly quenched by temperature. Owing to the presence of U^{3+} and U^{4+} ions in the host crystal, an energy transfer between these ions has been proved. Analyses of the nephelauxetic effect and crystal field splittings of the K_2UX_5 (X = Cl, Br or I) series of compounds have also been reported (Karbowiak *et al.*, 1998a).

The absorption spectra of $NH_4UCl_4 \cdot 4H_2O$ and $CsUCl_4 \cdot 3H_2O$ recorded at 298 and 4.2 K, presented in Fig. 5.38 (Karbowiak *et al.*, 2000) are typical for most uranium(III) compounds. In the 4000–15800 cm^{-1} region the spectra consist of relatively intense, sharp, and well-separated absorption lines.

A comparison of the spectra shows significant differences in the visible range connected with the appearance of strong and broad f–d bands, allowed by the Laporte rule. For $CsUCl_4 \cdot 3H_2O$ the first f–d bands are located at about 23000 cm^{-1}, while in $NH_4UCl_4 \cdot 4H_2O$ they are shifted about 5000 cm^{-1} toward the infrared region. For the isostructural series of complex halides of the composition U^{3+}:K_2LaX_5 (X = Cl, Br, I), the substitution of the Cl^- by I^- results in a significantly smaller shift of about 1000 cm^{-1} (Karbowiak *et al.*, 1998a). Drożdżyński (1985, 1991) and Karbowiak *et al.* (1996c) report a close relationship between the increase of covalence/decrease of the uranium–halogenide distances, and the red shift of the first intense f–d bands. The crystal-field symmetry is another factor, which can influence the position of the f–d bands. However, this seems to be a minor factor, since there is no simple dependence of the energy of the first f–d transition on the site symmetry of the U^{3+} ion. For example in K_2UCl_5 (C_s) and Cs_2NaUCl_6 (O_h) (Karbowiak *et al.*, 1998a,b) the first f–d transitions occur at similar energies of 14300 and 15000 cm^{-1}, respectively, while for UCl_3 (D_{3h}) they appear at 23000 cm^{-1} (Karbowiak *et al.*, 2002a). An extensive analysis of the $5f^3 \rightarrow 5f^2 6d^1$ transitions in low temperature absorption spectra of U^{3+} ions incorporated in various single crystals were reported by Seijo and Barandiran (2001), Karbowiak and Drożdżyński (2004) and Karbowiak (2005a,b). Temperature-induced line broadening and line shift measurements have been chosen as method for the determination of the electron–phonon coupling parameters for U^{3+} doped in K_2LaCl_5 (Ellens *et al.*, 1998), $LaCl_3$ and $LaBr_3$ single crystals (Karbowiak *et al.*, 2003d). The value of the electron–phonon coupling parameter, $\bar{\alpha}$, was found to be considerably lower in $LaCl_3$ than in K_2LaCl_5 but larger than that of Nd^{3+} in $LaCl_3$. The electron–phonon coupling is also stronger for U^{3+} in the tribromide as compared with the trichloride host; this has been attributed to a larger covalency of the first compound.

Intensity calculations of $5f^3 \rightarrow 5f^3$ transitions in tervalent uranium, based on the Judd–Ofelt theory were performed both for solution (Drożdżyński, 1978, 1984) and solid-state spectra (Drożdżyński and Conway, 1972, Karbowiak and

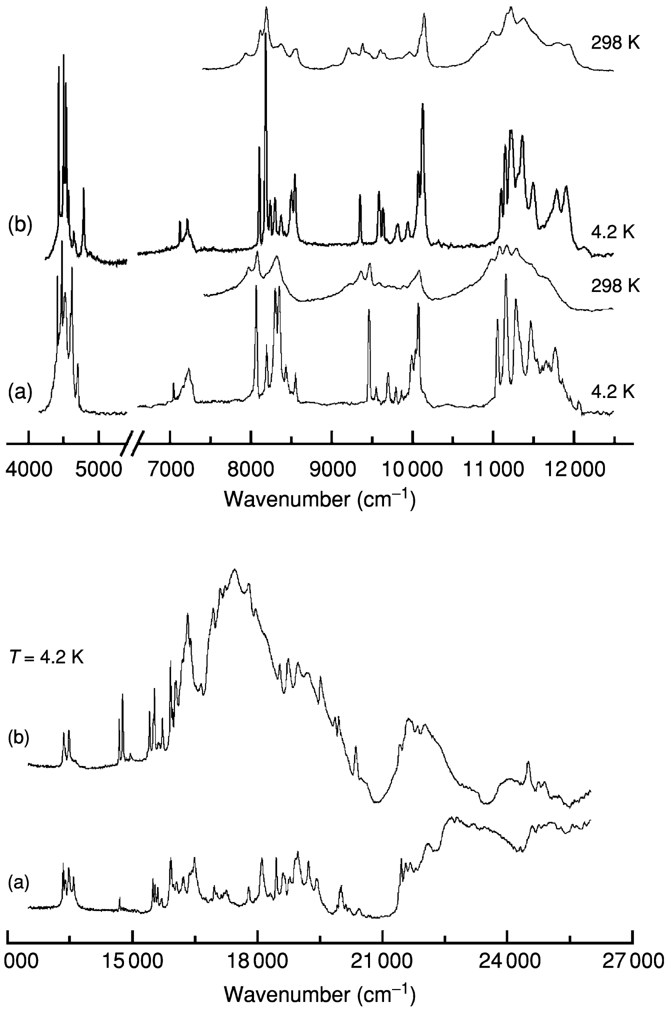

Fig. 5.38 *Absorption spectra of thin films of* $CsUCl_4 \cdot 3H_2O$ (*a*) *and* $NH_4UCl_4 \cdot 4H_2O$ *recorded at* 4.2 *and* 298 K (*from Karbowiak* et al., 2000 *reproduced by the permission of Elsevier*).

Drożdżyński, 2003). The analyses have shown a rather poor agreement between the observed and calculated oscillator strengths. So far, a relatively small r.m.s. deviation, of the order 10^{-6} to 10^{-7}, has been obtained only for the absorption spectra of UCl_3 in hexamethylphosphortriamide (Drożdżyński and Kamenskaya, 1978) and of UCl_3-doped $ZnCl_2$-based glass (Dereń *et al.*, 1998).

For almost all the halides and complex halides, magnetic susceptibility measurements were carried out over wide temperature ranges. The paramagnetic constants from the Curie–Weiss law $\chi'_{\mathrm{m}}. = C/(T - \theta)$ and the effective magnetic moments $\mu_{\mathrm{eff}} = 2.84\mu_{\mathrm{B}}$ were determined for a large number of compounds (see Table 5.25). The trihalides show remarkable cooperative effects, which were studied both experimentally (Murasik *et al.*, 1980, 1985, 1986) and theoretically (Łyżwa and Erdös, 1987; Plumer and Caillé, 1989). UCl_3 and UBr_3 undergo an unusual magnetic phase transition for actinide compounds. A one-dimensional, short-range magnetic order along the z-axis of the hexagonal lattice develops at about 15 K for UBr_3 and 22 K for UCl_3, which results from strong antiferromagnetic interactions between the nearest neighbors. A three-dimensional ordering appears in UBr_3 and UCl_3 when the uranium magnetic moments order to a '0+–' configuration in each plane perpendicular to the z-axis at $T_{\mathrm{N}} = 6.5$ and 5.3 K, respectively. At temperatures below $T_{\mathrm{t}} = 2.7$ K for UBr_3 and $T_{\mathrm{t}} = 2.5$ K for UCl_3 the magnetic moments exhibit smaller values and become oriented parallel to the equivalent x- or y-axis. The observed reorientation of the moments is reported to be rare in the actinide ions due to a usually strong anisotropy, which determines the direction of the moment (Santini *et al.*, 1999).

An extensive physical analysis of the magnetic interactions and magnetic ordering phenomena, as well as the crystal-field splitting in the K_2UX_5 (X = Cl, Br or I) series of compounds, were performed on the basis of the Ising model (Keller *et al.*, 1995). The application of elastic and inelastic neutron scattering experiments along with specific heat measurements made it possible to obtain a consistent picture of the magnetic phases. An analysis of the IR and Raman spectra of this series of compounds and of RbU_2Cl_7 is also available (Karbowiak *et al.*, 1996a; Hanuza *et al.*, 1999). Drożdżynski (1991) has summarized paramagnetic resonance measurements for U^{3+} ions substituted in CaF_2, SrF_2, and $LaCl_3$ single crystals. Some physical properties of tervalent uranium halides and related compounds are collected in Table 5.25.

(*i*) *Uranium trifluoride and uranium*(*III*) *fluoro complexes*

Uranium trifluoride

Uranium trifluoride is most conveniently prepared by reduction of UF_4 with metallic aluminum or finely powdered uranium. In the former case the reagents are placed in a graphite crucible and heated up to 900°C where the reaction proceeds smoothly and the excess of aluminum and by-products sublime from the reaction zone (Runnals, 1953). In the latter one, stoichiometric quantities of cleaned uranium turnings and UF_4 are placed in a nickel tube and heated to about 250°C in a stream of pure hydrogen (Warf, 1958). The finely divided UH_3 was decomposed at 400°C, after which the tube should be shaken in order to obtain an intimate mixture that was then heated to 700–900°C to give the pure trifluoride (Friedman *et al.*, 1970). The reduction with other metals such as Be, Mg, Ti, or Zr, as well as UN or U_2N_3, at 900–950°C has also been found suitable for the synthesis. The use of the nitrates has some technical advantages since they prevent the formation of corrosive by-products. Reduction with Li, Na, Cs, Mg, Ca, Sr, and Ba yields metallic uranium. The preparation of ultrapure UF_3 by reduction of UF_4 with hydrogen at 1020 to 1050 (± 20)°C has been reported by Berndt and Erdman (1973).

Uranium trifluoride is a gray to black solid. Separate crystals show a deep-violet color under the microscope. As compared to other uranium(III) compounds the trifluoride is remarkably stable on air at room temperature. At higher temperatures UF_3 oxidizes and at 900°C it is quantitatively converted into U_3O_8. The compound is thermally unstable even in an inert atmosphere and disproportionates to UF_4 and U at about 1000°C and to a smaller extent (0.1% per hour) also at 800°C. UF_3 is insoluble in water and cold aqueous acids but slowly undergoes oxidation. This proceeds with the formation of uranium(IV) and uranyl compounds at 100°C. UF_3 dissolves rapidly in nitric acid–boric acid mixtures. Chlorine, bromine, and iodine react to give UF_3X ($X = Cl$, Br or I).

UF_3 has the LaF_3-type structure but the symmetry is reported to be either trigonal (space group $P\bar{3}c1$, D_{3d}^4, No. 185) or hexagonal (space group $P6_3cm$, C_{6v}^3, No. 165). Two coordination numbers 9 and 11 are also taken into consideration (Taylor, 1976a). Both structures may be considered as distorted ideal polyhedra with a bimolecular hexagonal cell (space group $P6_3/mmc$) (Schlyter, 1953). The polyhedra are fully capped trigonal prisms in which fluorine atoms ($CN = 11$) are located on all corners and outside the two triangular and the three square boundary planes. The main difference between the different structures is a slight displacement of the atoms forming the prism and the atoms outside the triangular surfaces normal to *c*-axis (Taylor, 1976a). Other crystallographic data are listed in Table 5.25.

A good quality absorption spectrum of UF_3 was obtained by means of the teflon disk technique (Schmieder *et al.*, 1970) and in chlorinated naphthalene at 4.2 K (Drożdżyński and Karbowiak, 2005). For the latter data a crystal-field analysis has also been performed. There is a large shift of the L′S′J′ multiplets towards higher wave numbers, as compared with other U^{III} low-temperature spectra. Some absorption spectra were also recorded in fused-salt systems: LiF–Be_2, LiF–BeF_2–ZrF_4, and LiF–NaF–KF (Martinot, 1984).

The magnetic susceptibility of UF_3 has been measured between 2 and 300 K (Berger and Sienko, 1967) and between 293 and 723 K (Nguyen-Nghi *et al.*, 1964). For both temperature ranges a linear relationship of $1/\chi'_M$ vs T was reported. The effective magnetic moment of 3.67 BM is close to the free ion value.

Uranium trifluoride monohydrate and uranium(III) fluoro complexes

$UF_3 \cdot H_2O$ was prepared from an uranium(III) solution in 1 M HCl or in anhydrous methanol by precipitation with ammonium fluoride (Barnard *et al.*, 1973). The green gelatinous precipitate appears in the latter case to be brown after drying due to some U(IV) impurities. The hydrate is reported to be far more reactive than the anhydrous fluoride and is immediately oxidized in air, giving a pale green uranium(IV) substance. The compound was characterized by magnetic susceptibility measurements, but the results may not be reliable.

The formation of a number alkali fluorouranates(III) and complexes of UF_3 with ZrF_4 has been known for a long time (Bacher and Jacob, 1980). KUF_4, K_2UF_5, K_3UF_6, Rb_3UF_6, and Cs_3UF_6 were prepared by heating UF_4 and metallic uranium with the appropriate alkali fluoride at 1000°C (Thoma *et al.*, 1966). $NaUF_4$ and Na_2UF_5 were identified during investigations of the binary fused-salt system NaF–UF_3. Some of the complex fluorides were characterized by X-ray powder diffraction (Table 5.25) but more detailed information is still not available.

$UZrF_7$ was prepared by reduction of a mixture of UF_4 and ZrF_4, either with metallic zirconium or with metallic uranium at about 800°C; UZr_2F_{11} was identified in a systematic study of the $UZrF_7$–ZrF_4 binary system (Fonteneau and Lucas, 1974). The fluorides are not stable and slowly oxidize even at room temperature. The compounds were characterized by magnetic susceptibility measurements in the 100–300 K range and by X-ray powder diffraction analyses (Table 5.25).

(*ii*) *Uranium trichloride and uranium*(III) *complex chlorides*

Uranium trichloride

Uranium trichloride may be prepared by a number of methods (Brown, 1979; Drożdżyński, 1991). One of the most convenient is the action of gaseous hydrogen chloride on uranium hydride. Attractive alternative methods involve the reduction of uranium tetrachloride with zinc, metallic uranium, or uranium hydride.

$$UH_3 + 3HCl \xrightarrow{350^\circ C} UCl_3 + 3H_2$$

$$3UCl_4 + Al \xrightarrow{400^\circ C} 3UCl_3 + AlCl_3$$

Small amounts of pure UCl_3 may also be prepared by thermal vacuum decomposition of $NH_4UCl_4 \cdot 4H_2O$ (Drożdżyński, 1988a, 1991). The compound obtained by the latter method is reactive and tractable for synthetic purposes, in contrast to that obtained by reduction with metals.

Uranium trichloride is obtained either in the form of a fine olive-green powder or as dark-red crystals. It is not soluble in anhydrous organic solvents but it dissolves somewhat in glacial acetic acid, showing a characteristic transient red color. UCl_3 dissolves in polar organic solvents, provided the compound or the solvents have absorbed some gaseous hydrogen chloride before. In aqueous solutions it is more or less rapidly oxidized. UCl_3 reacts with chlorine to form a mixture of higher valence chlorides, and with bromine and iodine to yield $UBrCl_3$ and UCl_3I, respectively. The reaction with ammonia, acetonitrile, tetrahydrofuran (THF), and phenazine yields a number of unstable adducts.

UCl_3 is hygroscopic, but in contrast to other uranium halides no absorption of water is reported at p_{H_2O} less than 320 Pa (2.4 mmHg). It is a strong reducing agent both in solution and in solid state. Several metals such as calcium or lithium reduce UCl_3 to metallic uranium but the reaction has not been widely applied. UCl_3 melts at 837°C and disproportionates to U and UCl_4 at 840°C. A number of fused-salt systems containing UCl_3 have been investigated and the formation of some chloro complexes has also been reported (Bacher and Jacob, 1980).

Uranium trichloride has hexagonal symmetry (Zachariasen, 1948a,c; Murasik *et al.*, 1985; Schleid *et al.*, 1987) with the space group $P6_3/m - C_{6h}^2$. The coordination polyhedron is a symmetric tricapped trigonal prism arranged in columns in the *c*-direction. Each column is surrounded trigonally by three others at 1/2*c* in such a manner that the prism atoms of one chain become the cap atoms of the neighboring one. The packing view of UCl_3 along the [001] direction is shown on Fig. 5.39. The trichlorides Ac–Am and La–Nd have the same type of structure; some of the crystal data are listed in Table 5.25.

High-resolution polarized absorption spectra of $LaCl_3{:}U^{3+}$ single crystals (Karbowiak *et al.*, 2002) and unpolarized spectra of a polycrystalline UCl_3 sample in chlorinated naphathalene have been recorded at 4.2 K in the 4000–30000 cm^{-1} range (Sobczyk *et al.*, 2003). The experimental energy levels of the U^{3+} ion in the compounds were fitted to a semi-empirical Hamiltonian employing free-ion operators, one-electron crystal-field operators, and two-particle correlation crystal-field (CCF) operators, resulting in the determination of crystal-field parameters and the assignment/reassignment of the recorded $5f^3 \rightarrow 5f^3$ transitions. The effects of selected CCF operators on the splitting of

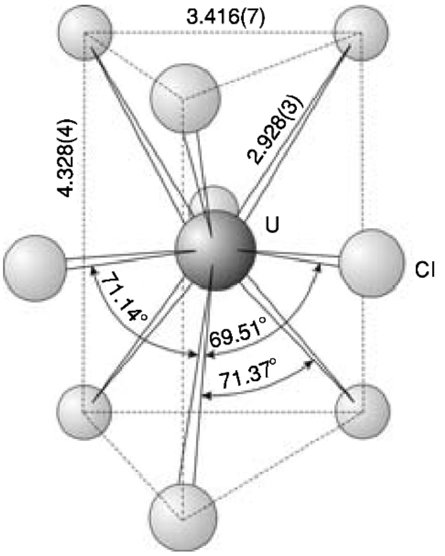

Fig. 5.39 *The tricapped trigonal prism configuration of halogen atoms in UCl_3 and UBr_3 (distances in Å are for UCl_3; after Murasik* et al., 1985).

some specific U^{3+} multiplets have also been investigated. The so far most accurate analysis of the band intensity, based on the Judd–Ofelt theory (Karbowiak and Drożdżyński, 2003), has been based on the obtained electronic wave functions and a room temperature absorption spectrum of UCl_3. A good agreement between the observed and calculated oscillator strengths has been obtained by combining the recorded band areas of some multiplets. In order to check the correctness of the calculations, the obtained intensity parameters, Ω_λ, have been used for the determination of transition probabilities and these in turn for the calculations of radiative lifetimes. A good-quality UCl_3 absorption spectrum has been obtained also by means of teflon disk technique (Schmieder *et al.*, 1970).

The magnetic properties of uranium trichloride have been the subject of extensive investigations (Santini *et al.*, 1999; Drożdżyński, 1991). The inverse magnetic susceptibility as a function of the temperature follows the Curie-Weiss law in two different temperature ranges and exhibits an antiferromagnetic transition at 22 K. Neutron diffraction studies revealed the existence of three-dimensional long-range anti-ferromagnetic ordering below the Néel temperature $T_N = 6.5K$ (Murasik *et al.*, 1981, 1985).

Uranium trichloride hydrates and hydrated uranium(III) chloro complexes

Two hydrates of UCl_3 are known, the heptahydrate, $UCl_3 \cdot 7H_2O$ and the hexahydrate, $UCl_3 \cdot 6H_2O$. The heptahydrate was obtained by reduction of an UCl_4 solution consisting of acetonitrile, propionic acid, and water (Drożdżyński, 1985) with liquid zinc amalgam in an inert atmosphere whereas the reduction is most conveniently accomplished in an all glass apparatus with provisions for precipitation, filtration, and drying in an inert gas atmosphere (Drożdżyński, 1979). It is interesting to note that a few years earlier Habenschuss and Spedding (1980) predicted the possible formation of this compound on the basis of ionic size considerations. $UCl_3 \cdot 7H_2O$ is a crystalline ink-blue solid, readily soluble in numerous organic solvents. The compound is relatively resistant to oxidation by air at temperatures lower than 15°C. At higher temperatures it loses some of its crystallization water and in high vacuum it may be completely dehydrated at 200°C (Drożdżyński, 1985).

X-ray single crystal analyses of the heptahydrate and of the less hydrated $UCl_3 \cdot 6H_2O$ compound have been reported (Mech *et al.*, 2005) (see Table 5.25). In the heptahydrate the crystals are built from separate $[U_2Cl_2(H_2O)_{14}]^{4+}$ units and Cl^- ions. The characteristic features of this structure are dimers, formed by two uranium ions connected through the (Cl1) bridging chlorine atoms. Whereas the basic units of the crystal structure of $UCl_3 \cdot 6H_2O$ are Cl^- anions and $[UCl_2(H_2O)_6]^+$ cations. The basic units of the crystal structure of $UCl_3 \cdot 6H_2O$ are Cl^- anions and $[UCl_2(H_2O)_6]^+$ cations. The U atom is eight-coordinated through six water molecules and two chlorine atoms. In this structure the characteristic feature is the existence of hydrogen bonds, which link the uranium eight-coordinated polyhedra, forming a three-dimensional network.

The presence of water molecules in the inner coordination sphere was also confirmed by the solid-state absorption spectrum of $UCl_3 \cdot 7H_2O$, which is very similar with that of the U^{3+} aquo ion (Drożdżyński, 1978) and exhibits significant differences in comparison to those of the less hydrated uranium(III) complex chlorides (Zych and Drożdżyński, 1986; Drożdżyński, 1988b). A detailed crystal-field level analysis, based on a very good quality low-temperature spectrum, is also available (Karbowiak *et al.*, 2001). The heptahydrate exhibits Curie–Weiss dependence in the temperature range 10 to 300 K. The derived magnetic moment $\mu_{\text{eff.}} = 2.95$ B.M. is much lower than the 'free ion' value of ca. 3.7 B.M., presumably due to the crystal field of the water molecules.

The synthesis and characterization of a number of hydrated complex chlorides of the formulas $MUCl_4 \cdot 5H_2O$ (Barnard *et al.*, 1972b), $MUCl_4 \cdot 4H_2O$ (M = K, Rb or NH_4) (Drożdżyński, 1988b; Karbowiak and Drożdżyński, 1993), $MUCl_4 \cdot 3H_2O$ (M = Cs, K, Rb, or NH_4) (Karbowiak and Drożdżyński, 1993, 1999), and $UCl_3 \cdot CH_3CN \cdot 5H_2O$ (Zych and Drożdżyński, 1986) have been reported.

The pentahydrates were prepared by shaking a U(III) solution in 11 M HCl with the appropriate halide MCl (M = K, Rb, or NH_4) at 0°C. The U^{III} solution was prepared either by dissolving $U_2(SO_4)_3 \cdot 8H_2O$ or by dissolving a uranium (III) double sulphate in 11 M HCl (Barnard *et al.*, 1972a). The preparation of the tetrahydrates can be achieved using a general route reported by Drożdżyński (1979). In this method the reduction of a solution of UCl_4, methyl cyanide, propionic acid, and water with zinc amalgam in anaerobic conditions generates an immediate precipitation of the tetrachlorouranate(III) tetrahydrate (Drożdżyński, 1988b). The formation of the pentahydrates has not been confirmed by X-ray investigations. Apart from some expected similarities between the compounds of the series, one can also note differences, e.g. that the tetrahydrates are reported to be readily soluble in dry methanol or ethanol, in contrast to the pentahydrates. The tetrahydrates are also much more resistant to oxidation and hydrolysis in dry air and temperatures below 15°C, and can be easily transformed into the anhydrous salts by thermal dehydration at high vacuum. One may note also a red shift of the $5f^3 \rightarrow 5f^3$ transitions and relatively large differences in the plots of the reciprocal susceptibilities as well as in the derived effective magnetic moments.

Structure investigations revealed that $(NH_4)UCl_4 \cdot 4H_2O$ belongs to the orthorhombic system, space group $P2_12_12$. The crystal is built up from separate $[U(H_2O)_4Cl_4]^-$ and NH_4^+ ions. The eight-coordinated U^{3+} polyhedra are connected by $O{-}H \cdots Cl$ hydrogen bonds forming a three-dimensional network (Karbowiak *et al.*, 1996c). X-ray powder diffraction patterns show that the other members of the series could also be indexed on the basis of the orthorhombic cell (Karbowiak *et al.*, 1996c). $(NH_4)UCl_4 \cdot 4H_2O$ is an excellent starting material for the preparation of numerous other uranium(III) compounds.

The $MUCl_4 \cdot 3H_2O$ series of compounds was also obtained by reduction of appropriate acetonitrile solutions of UCl_4 and MCl (where M = K, Rb, Cs, or NH_4) with liquid zinc amalgam, but using somewhat different conditions than those used to prepare the tetrahydrates (Karbowiak and Drożdżyński, 1993). In contrast to the deep purple-red colors of the penta- and tetrahydrates the latter ones show green to brown colors. In this series the first broad and strong $5f^3 \rightarrow 5f^2 6d^1$ bands were observed in the absorption spectra at wavenumbers higher than 21 000 cm^{-1}.

Single-crystal X-ray analysis is available for $CsUCl_4 \cdot 4H_2O$ (Krämer *et al.*, 1991). The compound crystallizes in the monoclinic system, space group: $P2_1/m$ (Table 5.25). Uranium has a coordination number of nine (tricapped trigonal prism) consisting of six chlorine atoms and three oxygen atoms (representing water) with mean distances of 2.957 and 2.552 Å, respectively. Cesium is surrounded by eight chlorine atoms in the shape of a distorted cube, which is capped by two non-bonded water ligands at a mean distance of 3.602 Å. One can view the structure as a linking of the polyhedra $[U(Cl1)_4(Cl2)_2(H_2O)_3]$ through two common edges of chloride (Cl1) ligands at two triangular faces of the trigonal prism of chloride ions to an infinite zigzag chain in the [010] direction. X-ray powder diffraction analyses show that the remaining three members of the series could be indexed on the basis of the same monoclinic cell, and that they presumably are isostructural.

For the tri- and tetrahydrates the first broad and strong $5f^3 \rightarrow 5f^2 6d^1$ bands are observed in the absorption spectra at about 21 500 and 16 000 cm^{-1}, respectively. The red shift of these bands has been attributed to the formation of inner sphere complexes with some of the uranium–ligand bond lengths of a markedly more covalent character than that of the U^{3+} aqua-ion, e.g. in $UCl_3 \cdot 7H_2O$ (Drożdżyński, 1991; Karbowiak *et al.*, 1996c). The magnetic susceptibility constants from the Curie–Weiss law are listed in Table 5.25.

Anhydrous uranium(III) chloro complexes

The largest group of well-characterized uranium(III) compounds is formed by chloro complexes such as $CsUCl_4$ (Karbowiak and Drożdżyński, 1998c), M_2UCl_5 (M = K, Rb, Cs. or NH_4) (Drożdżyński and Miernik, 1978; Meyer *et al.*, 1983), $SrUCl_5$ (Karbowiak and Drożdżyński, 1998b), $[(CH_3)_3N]_3UCl_6$ (Karbowiak *et al.*, 1996a); MU_2Cl_7 (M = K, Rb, Ph_4As or Ph_4P) (Drożdżyński, 1991; Karbowiak *et al.*, 1996b); Ba_2UCl_7 (Karbowiak *et al.* 1998d); M_2NaUCl_6 (M = K, Rb or Cs) (Aurov *et al.*, 1983; Volkov *et al.*, 1987), and Cs_2LiUCl_6 (Karbowiak and Drożdżyński, 1998a).

Most of the complex chlorides can be conveniently prepared by heating stoichiometric amounts of the component halides in graphite-coated quartz tubes. The $(NH_4)_2UCl_5$, $Ph_4AsU_2Cl_7$, and $Ph_4PU_2Cl_7$ compounds were obtained by reduction of appropriate uranium tetrachloride solutions in acetonitrile with liquid zinc amalgam (Drożdżyński, 1991; Drożdżyński and Miernik, 1978). Also the complexes with the general formulas M_2UCl_5 and MU_2Cl_7 can be prepared in this way (Drożdżyński, 1979). All the syntheses were carried out in an inert atmosphere or high vacuum of ca. 10^{-4} Pa. Spectroscopic studies and crystal-field analysis of U^{3+}:RbY_2Cl_7 and U^{3+}:Li_2NaYCl_6 single crystals were reported by Karbowiak *et al.* (1996b, 1977) and Karbowiak *et al.* (1996e, 1998b), respectively.

The formation of number of uranium(III) chloro complexes has also been observed during investigations of binary and ternary phase systems (Brown, 1979). The complexes display a variety of colors (Table 5.25). All of them are hygroscopic but are somewhat resistant to oxidation in dry air. Unlike UCl_3 the complex chlorides are readily soluble in numerous polar organic solvents.

K_2UCl_5 and Rb_2UCl_5 crystallize in the orthorhombic system and are isotypical with the K_2PrCl_5/Y_2HfS_5 structures, their space group is *Pnma*, $Z = 4$ (Krämer *et al.*, 1994). The coordination polyhedron is a monocapped trigonal prism [UCl_7], connected via two opposite common edges to chains, $[UCl1_{1/1}Cl2_{1/1}Cl3_{1/1}Cl4_{4/2}]^{-2}$, that run in the [010] direction of the unit cell. The relatively short U^{3+}–U^{3+} distance through the common edge, equal to 4.556 Å, is assumed to be responsible for antiferromagnetic transitions at 8.6 to 13.2 K. The temperature dependence of the inverse molar susceptibilities in the 20–300 K range follows the Curie–Weiss law in two temperature ranges, separated by a slight but apparent break at 130, 150, and 220 K, respectively, for K_2UCI_5, Rb_2UCl_5, and $(NH_4)_2UCl_5$. The effective magnetic moments range from 3.47 B.M. for $(NH_4)_2UCl_5$ to 3.99 B.M. for K_2UCI_5 (Drożdżyński and Miernik, 1978). Some other magnetic susceptibility constants determined from the Curie–Weiss law are listed in Table 5.25.

Solid-state electronic spectra of thin mulls of the compounds show all characteristic features of the uranium(III) complex anions with strong $5f^3 \rightarrow 5f^2 6d^1$ bands starting at ca. 18000 cm^{-1}. The complexes exhibit very similar far-IR spectra with one broad and not well-resolved band in the region 100–240 cm^{-1} assigned to U-Cl stretching modes. An analysis of magnetic phase transitions and crystal-field splittings in the K_2UX_5 (X = Cl, Br, or I) series of complex halides is reported by Keller *et al.*(1995).

Single-crystal X-ray data show that Cs_2NaUCl_6 (Spirlet *et al.*, 1988) crystallizes with the ideal cryolite arrangement. Each of the uranium or sodium ions is octahedrally surrounded by six chloride ions at the distance of 2.723(9) and 2.746(9) Å, respectively. The cesium ions (site symmetry T_d) are surrounded by 12 equidistant chloride ions with d(Cs–Cl) = 3.867(8) Å (for other data see Table 5.25). The enthalpies of formation of the hexachloro complexes are also available (Aurov and Chirkst, 1983; Schoebrechts *et al.*, 1989).

It is interesting to note the preparation of a reduced metallic uranium chloride which has been formulated as NaU_2Cl_6 or $(Na^+)(U^{3+})_2(e^-)(Cl^-)_6$ (Schleid and

Meyer, 1989). The extra electrons provided by the incorporation of the sodium atom are reported to occupy the 6d band of uranium. The compound is isostructural with $NaPr_2Cl_6$ and may be described as a stuffed derivative of UCl_3 (hexagonal symmetry, space group $P6_3/m$). Other available information about the compounds is compiled in Table 5.25.

Complexes of UCl_3 with neutral donor ligands

Ammonia adducts of the composition $UCl_3 \cdot 7NH_3$ and $UBr_3 \cdot 6NH_3$ were obtained by treatment of the halides with gaseous ammonia at room temperature and a pressure of 1013 hPa (Eastman and Fontana, 1958; Berthold and Knecht, 1965b, 1968). Since heating in a stream of nitrogen up to 45°C formed a relatively stable $UCl_3 \cdot 3NH_3$ complex, indicating that the compounds contain some loosely bound ammonia. At higher temperatures this adduct decomposes into $UCl_3 \cdot NH_3$, which is stable up to 300°C.

According to MacCordick and Brun (1970) the heating of UCl_3 with an excess of acetonitrile in sealed tube at 80°C results in the separation of a brown, hygroscopic solid of the formula $UCl_3 \cdot CH_3CN$. However, an attempt to repeat the preparation was unsuccessful (Barnard *et al.*, 1973).

A purple adduct of the composition $UCl_3(THF)_x$ has been prepared by reduction of a UCl_4 solution in THF with stoichiometric amounts of NaH or an excess of Na_2C_2. The obtained purple solution of $UCl_3(THF)_x$ is reported to be a useful starting material for numerous syntheses (Moody and Odom, 1979; Andersen, 1979; Moody *et al.*, 1982).

Hart and Tajik (1983) have reported the preparation of numerous air sensitive uranium(III) complexes with cyclic polyethers and aromatic diamines by reduction with liquid zinc amalgam in acetonitrile or acetonitrile/propionic acid solutions of UCl_4 and the appropriate ligand, e.g. $(UCl_3)_3$(benzo-15-crown-5)$_2 \cdot 1.5CH_3CN$ (yellow-orange), $(UCl_3)_3$(benzo-15-crown-5)$_2$ (deep red), UCl_3 (cyclohexyl-15-crown-5) (red-purple), $(UCl_3)_3$(18-crown-6)$_2$ (red-brown), $(UCl_3)_5$(dibenzo-18-crown-6)$_3$ (deep-red), $(UCl_3)_5$(*cis-syn-cis*-dicyclohexyl-18-crown-6)$_3$ (red), UCl_3(1,10 phenantroline)$_2$ (violet-purple) and UCl_3(2,2′-bipyridile)$_2$. The complexes are insoluble or react with common organic solvents. The preparation of several trivalent uranium complexes with crown ethers, oxygen donor or amine ligands has also been reported by other authors e.g. UCl_3(15-crown-5)(red), UCl_3(18-crown-6), UCl_3(benzo-15-crown-5) (red) by Moody *et al.* (1979, 1982), as well as $(UCl_3)_3$(18-crown-6)$_2$ (red-brown), $(UCl_3)_2$(2,2′-bipyridine)$_3$ (bright-green) and $(UCl_3)_2$(dimethoxyethane)$_3$ (brown) by Rossetto *et al.* (1982). All complexes are hygroscopic and more or less rapidly oxidized by atmospheric air. They exhibit some characteristic features of U(III) absorption spectra with very intense f–d transitions in the visible and/or ultraviolet region. Infrared data are indicative to decide if the coordination takes place through the ligand nitrogen or oxygen atoms. Some of the complexes have also been characterized by magnetic susceptibility measurements at 298 K (Hart and Tajik, 1983).

(*iii*) *Uranium tribromide and uranium*(*III*) *bromo complexes*

Uranium tribromide

Uranium tribromide can most conveniently be prepared by the reaction of uranium hydride with gaseous hydrogen bromide at 300°C. The method is also suitable for a large-scale preparation (Brown, 1979). Alternative methods include the reduction of UBr_4 by metallic zinc or finely divided uranium at about 600°C. Since UBr_3 reacts with quartz at that temperature, the reaction ought to be performed in a sealed tantalum or molybdenum vessel. In small quantities it may be readily prepared by thermal vacuum decomposition of $NH_4UBr_4 \cdot 5CH_3CN \cdot 6H_2O$ (Zych and Drożdżynski, 1990a). Other preparation procedures such as a direct combination of the elements or the reaction between uranium oxalate and gaseous hydrogen bromide seem to be less convenient (Brown, 1979).

UBr_3 is a dark-brown substance, much more hygroscopic and sensitive to oxidation in air than UCl_3. Rapid oxidation occurs on dissolution in water and in numerous organic solvents. It gives, however, somewhat more stable solutions in formamide, methyl acetate, dimethylacetamide, and acetic acid. Reactions with chlorine and bromine yield UCl_4 and UBr_4, respectively. UBr_3 is reduced by calcium to metallic uranium at high temperatures.

Uranium tribromide is isostructural with UCl_3. The unit cell data are given in Table 5.25. The interatomic distances of the tricapped trigonal prismatic coordination polyhedron obtained from neutron diffraction studies (Levy *et al.*, 1975) and by Krämer and Meyer (1989) (values in parentheses) are: d(U–Br) = 3.145 Å (3.150 Å) to the three capping Br atoms, d(U–Br) = 3.062 Å (~3.069 Å) to the six Br atoms at the prism vertices, d(Br–Br) = 3.652 Å (3.663 Å) at the trigonal prism face edge and d(U–U) = 4.441 Å (4.448 Å) along the c-direction.

Using low-temperature, high-resolution absorption and fluorescence spectra of UBr_3 doped into single crystals of $LaBr_3$ (Paszek, 1978) and K_2LaBr_5 (Karbowiak *et al.*, 1998a) a complete crystal-field analysis in the 4000–22000 cm^{-1} absorption range has been performed. Magnetic susceptibility measurements in the 4.5–483 K range show an antiferromagnetic transition at $T_N = (15 \pm 0.5)$ K. The effective magnetic moments equal to 3.92 and 3.57 B.M. have been determined from the temperature ranges where a plot of $1/\chi_M$ against T is linear.

Uranium tribromide hexahydrate

Uranium tribromide may be converted to the hexahydrate by controlled exposure to oxygen-free water vapor (Brown *et al.*, 1968). On prolonged pumping the obtained red-colored hexahydrate slowly loses most of the coordinated water until the composition approximates $UBr_3 \cdot H_2O$. Complete dehydration occurs with a slow and gradual increase of temperature to about 100°C. X-ray powder diffraction pattern shows that $UBr_3 \cdot 6H_2O$ is isostructural with the monoclinic lanthanide trihalide hexahydrates (Table 5.25). Further information is not available.

Uranium(III) bromo complexes

Bromouranates(III) of the composition M_2UBr_5 and M_3UBr_6 ($M = K$, Rb or Cs) have been identified during investigations of the binary fused-salt systems (Vdovenko *et al.*, 1974a; Volkov *et al.*, 1987). The pentabromouranates(III) may also be prepared by fusion of the appropriate components. Complexes of the M_3UBr_6 type are high-temperature phases and decompose on cooling into the alkali bromide and the corresponding pentabromouranate(III). The melting points and regions of existence of the hexabromouranates(III) increase with an increase in the atomic number of the alkali metal. An opposite tendency is observed in the series of pentabromouranates(III) (Vdovenko *et al.*, 1974a). Suglobova and Chirkst (1978a) have reported the thermodynamic properties of some of the bromo complexes.

X-ray powder diffraction analyses reveal that the hexabromouranates(III) have a face-centered cubic symmetry whereas the pentabromouranates(III) are isostructural with the rhombic Tl_2AlF_6. On this basis, it has been assumed (Suglobova and Chirkst, 1978b) that the structure of the pentabromouranates (III) contains distorted UBr_6 octahedra, which combine into parallel chains through common vertices. Aurov *et al.* (1983) and Aurov and Chirkst (1983) have reported X-ray powder diffraction and thermodynamic data for K_2NaUBr_6 and Cs_2NaUBr_6 by (Table 5.25).

A royal-blue $UBr_3(THF)_4$ adduct has been obtained by a gentle dissolution of uranium metal turnings in THF at a reaction temperature near 0°C (Avens *et al.*, 1994). The compounds $K_2UBr_5 \cdot 2CH_3CN \cdot 6H_2O$, $Rb_2UBr_5 \cdot CH_3CN \cdot 6H_2O$ and $(NH_4)[UBr_2(CH_3CN)_2(H_2O)_5]Br_2$ were obtained from acetonitrile solutions of UBr_4 and the appropriate ammonium or alkali metal bromide, by reduction with liquid zinc amalgam (Zych and Drożdżyński, 1990b, 1991; Zych *et al.*, 1993). All compounds are well characterized by various physical methods (Table 5.25). Single crystal X-ray data are available for $(NH_4)[UBr_2(CH_3CN)_2(H_2O)_5]Br_2$, (Zych *et al.*, 1993).

(*iv*) *Uranium(III) iodide and uranium(III) iodo complexes*

Uranium triiodide

A convenient and widely used method for the preparation of uranium triiodide involves the action of iodine vapors on finely divided uranium metal, either in sealed or flow systems at 570 and 525°C, respectively. Large quantities of high purity UI_3, in the form of black crystals, are collected in the 375–450°C condensing zone of a flow system apparatus first reported by Gregory (1958). Alternative procedures employ the reduction of uranium tetraiodide with zinc metal or finely divided uranium metal, reaction between uranium hydride and methyl iodide, and vacuum thermal decomposition of UI_4 at 225–235°C (Brown, 1979).

UI_3 is a jet-black, highly hygroscopic crystalline solid, sensitive to oxidation in air. Even at elevated temperatures the triiodide is corrosive and attacks glass, which at 800°C is reduced to silicon. The compound reacts with iodine, methylchloride, and uranium tetrachloride to yield UI_4, UCl_4, and $UClI_3$, respectively. UI_3 dissolves in aqueous solutions, methanol, ethanol, ethyl acetate, dimethylacetamide, and acetic acid forming unstable U(III) solutions. Spontaneous oxidation within 1 min was observed in organic solvents like dioxan, pyridine, acetonitrile, dimethylformamide, or acetone (Barnard *et al.*, 1973).

UI_3 possesses the orthorhombic $PuBr_3$-type structure (Zachariasen, 1948a). The structure (space group $Ccmm$ - D_{2h}^{17}) was studied in detail also by neutron diffraction profile analysis (Levy *et al.*, 1975; Murasik *et al.*, 1981). The coordination polyhedron is a distorted bicapped trigonal prism layered in planes perpendicular to the *a*-axis.

Diffuse reflectance spectra have been reported in the 4000–30000 cm^{-1} range at room temperature and 90 K (Barnard *et al.*, 1973). In the series of uranium (III) halides one may observe a pronounced red shift of the first $5f^3 \rightarrow 5f^2 6d^1$ bands from about 23000 cm^{-1} in the spectrum UF_3 to about 13400 cm^{-1} forUI_3.

Magnetic susceptibility measurements have shown an antiferromagnetic transition at $T_N = (3.4 \pm 0.2)$ K as well as a second susceptibility maximum at 1.5 K. UI_3 exhibits a first-order magnetic phase transition. The compound orders antiferromagnetically at $T_N = 2.6$ K, resulting in the appearance of a magnetic sublattice (Parks and Moulton, 1968). Neutron scattering investigations reveal hysteresis of the integretated neutron intensity of the magnetic reflections versus temperature, which confirms that the phase transition is of the first order (Murasik *et al.*, 1986).

Complexes with neutral donor ligands

The reaction of elemental iodine with an excess of oxide-free uranium metal turnings in appropriate coordinating solvents at 0°C yields dark purple $UI_3(THF)_4$, purple $UI_3(dme)_4$, black $UI_3(py)_4$ (Avens *et al.*, 1994), and a dark brown $UI_3(CH_3CN)_4$ (Drożdżyński and du Preez, 1994) (THF, tetrahydrofuran; dme, 1,2-dimethoxyethane; py, pyridine). These organic-solvent soluble Lewis base adducts are reported to be key starting materials for the preparation of variety of inorganic and organometallic uranium complexes. Single-crystal X-ray diffraction data show that $UI_3(THF)_4$ is mononuclear with a pentagonal bipyramidal coordination geometry about the uranium ion. Two iodide atoms, with an average U–I lengths of 3.111(2) Å are axially coordinated. The third iodide atom and the four THF ligands lie in the equatorial plane with the U–I distance of 3.167(2) Å and average U–O distances of 2.52(1) Å (Avens *et al.*, 1994). Other available information is listed in Table 5.25.

(*v*) *Uranium*(*III*) *oxide halides and mixed halides*

The uranium(III) oxide halides UOCI, UOBr, and UOI were prepared by heating stoichiometric mixtures of UO_2X_2, UO_2, and U or UX_4, U_3O_8 and U (X = Cl, Br or I), for 24 h at 700°C (Levet and Noël, 1981). The chemical properties of UOCI, UOBr, and UOI have not been reported.

The X-ray powder diffraction patterns are consistent with the tetragonal PbFCl-type of structure (*P*4/*nmm*). In a recent investigation, the structure was refined by single-crystal X-ray analysis and the atomic positions were determined (Schleid and Meyer, 1988). A plot of the inverse paramagnetic susceptibility against temperature follows the Curie–Weiss law from about 220 to 300 K with μ_{eff} of 3.40, 3.67, and 3.56 B.M. for UOCl, UOBr, and UOI, respectively. All of the oxide halides are weak ferromagnets with nearly the same transition temperatures ranging from 190 to 183 K. Some IR data are also available (Levet and Noël, 1981).

The preparation of a number of uranium(III) mixed halides with the general formulas UXY_2 and UX_2Y, where X = Cl or Br and Y = Cl or I were reported (Gregory, 1958), but very little information about their properties is available. $UClBr_2$ was obtained by reduction of UCl_3Br with hydrogen at 400°C. The UBr_3 by-product is removed from the substance by treatment with iodine. One of the most convenient methods for the preparation of UCl_2Br is reported to be the fusion of a 2:1 molar ratio of UCl_3 and UBr_3 at 850°C. The solid-state reaction between UCl_3 and UI_3 has been also applied successfully for the preparation of $UClI_2$. The remaining mixed halides, i.e. UCl_2I, UBr_2I, and $UBrI_2$ have usually been obtained by thermal decomposition of UCl_2I_2 and UBr_2I_2 at 400°C, and of $UBrI_3$ at 375°C (see also Table 5.25).

(b) Tetravalent halides and complex halides

Uranium tetrahalides and complex halides have so far been the most extensively investigated group of uranium compounds besides those in the 6+ oxidation state. The tetrahalides are not stable on exposure to air however with some exceptions, e.g. that of UF_4. They are more or less hygroscopic and after a time the compounds get oxidized in air. The large chemical stability of UF_4 is mainly due to its high lattice energy. Apart from the fluorides most of the compounds are readily soluble in polar solvents. Aqueous solutions are slowly oxidized to U(VI) species, but in pure and thoroughly deoxygenated solvents U^{4+} is fairly stable. The typical colors vary from pale olive green to deep bluish-green. In few cases black, brown, and blue colors have also been noticed (Table 5.26). The synthesis of binary uranium(IV) halides usually requires strictly oxygen-free conditions. The coordination polyhedra in the binary tetrahalides are more or less distorted forms of a square antiprism (UF_4), a dodecahedron (UCl_4), or a pentagonal bipyramid (UBr_4). The tetrahalides form stable solid complexes with a large variety of ligands, e.g. of the UX_4L_2-type (X = Cl. Br, or I)

---

[*] Peritectic decomposition point.

[†] Values recommended by the Nuclear Energy Agency (Guillaumont *et al.*, 2003) .

[a] Values have been selected in part from review articles (Brown, 1979, Bacher and Jacob, 1980; Freeman,1991; Grenthe *et al.*,1992; Guillaumont *et al.*, 2003);

[b] m.p. = melting point (°C); b.p(°C). = boiling point; (cr) = crystalline; (g) = gaseous; thermodynamic values in kJ mol^{-1}, or J $K^{-1}mol^{-1}$ at 298.15 K, unless otherwise mentioned; $\Delta_f G_m^o$, standard molar Gibbs energy of formation; $\Delta_f H_m^o$– standard molar enthalpy of formation; S_m^ostandard molar entropy; $C_{p,m}^o$, standard molar heat capacity; log p (mm Hg) = $-AT^{-1} + B - C \log T$: vapour pressure equation for indicated temperature range; IR = infrared active; L = lattice vibrations; val. = valence vibrations; def. = deformation vibrations; all values in cm^{-1}; s:strong; m: medium; w: weak; sh: shoulder; Energy levels parameters: F_k, F^k, ζ_{5f} = electrostatic and spin–orbit interaction parameters; α, β, γ; = two-body correction; M^j ($j = 0$, 2 and 4) = spin-spin and spin-other-orbit relativistic corrections; P^k = the electrostatically correlated spin-orbit perturbation parameters; B_q^k = crystal-field parameters; values in brackets indicate parameter errors; standard deviation: $rms = \sum_i \left[(\Delta_i)^2/(n-p)\right]^{1/2}$[$cm^{-1}$], where Δ_i is the difference between the observed and calculated energies, n is the number of levels fitted and p is the number of parameters freely varied.

[c] All values are in Å and angles are in degrees; CN, coordination number; d represents density in g cm^{-3}, V = molar volume [cm^3 mol^{-1}].

[d] Temperature range with linear relationship of χ_M^{-1} against T.

with arsine oxides or phosphine oxides (du Preez *et al.*, 1977b; du Preez and Zeelie, 1987).

Tetravalent uranium has a [Rn]$5f^2$ electronic configuration. The ground state is nominally $^3H_4$. The earlier studies of absorption spectra of tetravalent halides in the solid state, aqueous solutions, organic solvents, and in doped host crystals have been compiled in a review article by Carnall (1982). Krupa (1987) analyzed the spectroscopic properties of the ions in solids with their characteristic $5f^2 \rightarrow 5f^2$ transitions. In contrast to the uranium(III) spectra, the spin–orbit interactions in different compounds are of the same order of magnitude and the f–d transitions have been observed at higher energies beginning near 40000–45000 cm^{-1}. For a number of halides and complex halides, low-temperature absorption spectra have been recorded and the energy levels of the U^{4+} ion in different site symmetries were assigned and fitted to a semiempirical Hamiltonian representing the combined atomic and crystal-field interactions. An analysis of octahedral UX_6^{2-} spectra for a series of $(NEt_4)_2UX_6$ salts (X = F, Cl, Br or I) was reported by Wagner *et al.* (1977). The authors have noticed that the Slater parameter F^2 diminishes by ~20% for the series and the crystal-field parameters are different from those of the comparable octahedral PaX_6^{2-} and UX_6^{2-} halides. Analyses of the energy-level structure of U^{4+} ion doped in an isomorphic series of tetragonal ($I4_1/amd$) host crystals such as $ThSiO_4$, $ThCl_4$, and $ThBr_4$ (Delamoye *et al.*, 1983; Simoni *et al.*, 1988; Malek *et al.*, 1986a,b; Malek and Krupa, 1994) led to consistent sets of free ion and crystal-field parameters with a least square deviation (r.m.s.) between 36 and 71 cm^{-1}. In these host crystals, U^{4+} experiences a rather weak crystal field, which justifies the same theoretical approach as for the Ln^{3+} ions; this is in contrast to that in higher symmetry sites as found in $U(BD_4)_4/Hf(BD_4)_4$ (site symmetry T_d; Rajnak *et al.*, 1998), Cs_2UX_6 (X = Cl or Br) (site symmetry O_h; Johnston *et al.*, 1966; Satten *et al.*, 1983) or U^{4+}: $CsCdBr_3$ (disturbed O_h site symetry; Karbowiak *et al.*, 2005b) where the crystal field splitting is approximately twice as large with the r.m.s. deviation of 100 to 150 cm^{-1}. As a result, mixing of crystal field components of different multiplets in close proximity may occur. In an analysis of the absorption spectrum of Cs_2UBr_6 single crystals, Faucher *et al.* (1996) have shown that the inclusion of configuration interactions with the higher lying $5f^17p^1$ electronic configuration in the fitting procedure may considerably improve the r.m.s. deviation.

An analysis of (U^{4+}, U^{3+}):BaY_2Cl_7 single crystals (Karbowiak *et al.*, 2003b) enabled the assignment of 60 observed $5f^2 \rightarrow 5f^2$ transitions from absorption, excitation, and luminescence spectra, which encompasses all but the $^1S_0$ multiplet. A comparison of the scalar crystal field parameters,

$$N_v = \left[\sum_{k,2} (B_2^k)^2 \frac{4\pi}{(2k+1)} \right]^{1/2}$$

(Auzel and Malta, 1983), indicates that the main factor determining the crystal-field strength is not the nature of the ligand but the site symmetry of the central ion; this is in contrast to that for Ln^{3+} and U^{3+} ions. Energy transfer has been demonstrated between uranium ions in the 3+ and 4+ oxidations states. A very strong anti-Stokes emission was observed for the U^{4+} ions.

In all cases in which the uranium ions are occupying sites of inversion symmetry, as in UCl_6^{2-}, the observed band structure consists almost exclusively of vibronic side bands and their progressions could be used to deduce the electronic transitions. The analysis of absorption spectra of UF_4 in a KBr pellet at 4 K as well as of U^{4+}(aq.) at 298 K have been reported by Cohen and Carnall (1960) and Carnall *et al.* (1991). The authors have also compared the crystal-field interactions of UF_4, NpF_4, and PuF_4. The absorption spectrum of thin films of a mixture of UF_4 with chlorinated naphthalene (refraction index 1.635) at 7 K is shown in Fig. 5.40 (Drożdżyński and Karbowiak, 2005) and is typical for most uranium(IV) compounds. In this region the spectra consist of relatively intense and sharp absorption lines. The intra-configurational $5f^3 \rightarrow 5f^3$ transitions result in 91 non-degenerated crystal field levels.

Magnetic susceptibility measurements have been carried out over wide temperature ranges for almost all halides and complex halides. The paramagnetic constants from the Curie–Weiss law $\chi'_m = C/(T - \theta)$ and the effective magnetic moments ($\mu_{eff} = 2.84\sqrt{c}\mu_{B+}$) for some of the compounds are collected in Table 5.26. Hexachloro uranates(IV) show temperature-independent paramagnetism between 4 and 300 K with $\chi_M = 2000 \times 10^{-6}$ emu.

(*i*) *Uranium tetrafluoride and complex uranium(IV) fluoro compounds*

Uranium tetrafluoride

Uranium tetrafluoride has important industrial applications in the conversion of uranium ore to UF_6 and in the production of UO_2. The former is a key compound in the uranium enrichment process and UO_2 is a nuclear fuel. The usefulness of UF_4 in these two processes depends on its large chemical stability and an almost complete insolubility in aqueous solutions. Fluoride melts containing UF_4 have also proved to be suitable in 'homogeneous reactors'. The preparation of UF_4 has been extensively investigated (Brown, 1968, 1979; Bacher and Jacob, 1980; Freestone and Holloway, 1991). Most of the procedures are based either on precipitation from aqueous solutions or on high-temperature reactions in anhydrous conditions. In the first method, aqueous uranyl solutions are reduced to U(IV) by $SnCl_2$, $Na_2S_2O_4$, $FeSO_4$, CuCl, $CrCl_3$, $TiCl_3$, and SO_2 (combined with Cu^{2+}ions), or electrochemically; after reduction, two hydrates, $UF_4 \cdot 2.5H_2O$ and $UF_4 \cdot nH_2O$, with $0.5 < n < 2$, are obtained by precipitation with F^- (Allen *et al.*, 1950; Anderson *et al.*, 1950; Dawson *et al.*, 1954). The preparation from aqueous solutions based on electrolytic reductions of uranyl solutions has found industrial application in the Excer Process (ion exchange conversion, electrolytic reduction (Higgins and Roberts, 1956; Marinsky, 1956; Bacher and Jacob, 1980).

Since it is difficult to remove water without hydrolytic reactions, UF_4 produced by aqueous processes is not suitable for reduction to metal or for conversion to UF_6. Consequently, it has been customary to prepare UF_4 by high-temperature reactions. One of the most convenient methods to produce UF_4 on a large scale employs heating of UO_2 in an excess of anhydrous HF at 400–600°C.

$$UO_2 + 4HF \xrightarrow{550^\circ C} UF_4 + 2H_2O$$

This and similar methods result in the formation of a highly reactive form of the dioxide. If the starting material is a non-stoichiometric oxide, it is essential to insert H_2 in order to avoid reactions such as:

$$U_3O_8 + 8HF \rightarrow 2UO_2F_2 + UF_4 + 4H_2O$$

Ruehle (1959) describe the synthesis of UF_4 using a stirred fluidized-bed hydrofluorination reactor. The chemistry of the reaction has been discussed by Dawson *et al.* (1954).

On a large scale the compound may be prepared by thermal decomposition of $UO_4 \cdot 2H_2O$ to UO_3 at 250°C followed by reduction with hydrogen to UO_2 at 600°C and fluorination to UF_4 with NH_4HF_2 at 150°C (Van Impe, 1954). Alternatively, UF_4 may be obtained in a similar route using uranium(IV) acetate or by reaction of UO_2 with SF_4 at 500°C.

Other satisfactory methods involve the direct reduction of UO_3 to UF_4 by ammonia–hydrogen fluoride mixtures at 500–750°C and by NH_4F, NH_4HF_2, or a mixture of NH_4HF_2 and hydrazine fluoride. Also various freons, in particular, CF_2Cl_2, are useful fluorinating agents for UO_2, UO_3, and $(NH_4)_3U_4O_{16}F_3$ (Evers and Reynolds, 1954; Van Impe, 1954).

Attractive alternatives for the preparation of smaller amounts include the heating of metallic uranium with anhydrous hydrogen fluoride in a sealed tube at 225–250°C and treating UH_3 or uranium with hydrogen fluoride vapours at 250–350°C or with a mixture of $H_2 + HF$ at 250°C (Brown, 1979).

Since UF_6 is the starting material for ^{235}U enrichment, it is also a convenient preparatory material for enriched metallic uranium via uranium tetrafluoride. The preparation of UF_4 from UF_6 may be performed by:

(i) reduction with H_2 in the gaseous phase (Smiley and Brater, 1958, 1960; Bacher and Jacob, 1980)

$$UF_6 + H_2 \overset{630^\circ C}{\rightarrow} UF_4 + 2HF$$

(ii) reduction with chlorinated hydrocarbons C_2HCl_3, C_2Cl_4, and CCl_4 (Bacher and Jacob, 1980, 1986)

$$UF_6 + 2CCl_4 \xrightarrow{200^\circ C,\, p=29\, bar} UF_4 + 2CCl_3F + Cl_2$$

(iii) the reaction with Me_3SiX (Brown *et al.*, 1983)

$$UF_6 + 2Me_3SiX \rightarrow 2Me_3SiF + X_2 + UF_4 (X = Cl\ or\ Br)$$

On technical scale the reaction (i) may be performed either in a 'hot-wall reactor', by heating the outside wall of the reactor up to 650°C, or in a 'cold-wall reactor' in which the energy is supplied by the reaction

$$F_2 + H_2 \rightarrow 2HF$$

The temperature of the reactor wall is kept between 150 and 200°C. In order to achieve a complete conversion in the reactions (ii) and (iii), a substantial excess of CCl_4 and a molar ratio 1:2 of UF_6 to Me_3SiX is essential (Bacher and Jacob, 1980; Hellberg and Schneider, 1981).

Uranium tetrafluoride is an emerald-green high melting polymeric solid, entirely insoluble in water. However it may be dissolved in the presence of reagents that can form fluoride complexes, such as Fe^{3+}, Al^{3+}, or boric acid, for example. It is a good starting material for the synthesis of UF_6 and production of uranium metal by reduction with calcium or magnesium. The reduction may also be performed with Li, La, or Al whereas Zr, Be, Ti, or hydrogen leads to uranium trifluoride. The compound is stable in air at room temperature, which makes it useful as an intermediate product in the conversion of uranium ore to UF_6. For sublimation *in vacuo*, a stainless steel tube with a molybdenum liner has been used (Dawson *et al.*, 1954). Uranium tetrafluoride reacts with strong oxidizing reagents such as Ce^{4+}, concentrated perchloric acid, nitric acid and, nitric acid–boric acid or sulphuric acid–ammonium persulphate mixtures with the formation of the appropriate uranyl salt solutions.

UF_4 is monoclinic, with the same structures as those of zirconium and hafnium tetrafluorides. The structure at different temperatures has been examined in detail by Kern *et al.* (1994), using neutron diffraction on polycrystalline samples. The unit cell of UF_4 contains 12 formula units with four (U1) and eight (U2) sites having C_2 symmetry. Each uranium atom has eight fluorine neighbors arranged in a slightly distorted square antiprism. A basic repeating unit of five uranium atoms is arranged in a slightly distorted pyramid. Four of them are forming a rhomb-shaped base, and the fifth comprises the apex of the pyramid. For other details see Table 5.26.

The thermodynamic properties of UF_4 have been analyzed in detail by Rand and Kubaschewski (1963), Kubaschewski and Alcock (1979), and Fuger *et al.* (1983). The heat capacity from 1.3 to 20 K has been measured by Burns *et al.* (1960) and between 5 and 300 K by Osborne *et al.* (1955).

Carnall *et al.* (1991) have reported an analysis of the low-temperature crystal-field absorption spectrum of UF_4. The authors found a good agreement between the experimentally observed and calculated band structure using an effective Hamiltonian with orthogonalized free-ion operators. The initial crystal-field parameter values were calculated on the basis of a superposition model for An^{4+} sites with C_2 symmetry. The values obtained are listed in Table 5.26. The parameters have been obtained in a fit of 69 observed crystal-field levels of UF_4; the r.m.s. error is 31 cm^{-1}. The spin–spin and spin–orbit parameters, $M^0 = 0.775$, $M^2 = 0.434$, and $M^4 = 0.294$, were assigned on the basis of *ab initio* calculations and were not varied in the fitting. The electrostatically correlated spin–orbit perturbation parameters P^4 and P^6 were constrained by keeping the ratios P^4/P^2 and P^6/P^2 constant, equal to 0.5 and 0.1, respectively. The magnitude of the total crystal-field strength expressed by the scalar parameter N_v (Auzel and Malta, 1983), is equal to 2700 (assuming the C_{2v} approximation).

Uranium tetrafluoride hydrates

The reaction of U(IV) solutions with 4–20% aqueous fluoride solutions results in the precipitation of $UF_4 \cdot 2.5H_2O$. A number of hydrates with smaller water content, $UF_4 \cdot nH_2O$ (where $0.5 < n < 2$), was obtained by controlled thermal decomposition. $UF_4 \cdot 2.5H_2O$ is the most stable one: in vacuum up to 25°C and in air up to 100°C. The compound may be converted to $UF_4 \cdot 0.5H_2O$ at 100–120°C with the maintenance of its structure. A complete dehydration occurs at 500–550°C in a stream of N_2 or HF. However, it still retains some of the structure of $UF_4 \cdot 2.5H_2O$ and, contrary to UF_4, it may be readily rehydrated to $UF_4 \cdot 2.5H_2O$. All UF_4 hydrates with lower water content may also be gradually converted back to this stable form. The solubility of $UF_4 \cdot 2.5H_2O$ in water is 0.1 $g \cdot L^{-1}$ (Bacher and Jacob, 1980).

$UF_4 \cdot 2.5H_2O$, $UF_4 \cdot 2H_2O$, and $UF_4 \cdot 4/3H_2O$ have orthorhombic *Pnma*, cubic $Fm\bar{3}m$, and a monoclinic structure, respectively, as revealed by X-ray diffraction and NMR data. Crystallographic data are given in Table 5.26.

The three-dimensional network contains channels in which coordinated and free water molecules are located (Zadneporovskii and Borisov, 1971).

Complex uranium(IV) fluorides

Metal fluoride–uranium tetrafluoride fused salt systems have been extensively studied because of their usefulness as fertile fuel materials, coolants, and heat transfer media in the Molten-Salt Reactor Experiment (MSRE), Molten-Salt Breeder Reactor, and the Aircraft Nuclear Propulsion (ANP) projects. Numerous ternary and polynary uranium(IV) fluorides have been characterized by determination of their crystallographic parameters (see Table 5.26) but there are fewer studies of their chemical and thermodynamic properties. The application of the compounds in molten-salt reactor technology has been reviewed in a number of articles (Thoma and Grimes, 1957; Thoma, 1959, 1971, 1972; Grimes and Cuneo, 1960; Rosenthal *et al.*, 1972; Grimes, 1978). Caillat (1961), Brown (1968), Bacher and Jacob (1980), Martinot (1984), Bagnall (1987), Freestone and Holloway (1991) and others have reviewed their general properties. Various complex compounds are listed in Table 5.27 with an indication of their melting behavior when available.

A number of ternary and quaternary fused salt systems such as LiF–BeF_2–UF_4 (Thoma, 1959; Jones *et al.*, 1959) and NaF–BeF_2–UF_4 (Thoma, 1959) were important for the MSRE and ANP projects. The $MgUF_6$ and $CaUF_6$ fluorides are of importance for the production of uranium by high-temperature reduction of UF_4 with calcium or magnesium. Systems with ammonium or hydrazinium cations have found application in the preparation of high-purity UF_4 by decomposition of the corresponding complex fluorides. A typical phase diagram of some importance for the molten-salt reactor projects is presented in Fig. 5.41.

The general methods for the preparation of the compounds (Bacher and Jacob, 1980; Freestone and Holloway, 1991) include: (i) solid state reaction between the component fluorides in an inert atmosphere; (ii) reactions between UF_4 or UO_2 and the alkali metal fluoride or carbonate in HF or HF–O_2 mixtures; (iii) reductions of UF_6 with appropriate alkali metal fluorides; (iv) controlled thermal decomposition of tetravalent uranium fluoro complexes of higher stoichiometry (e.g. $(NH_4)_4U^{IV}F_8$) or the treatment of other fluoro complexes with fluorine, (v) precipitation from aqueous solutions, followed by heating in air, *in vacuo* or fluorine, and (vi) hydrogen reduction of higher valence state fluoro complexes and precipitation from aqueous solutions.

The structures for the majority of the fluoro complexes are well established; typical examples are those with the UF_7^{3-}, UF_8^{4-} anions, but octahedral UF_6^{2-} complexes are also known. The cubic K_3UF_7 structure contains UF_7^{3-} pentagonal bipyramids, while the uranium coordination in Li_4UF_8 is described as a bicapped triangular prism (Brunton, 1967; Freestone and Holloway, 1991). Compounds of the $M^{II}UF_6$ (M^{II} = Ca, Sr, Ba, or Pb) adopt the LaF_3 structure (Keller and Salzer, 1967). U(IV) in $LiUF_5$, KU_2F_9, and $M^IU_3F_{13}$ (M^I = Rb or

NH_4) has tricapped trigonal prism coordination geometry. A structure with linear chains of polyhedra with a distorted cubic arrangement has been proposed for γ-Na_2UF_6 (Zachariasen, 1948a). Infinite chains are also present in the β_1-K_2UF_6 structure, where they are formed by tricapped trigonal prisms that share the triangular faces perpendicular to the three-fold axis of the ideal polyhedron (Zachariasen, 1948a). The structure of Rb_2UF_6 (Kruse, 1971) consists of infinite chains of $[UF_8]$ units with triangular faced dodecahedral geometry (of the K_2ZrF_6-type) whereas in $(NH_4)_2UF_6$ the chains of antiprism are linked by s edges on opposite square faces (Penneman *et al.*, 1974). Compounds of the $M^I_7U_6F_{31}$ type (M^I = Na, K, Rb, or NH_4) are isostructural with $Na_7Zr_6F_{31}$ (Burns *et al.*, 1968) and have a coordination geometry that is approximately square antiprismatic. The six antiprisms share corners to form an octahedral cavity, which encloses one F atom. Additional information on the structures and crystallographic data of uranium(IV) fluoro complexes are given in Table 5.26.

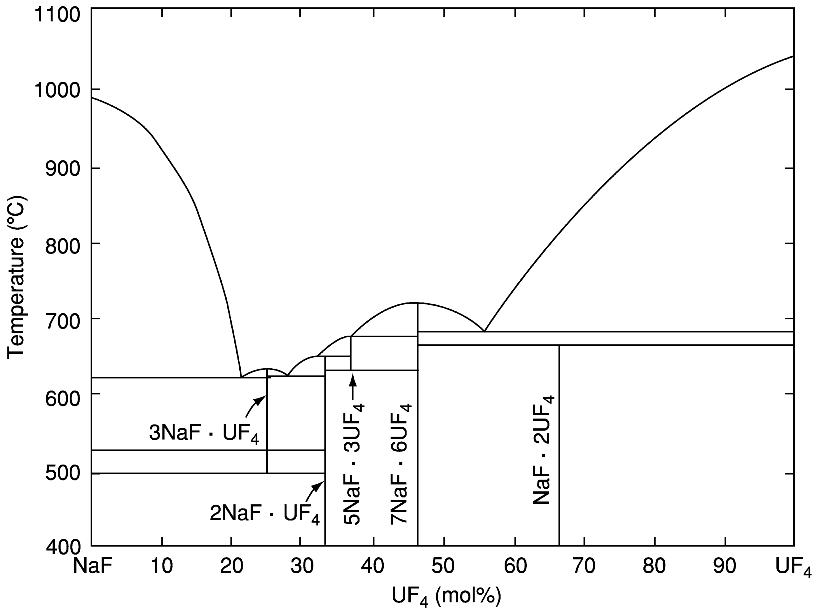

Fig. 5.41 *Phase diagram of the NaF–UF_4 system* (*Thoma,* 1959).

Numerous UF_4 complexes with quaternary ammonium compounds such as amines, pyridine, quinoline, and guanidine have been chemically and structurally characterized (Bacher and Jacob, 1980).

(*ii*) *Uranium*(IV) *oxide fluorides and nitride fluorides*

The melting of stoichiometric amounts of UO_2 and UF_4 yields UOF_2. From aqueous U(IV) solutions, the green hydrates $UOF_2 \cdot 2H_2O$ and $UOF_2 \cdot H_2O$ precipitates. Numerous non-stoichiometric uranium oxide fluorides, rich in oxygen, have been obtained by interactions of UF_4 with uranium oxides in the absence of oxygen at 400–550°C (Bacher and Jacob, 1980). The uranium atoms have an oxidation number that is either 5+, or a mixture of 5+ and 6+. In $UO_2F_{0.25}$, the oxidation number is 4+ and 5+. The compounds are non-volatile or difficult to volatilize; they have structures related to that of uranium oxide. The crystallographic data of $UO_2F_{0.25}$ are given in Table 5.26.

Heating of uranium nitride ($UN_{1.33}$) and uranium tetrafluoride leads to the formation of nitride fluorides of composition between UNF and $UN_{0.98}F_{1.20}$. The formal oxidation number of uranium in these compounds varies between 4 and 4.14. A tetragonal high-temperature and an orthorhombic low-temperature phase have been claimed to exist in this composition range. X-ray investigations of the tetragonal phase revealed a close structural relationship with lanthanum oxide fluoride (Jung and Juza, 1973). The interaction of uranium nitride with an excess of UF_4 at 950°C leads to UF_3 and with an excess of UN to UNF (Tagawa, 1975).

(*iii*) *Uranium tetrachloride and uranium*(*IV*) *complex chlorides*

Uranium tetrachloride

Uranium tetrachloride is a suitable starting material for the synthesis of a large range of uranium compounds due to its ease of preparation and solubility in numerous polar organic solvents. It has also found application as charge material for calutron ion sources in the electromagnetic separation of uranium isotopes (Akin *et al.*, 1950). Since it has been the subject of an extensive research, numerous methods for the synthesis have been developed (Brown, 1979). Most of them are based on chlorination of uranium oxides with an extensive range of powerful chlorinating agents such as CCl_4, $COCl_2$, $SOCl_2$, S_2Cl_2, Cl_2, $Cl_2C{=}CClCCl_3$ as well as of S_2Cl_2/Cl_2 and Cl_2/He mixtures that can be used both in gaseous and liquid phases. The direct combination of uranium and chlorine leads to a complex mixture of uranium chlorides and does not yield pure UCl_4. This may most conveniently be obtained either by liquid-phase chlorination of UO_3, $UO_4 \cdot 2H_2O$, U_3O_8, UO_2Cl_2 (but not UO_2) with hexachloro propene, $Cl_2C{=}CCl{-}CCl_3$ (Hermann and Suttle, 1957) or by converting UO_2 to the tetrachloride by carbon tetrachloride at 450°C (Brown, 1979):

$$UO_2 + CCl_4 \overset{450^\circ C}{\rightarrow} UCl_4 + CO_2$$

Since the particle size of uranium dioxide is important for the synthesis, a reactive form of UO_2 should be used, formed by decomposition of uranyl oxalate in presence of hydrogen at 300°C. On laboratory scale, the simplest method involves the refluxing of UO_3 with a five-fold excess of hexachloro propene (b.p. 210°C) at atmospheric pressure. Uranium tetrachloride is insoluble in the reaction mixture and precipitates quantitatively as the reaction progresses. Due to extensive hydrolysis, the anhydrous chloride cannot be recovered from aqueous solutions.

In syntheses involving chlorine or the higher uranium oxides, usually small amounts of UCl_5 are formed. This is, however, thermally unstable and loses chlorine by heating in a stream of carbon dioxide or nitrogen. Uranium tetrachloride may be easily purified by sublimation *in vacuo*, or in a stream of a dry inert gas. A recommended route is also vapor-phase transport by the $UCl_4 \cdot AlCl_3$ complex, which proceeds rapidly already at 350°C (Gruen and McBeth, 1968). The chorination of UO_3 using liquid CCl_4 was used on a large scale to obtain UCl_4, which was used as charge material for the calutron ion sources used in the electromagnetic separation of uranium isotopes. Under a pressure of 20 atm, the chlorination yielded UCl_5, which was thermally decomposed to UCl_4 in an inert gas. Details of these processes can be found in Akin *et al.* (1950).

Uranium tetrachloride forms dark-green hygroscopic crystals, which must be handled in a dry atmosphere. At 600°C, in air it converts into U_3O_8. The compound is insoluble in non-polar organic solvents such as chloroform or carbon tetrachloride but dissolves readily in numerous polar solvents, usually with complex formation, which enables the recovery of the anhydrous compound by evaporation. In water, it undergoes hydrolysis, which is complete at 100°C. The reaction of UCl_4 with hydrogen, zinc, or UN results in the formation of uranium trichloride. Reaction with HBr or HI yields UBr_3 and UI_3, respectively. Reduction to uranium metal takes place when the tetrachloride is heated with Li, Na, K, Mg, Ca, and Al.

Metallic uranium is also obtained by electrolytic reduction of molten UCl_4 or its solutions in fused salts media such as NaCl–KCl. Reduction with magnesium also leads to metallic uranium, whereas insoluble U(III) species are formed on reduction with Zn, Pb, and Bi. Uranium trichloride is formed in a LiCl–KCl melt by reduction with uranium or aluminum. The interaction of UCl_4 with chlorine at 115–125°C yields mixtures of UCl_5 and UCl_6, whereas in fused salt media at 400–700°C it leads to the formation of UCl_6. The reaction with fluorine gas, HBr, or HI converts UCl_4 to UF_6, UBr_4, and mixed chloride iodides, respectively.

Uranium tetrachloride crystallizes in the space group $I4_1/amd$, with tetragonal symmetry; it is isostructural with other actinide tetrachlorides. Each uranium atom is bonded to eight chlorine atoms in a dodecahedral arrangement. The crystallographic data are listed in Table 5.26. High-quality absorption spectra of UCl_4 were obtained (Brown, 1979) both for powdered samples, single crystals, in the vapor phase, and in a nitrogen matrix at 4 K (Clifton *et al.*, 1969). Numerous spectra were also recorded in different non-aqueous solvents. Successful investigations of U^{4+} spectra in the solid state started with a parametric analysis of U^{4+}-doped $ThBr_4$ single crystals by Delamoye *et al.* (1983). On this basis, consistent sets of atomic and crystal field parameters have been obtained also for isomorphic $ThCl_4$:U^{4+} and UCl_4 of D_{2d} symmetry (Malek *et al.*, 1986a,b). The data for UCl_4 are listed in Table 5.26. The parameters have been obtained by fitting 60 observed crystal-field levels of UCl_4 with a r.m.s. error of 60 cm^{-1}. The configuration interaction parameter $\gamma = 1200$, the spin–spin and spin–other orbit parameters, $M^0 = 0.99$, $M^2 = 0.55$ and $M^4 = 0.38$, and the electrostatically correlated spin–orbit perturbation parameters $P^2 = P^4 = P^6 = 500$ (all in cm^{-1}) have been used as constants in the fitting (Malek *et al.*, 1986b). The magnitude of the total crystal-field strength expressed by the scalar parameter (Auzel and Malta, 1983) N_v is equal to 1224.

The magnetic susceptibility of UCl_4 has been measured in wide temperature ranges: 100–350 K, $\mu_{eff} = 3.18$ B.M.; 350–500 K, $\mu_{eff} = 3.18$ B.M., $\theta = -31$ K (Bommer, 1941); 77–500 K, $\mu_{eff} = 3.29$ B.M., $\theta = -62$ K (Dawson, 1951); 77–450–775; 825–1200 K, $\mu_{eff} = 3.33$, 3.50, and 3.60 B.M., respectively (Trzebiatowski and Mulak, 1970). A deviation from the Curie–Weiss law was found at very low temperatures. The best fit between the experimental and the calculated curves was achieved using the values obtained by Hecht and Gruber (1974) with $A_6^4\langle r^6\rangle$ increased to 1561.8 cm^{-1}. The crystal-field parameters deduced by Mulak and Żołnierek (1977) are different from those obtained from spectroscopic data.

It has been shown (Gamp *et al.*, 1983) that the previous susceptibility measurements made on powdered UCl_4 samples are not reproducible because of a re-orientation effect caused by the high anisotropy of the susceptibility of this material. For single crystals, the anisotropic magnetic susceptibility $\chi_{\|}$ (along the tetragonal axis), measured between 1.6 and 350 K, is found to be almost temperature-independent and about 30 times smaller than $\chi_{\perp}$ at low temperatures (Gamp *et al.*, 1983). Chlorine-35 nuclear quadrupole resonance has been observed in solid UCl_4 at 77 K and a frequency of (6.24 ±0.03) MHz (Carlson, 1969). Some other physical data are summarized in Table 5.26.

Complex uranium(*IV*) *chlorides*

A large number of hexachloro uranium(IV) compounds of the formulas $M^I_2UCl_6$ and $M^{II}UCl_6$ have been prepared by reactions in non-aqueous and aqueous media and by solid state reactions of the component halides (where M^I = Li, Na, K, Rb, Cs, Ag, $N(CH_3)_4$, $N(C_2H_5)_4$, $As(C_6H_5)_4$, C_5H_5NH, $N(CH_3)_2(C_6H_5CH_2)_2$, $P(C_2H_5)_3H$, $P(C_4H_9)_3H$, $P(C_6H_5)_2H_2$, $P(C_2H_5)_4$ etc. and M^{II} = Be, Ca, Ba, Sr, etc.). The chlorination of a mixture of U_3O_8 and NaCl at high temperatures yields Na_2UCl_6. The formation of numerous complex tetravalent chloro compounds (see Table 5.27) has also been observed during investigations of binary and ternary fused salt systems containing UCl_4.

The results of investigations on phase equilibria, spectroscopic and electrochemical properties of uranium tetrachloride in molten salt systems have been reviewed by Brown (1979) and Martinot (1984). Investigations of Gruen and McBeth (1968, 1969) and Schäfer (1975) and Binnewies and Schäfer (1974) have given evidence for the existence of uranium(IV) vapor phase complexes such as $UCl_4 \cdot AlCl_3$, $TlUCl_5$, $CuUCl_5$, Tl_2UCl_6, TlU_2Cl_9, $BeUCl_8$, In_2UCl_{10}, $ThUCl_8$, and Cu_2UCl_5. In the UCl_4–HCl–H_2O system, five hydrates have been identified among which $UCl_4 \cdot 9H_2O$ and $UCl_4 \cdot 5H_2O$ are stable at 0 and 40°C, respectively (Brown, 1979).

The action of oxygen and nitrogen donor ligands on UCl_4 solutions in non-aqueous solvents results in the formation of stable adducts of different UCl_4 to ligand stoichiometries (Brown, 1979; du Preez and Zeelie, 1989):

- (1:1): methylene bis-diphenylphosphine, ethylene bis-diphenylphosphine, α-α-dimethylmalonamide;
- (1:2): pyridine, triphenylphosphine oxide, 1,2–dimethoxyethane, 1,2-bis-methylthioethane, 1,10-phenanthroline, 1,8-diaminonaphthalene, 1,2-diaminobenzene, dimethyl sulfoxide, di-*tert*-butylsulfoxide;
- (1:2, 1:6): trimethylphosphine oxide;
- (1:2, 1:4): ammonia;
- (1:3): dioxan, tetrahydrofuran, trimethylphosphine, pyrrolidine;
- (1:4): phosphorous oxide trichloride, ROH (R = CH_3, C_2H_5, C_3H_9, i-C_3H_9), ethylenediamine, piperidine, methyl cyanide;
- (1:6): acetamide, hydrazine;

- (1:7, 1:5, 1:3): dimethylsulphoxide;
- (2:3): malonamide, glutaramide, dimethylglutaramide;
- (2:5):dimethylformamide, pyrazine, 1,2-diaminobenzene, pyrazine-2-carboxamide; dimethylacetamide.

In alternative syntheses, the reaction between uranium tetraacetate and acetates of M^I cations (M^I = K, Rb, Cs, NH_4, or $N(CH_3)_4$) in an acetyl chloride–acetic acid mixture has been used. The use of $CsUCl_6$ as a convenient starting material for the preparation of the complexes has also been reported.

The chlorine atoms may by replaced by a variety of anions in metathetic reactions involving uranium tetrachloride in non-aqueous media such as formic acid, acetic acid, sodium diethyldithiocarbamate (Nadtc), tertaethylammonium diethyldiselenocarbamate ($N(C_2H_5)_4$dsc), sodium acetylacetonate (Na-acac), tropolone (Htrop), $LiNR_2$ (R = C_2H_5, C_3H_7, C_6H_5, KC_5H_5), $NaNH_2$ (in NH_3), $NaBH_4$, and many other compounds. Electrochemical oxidation of anodic uranium into acetonitrile solutions of Cl_2 results in the formation of $UCl_4 \cdot 4CH_3CN$ in good yield. The compound may be converted into other UCl_4 adducts, e.g. with dimethylsulfoxide (1:3), 2,2′-bipyridine (1:2), Ph_3PO (1:2) etc. (Kumar and Tuck, 1984).

The chloro complexes are to some extent soluble in organic solvents such as ethanol, methyl cyanide, thionyl chloride, nitromethane, etc. with the exception of the compounds containing alkali metal cations. In aqueous hydrochloric acid solutions, the solubility of the complexes decreases markedly with the increase of the acid concentration. Liquid zinc amalgam reduction of solutions of M_2UCl_6 (where M = NH_4, K, or Rb) with an excess of NH_4Cl, KCl, or RbCl in anhydrous methyl cyanide results in the formation of the trivalent complexes, M_2UCl_5 (Drożdżyński and Miernik, 1978).

The crystallographic data of the hexachloro uranium(IV) compounds are listed in Table 5.26. The compounds with Cs^+, Rb^+, $N(CH_3)_4^+$, $As(C_2H_5)_4^+$, $P(C_6H_5)H^+$, and other cations exhibit a non-magnetic ground state A_1 with no thermal population of the excited states of the ground multiplet $^3H_4$, resulting in a temperature-independent paramagnetism between 4 and 350 K with $\chi_{mole} \cong 2000 \times 10^6$ cm^3 mol^{-1}. The magnetic susceptibility of Rb_2UCl_6 and Cs_2UCl_6 has been measured at higher temperatures and show an approximate Curie–Weiss dependence above 400 K. The magnetic susceptibilities of other chloro compounds (with M = Li, Na, or K) have a somewhat more complex temperature dependence with limited ranges of temperature-independent paramagnetism, e.g. $KUCl_5$ exhibits Curie–Weiss dependence in the 77 to 600 K and 600–1200 K ranges with $\mu_{eff} = 3.52$ and 3.64 B.M., respectively. Solid state reactions of stoichiometric mixtures of Cs_2UCl_6 and Sb_2O_3 at 300°C *in vacuo* yields a dark olive brown uranium(IV) oxochloro compound of the formula Cs_2UOCl_4, for which Watt *et al.* (1974) reported infrared and powder diffraction data.

(*iv*) *Uranium*(*IV*) *oxychloride and oxochloro complexes*

$UOCl_2$ can be prepared by heating uranium dioxide in an excess of molten uranium tetrachloride followed by vacuum sublimation of the excess of tetrachloride at about 450°C (Brown, 1979), or by the following reaction:

$$3UCl_4 + Sb_2O_3 \rightarrow 3UOCl_2 + 2\,SbCl_3$$

This latter synthesis ought to be carried out *in vacuo* around 400°C where by-products sublimate from the reaction zone (Bagnall *et al.*, 1968).

Uranium(IV) oxide dichloride is a green, moisture-sensitive, and thermally unstable solid. It readily dissolves in water and aqueous nitric acid, but is insoluble in organic solvents. At 170°C, CCl_4 may convert the compound to the tetrachloride; anhydrous liquid hydrogen fluoride may convert it to the tetrafluoride.

$UOCl_2$ is isostructural with some $MOCl_2$ oxychlorides (where M = Pa, Th, or Np). The oxychlorides crystallize in the orthorhombic system (see Table 5.26) and the structure contains $U_3O_3Cl_3$ chains running parallel to the *c*-axis that are linked by chlorine bridges. There are three types of polyhedra around the non-equivalent uranium atoms in the chains: around U(1), dodecahedra (CN = 8; from 3O and 5 Cl); around U(2), tricapped trigonal prism (CN = 9; 4O, 5Cl) and around U(3) monocapped trigonal prisms (CN = 7; 3O, 4Cl) (Taylor and Wilson, 1974a); all coordination polyhedra are distorted from the ideal shape. A dark olive-brown to blue-brown oxochloro complex of the formula Cs_2UOCl_4 was prepared by heating together Cs_2UCl_6 with Sb_2O_3 at 300°C *in vacuo* (Watt *et al.*, 1974).

(*v*) *Uranium*(*IV*) *perchlorates*

Uranium(IV) perchlorate, $U(ClO_4)_4$, is unknown, but a few uranium(IV) perchlorato compounds have been isolated. Bagnall *et al.* (1962) and Bagnall and Wakerley (1974) have described the preparation and reactions in non-aqueous media of oxygen donor complexes of the formula $U(ClO_4)_4 \cdot 4L$ (L = octamethyl phosphoramide) and $U(ClO_4)_4 \cdot 4L'$ (L′ = dimethylacetamide, trimethylphosphine oxide, or hexamethylphosphoramide). Interaction of solid U $(HPO_4)_2 \cdot xH_2O$ with 10 M $HClO_4$ results in the formation of hydrated phosphate perchlorates of the formula $U(H_2PO_4)_2(ClO_4)_2 \cdot xH_2O$ ($x = 4$ and 6).

(*vi*) *Uranium tetrabromide and uranium*(*IV*) *complex bromides*

Uranium tetrabromide

A wide variety of methods for the preparation of uranium tetrabromide have been reported (Brown, 1979); the product may then be purified by sublimation *in vacuo* or in a stream of an inert gas. Since the compound is extremely moisture-sensitive, the carrier gases must be carefully dried. The most convenient and widely used preparation methods involve (i) the conversion of UO_2 or

U_3O_8 to the tetrabromide by heating, with a mixture of carbon, in a stream of bromine at 700–900°C, (ii) reactions between UO_2, UO_3, or $UOBr_3$ with carbon tetrabromide at about 170°C, (iii) reactions between UO_2 and a sulfur–bromine mixture under reflux at about 170°C, and (iv) direct bromination of uranium metal, either in a flow system, for example, a helium–bromine mixture at about 650°C, or in sealed evacuated vessels at 500–700°C.

Uranium tetrabromide is a deep brown, very hygroscopic solid, insoluble in non-polar organic solvents but soluble or reacting with numerous polar solvents. HBr is evolved on dissolution in methanol, ethanol, phenol, acetic acid, aniline, or on exposure to moist air. In non-aqueous solvents, the tetrabromide forms complex compounds with numerous organic ligands such as nitriles, amides, sulfoxides, phosphine oxides, or arsine oxides, e.g. $UBr_4 \cdot 4CH_3CN$, $UBr_4 \cdot 4CH_3CON(CH_3)_2 \cdot CH_3COCH_3$, $UBr_4 \cdot nCH_3CON(CH_3)_2$ ($n = 2.5$ or 5), $UBr_4 \cdot 8CO(NH_2)_2$, $UBr_4 \cdot 6(CH_3)_2SO$, $UBr_4 \cdot 2L$ (L = $(C_6H_5)_3PO$, $[(CH_3)_2N]_3PO$, $(C_2H_5)_3PO$, $(CH_3)_3AsO$, $(C_6H_5)_3AsO$, $(C_2H_5)_3AsO$, $(CH_3)_3AsO$, $UBr_4 \cdot 6(CH_3)_3PO$, $UBr_4 \cdot 6L'$ (L′ = $(CH_3)_3AsO$ and $(C_2H_5)_3AsO$). Reduction with alkali or alkaline earth metals at high temperatures and hydrogen at 450–700°C yields uranium metal and uranium tribromide, respectively. Uranium tetrabromide may be converted to the tetrachloride by chlorine and to UO_2Br_2 by dry oxygen at 150–160°C. The preparation and crystal structure of octaaquabromo uranium(IV) tribromide monohydrate, $[UBr(H_2O)_8]Br_3(H_2O)$ (Table 5.26) have been reported by Rabinovich *et al.* (1998).

Uranium tetrabromide crystallizes in the monoclinic space group *C*2/*m* (see Table 5.26), with pentagonal bipyramid coordination at the uranium atom; the polyhedra are linked into infinite two-dimensional sheets by double bromine bridges between the uranium atoms (Taylor and Wilson, 1974d,e).

Good-quality low-temperature absorption spectra as well as solution, reflectance, and transmission spectra of UBr_4 are available. The energy level parameters obtained from least-squares fitting of the observed and calculated energy levels are listed in Table 5.26. Absorption bands observed in the range 41 400–32 160 cm^{-1} were assigned to $5f^2 \rightarrow 5f^1 6d^1$ transitions; a charge transfer band was identified at 30 165 cm^{-1}. Magnetic susceptibility measurements reveal a Curie–Weiss behavior in the temperature range 77–569 K, with $\theta = -35$ K and $\mu_{eff} = 3.12$ B.M (Brown, 1979; Dawson, 1951).

Uranium(IV) *ternary and polynary bromides and bromo compounds*

Cooling curves obtained from melting point diagrams show that only complexes of the M_2UBr_6-type are formed in the UBr_4–MBr system (M = Na, K, Rb, or Cs). They may conveniently be prepared by heating the component bromides in evacuated silica ampoules (Vdovenko *et al.*, 1973a,b). In addition to synthetic methods, phase transitions and crystallographic data for Li_2UBr_6 have been reported (Maletka *et al.*, 1998). Hexabromo compounds containing large organic cations are formed in anhydrous methyl cyanide solutions as a result of reactions at 0°C between UBr_4 and a number of alkylammonium or phosphonium bromides, e.g. $[N(CH_3)_4]_2UBr_6$, $[N(C_2H_5)_4]_2UBr_6$, (Brown, 1979). Hexabromouranates(IV) may also be prepared by reactions of UBr_4 with aniline, ethylenediamine, and 8-hydroxyquinoline (Sara, 1970).

$UBr_4 \cdot 2CH_3CN$ in good yield is formed by electrochemical oxidation of uranium in CH_3CN/Br_2 solution under an inert atmosphere. Using a two-fold excess of different neutral ligands in a solution of this compound in acetone gives rise to UBr_4 adducts, e.g. $UBr_4 \cdot 2Ph_3O$ and $UBr_4 \cdot 6$dmso (dmso = dimethylsulfoxide) (Kumar and Tuck, 1984). The preparation of UBr_4 adducts has also been reported by du Preez and Zeelie (1989), e.g. $UBr_4 \cdot (tbso)_2$ (tbso = di-*tert*-butyl phosphoxide), $UBr_4(dmso)_2$ (dimethylsulfoxide) and $UBr_4 \cdot 4CH_3CN$. Evaporation of UBr_5 solutions containing 1 or more than 3 mol equivalents of methyl cyanide in dichloromethane yields $UBr_4 \cdot CH_3CN$ and $UBr_4 \cdot 3CH_3CN$, respectively. The synthesis, crystal structure, and IR data of $P(C_6H_5)_4UBr_6$, $P(C_6H_5)_4[UBr_6] \cdot 2CCl_4$, $[P(C_6H_5)_4]_2[UBr_6] \cdot 4CH_3CN$, and $[P(C_6H_5)_4]_2[UO_2\ Br_4] \cdot 2CH_2Cl_2$ were reported by Bohrer *et al.* (1988) (see Table 5.26).

The hexabromo complexes containing large organic cations have green-blue color; they dissolve readily in water, aqueous hydrobromic acid, and a number of polar non-aqueous organic solvents. They may be purified by crystallization, e.g. from methylcyanide or nitromethane. The compounds react with aqueous ammonia and liquid ammonia forming hydrous oxides and the insoluble $[N(C_2H_5)_4]_2UBr_6$ complex, respectively.

Rb_2UBr_6, Cs_2UBr_6, and $[N(CH_3)_4]_2UBr_6$ crystallize with face-centered cubic symmetry. The crystallographic data of these and some other hexabromouranates(IV) are listed in Table 5.26. Spectroscopic and magnetic susceptibility investigations performed for a number of octahedral uranium(IV) chloro- and bromo-complex compounds by Day and Venanzi (1966) show a temperature-independent paramagnetism, which results from interactions between the A_1 ($^3H_4$) ground state and the first excited state T_1 ($^3H_4$). Using the relative field strengths obtained from magnetic data, the authors have obtained the following values of the energy parameters: $\Delta = 1177\ cm^{-1}$ and $\theta = 2096\ cm^{-1}$ [where $\Delta = 8/33\ (B_0^4 + 35/13 B_0^6)$ and $\theta = 2/33\ (5B_0^4 - 210/13 B_0^6)$; $B_0^4 = 6481.5\ cm^{-1}$, $B_0^6 = 804\ cm^{-1}$]. The observed interactions are in an octahedral field best described by the orbital energy differences $\Delta(a_{2u} \rightarrow t_{2u})$ and $\theta(t_{2u} \rightarrow t_{1u})$.

Spectroscopic investigations reveal a coordination geometry with octahedral geometry both in the solid and in non-aqueous solutions; vibronic side bands are prominent in the spectra of the complexes and permit the assignment of a number of electronic transitions and the determination of the electrostatic, spin–orbit, and crystal-field parameters, e.g. for Cs_2UBr_6: (Johnston *et al.*, 1966) and for $[N(C_2H_5)_4]_2UBr_6$: (Wagner *et al.*, 1977) (see Table 5.26). From the spectral data the following ligand field parameters have been obtained: $\theta = 2378$, $\Delta = 828\ cm^{-1}$, $\zeta_{5f} = 1792\ cm^{-1}$ (or $B_0^4 = 6592.5\ cm^{-1}$, $B_0^6 = 1194.8\ cm^{-1}$) and $\theta = 2336$, $\Delta = 1127\ cm^{-1}$, $\zeta_{5f} = 998.95\ cm^{-1}$ (or $B_0^4 = 6946.5\ cm^{-1}$, $B_0^6 = 998.95\ cm^{-1}$) for Cs_2UBr_6 and $[N(C_2H_5)_4]_2UBr_6$, respectively. As one would expect the $5f^2 \rightarrow 5f^1 6d^1$ transitions, recorded for $[N(C_2H_5)_4]_2UBr_6$, lie between those observed for the hexachloro and hexaiodo uranates(IV), i.e. at 27400(sh), 29400, 30400, 31500(sh), 33100, 37000, and 39000 cm^{-1} (Ryan, 1972). Spectral investigations of the compound in non-aqueous solvents reveal hydrogen bonding to primary, secondary, and tertiary alkylammonium ions that partially distorts the octahedral field in the UBr_6^{2-} complex, making the $5f^2 \rightarrow 5f^2$ electronic transitions allowed. The analysis of the visible and near IR spectra demonstrates vibronic frequencies within the ranges: 180–184 cm^{-1} (ν_3), 72–74 cm^{-1} (ν_4), and at 58 cm^{-1} (ν_6).

(*vii*) *Uranium*(*IV*) *oxide dibromide and nitride bromides*

Useful preparative methods for $UOBr_2$ (Brown, 1979) involve heating of UO_2 in a stream of CS_2 at 900°C to form $U_3O_2S_4$ followed by bromination at 600°C:

$$U_3O_2S_4 + 6Br_2 \rightarrow 2UOBr_2 + UBr_4 + 2S_2Br_2$$

or by heating of stoichiometric amounts of Sb_2O_3 and UBr_4 at about 150°C *in vacuo* (Bagnall *et al.*, 1968):

$$Sb_2O_3 + 3UBr_4 \rightarrow 3\,UOBr_2 + 2SbBr_3$$

Uranium(IV) oxide dibromide is a non-volatile, pale yellow, air-sensitive solid, readily soluble in water with the formation of a green solution from which a black solid slowly deposits. It decomposes above 600°C *in vacuo* to form UO_2 and UBr_4. The reported thermodynamic data (Greenberg and Westrum, Jr., 1956; Rand and Kubaschewski, 1963; Grenthe *et al.*, 1992; Guillaumont *et al.*, 2003) are listed in Table 5.26.

As in the corresponding chloride systems, the ammonolysis of UBr_4 at elevated temperatures leads to the formation of uranium nitride via amido, imido, and nitride bromides (Burk, 1967; Burk and Naumann, 1969). Since the composition of the decomposition products varies with temperature, the pure phases cannot easily be obtained (Brown, 1959). Juza and Meyer (1966, 1969) have obtained a dark-brown $UN_{1.03}Br_{1.03}$ phase on heating UBr_4-ammoniates at 400°C in gaseous ammonia. The compound can also be prepared by solid-state reactions of UN with UBr_4 at 600–900°C. It is insoluble in water and has the BiOCl-type structure with the space group *P*4/*nmm*. The crystallographic data are listed in Table 5.26.

(*viii*) *Uranium tetraiodide and uranium*(*IV*) *complex iodides*

Uranium tetraiodide

The most convenient and widely used method for the preparation of UI_4 involves the direct combination of the elements at about 500°C, either in a gas-flow system or in sealed vessels (see Brown, 1979); it is a black, moisture-sensitive solid. It rapidly decomposes on exposure to air and is also thermally

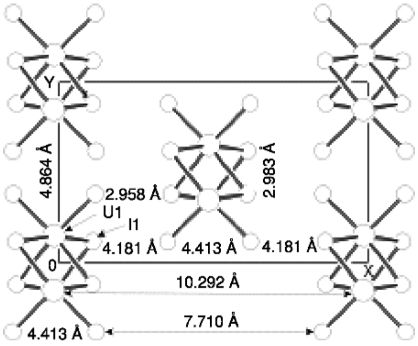

Fig. 5.42 *View along zigzag chains in UI_4 (distances are taken from Levy* et al., 1980).

unstable, liberating iodine with the formation of UI_3. The tetraiodide may also readily be reduced to UI_3 by hydrogen at moderate temperatures. The interaction of UI_4 with chlorine yields UCl_4, and with uranium tetrahalides it forms the mixed halides: UCl_2I_2, $UClI_3$, UBr_2I_2, and $UBrI_3$. Like other uranium halides the tetraiodide also forms complexes with organic ligands, e.g. $UI_4 \cdot 4$dma (dma = dimethylacedamide), $UI_4 \cdot 2$tbso (tbso = di-*tert*-butyl sulfoxide), $UI_4 \cdot 8$dmso (dmso = dimethyl sulfoxide), $UI_4 \cdot 6$dibso (dibso = di-isobutylsulfoxide), $UI_4 \cdot xNH_3$ (x = 4, 5, or 10) and $UI_4 \cdot 8$L (L = ε-caprolactam, α-$UI_4 \cdot$ tpao$_2$, β-$UI_4 \cdot$ tpao$_2$, $UI_4 \cdot$ tpao$_4$, and $UI_4 \cdot$ tpao$_6$ (tpao = triphenylarsine oxide) (Brown, 1979; du Preez and Zeelie, 1987, 1989).

The crystal structure of UI_4 has been solved using X-ray and powder neutron diffractions (Levy *et al.*, 1980; Taylor, 1987). The monoclinic structure (Table 5.26) contains uranium atoms with an approximately octahedral coordination, where the uranium atoms are linked by double iodide bridges, forming zigzag chains (Fig. 5.42). Two terminal iodide ions in the *cis* position are completing the coordination sphere of the uranium atom.

Uranium(iv) iodo complexes

Hexaiodo uranium(iv) compounds of the M_2UI_6-type (where M = $N(C_2H_5)_4$, $N(C_4H_9)_4$, $N(C_6H_5)(CH_3)_3$, and $As(C_6H_5)_4$) have been obtained from reactions of the component halides in anhydrous methyl cyanide followed by crystallization in an ice bath or by vacuum evaporation of the solvent. Alternatively, the treatment of uranium(iv) hexachloro or hexabromo complexes with anhydrous liquid hydrogen iodide may be used (Bagnall *et al.*, 1965; Brown *et al.*, 1976). The hexaiodo uranium(iv) compounds are stable, but extremely moisture-sensitive, red colored solids. Exposure to the atmosphere, addition of dilute aqueous acids, or ammonia results in immediate decomposition. The compounds are soluble in anhydrous methyl cyanide and acetone and liberate iodine on heating above 200°C.

From an analysis of the spectral data for $[N(C_2H_5)_4]_2UI_6$ the following electrostatic, spin–orbit, and crystal-field parameters were obtained (in cm^{-1}): $F^2 = 38188(2422)$, $\zeta_{5f} = 1724(39)$, $B_0^4 = 6338(676)$, and $B_0^6 = 992(252)$ (Wagner *et al.*, 1977). Magnetic susceptibility measurements of $[As(C_6H_5)_4]_2UI_6$ have shown that the compound exhibits a temperature-independent paramagnetism in the 84–300 K range with $\chi_{\text{mole}} = 2146(30) \times 10^{-6}$ cm^3 mol^{-1} (Bagnall *et al.*, 1965), analogous to that in the hexachloro and hexabromo uranium(IV) compounds.

(*ix*) *Uranium*(*IV*) *oxide di-iodide and nitride iodide*

UOI_2 can be prepared by heating U_3O_8, U, and I_2 at 450°C in a sealed Pyrex tube. The compound is iso-structural with $UOCl_2$ (orthorhombic symmetry in space group *Pbam*, see Table 5.26) and has $\mu_{\text{eff}} = 3.34$ B.M, as determined from magnetic susceptibility measurements (Levet and Noël, 1979).

The reaction of uranium tetraiodide with gaseous ammonia at temperatures above ~350°C yields uranium nitride iodide, UNI. It may be also obtained by heating uranium nitride with uranium tetraiodide. The compound has tetragonal symmetry (space group *P*4/*nmm*) and is iso-structural with the chloride and bromide analogues (see Table 5.26).

(*x*) *Uranium*(*IV*) *mixed halides and mixed halogeno compounds*

Phases of the composition of $UClF_3$, UCl_2F_2, and UCl_3F occur in the UCl_4–UF_4 system. All are melting incongruently and are thermally unstable, the order being $UClF_3 > UCl_2F_2 > UCl_3F$. The last compound may be prepared by (i) chlorination of UO_2F_2 in refluxing hexachloropropene, (ii) chlorination of UF_3 with chlorine at 350–380°C and by heating of UF_4 in a CCl_4 vapor at 420°C. UCl_3F, obtained in this way, is somewhat contaminated with unreacted starting materials and by-products (UCl_4 or $UOCl_2$). The X-ray powder data obtained for UCl_3F are listed in Table 5.26. A number of ternary chloride fluorides were identified in the $M^{I}Cl$–UF_4 and $M^{II}Cl_2$–UF_4 phase diagrams (where M^{I} = Li, Na, K, Rb, or Cs and M^{II} = Mg or Ca) (Brown, 1979).

The preparation and thermodynamic data of uranium(IV) mixed halides containing bromine have been reported by MacWood (1958). Solid-state reactions of stoichiometric quantities of UCl_4 and UBr_4 yield $UBrCl_3$ at 750°C and UBr_2Cl_2 and $UBrCl_3$ at 590°C. The former may also be prepared by bromination of UCl_3 at 500°C. Some thermodynamic data of these compounds are listed in Table 5.26.

The following mixed tetravalent halides containing iodide anions: (i) UCl_3I, (ii) UCl_2I_2, (iii) $UClI_3$, (iv) UBr_3I, (v) UBr_2I_2, and (vi) $UBrI_3$ (Brown, 1979) have be obtained in pure form. Satisfactory preparation methods involve: (i) iodination of UCl_3 at 500°C in a atmosphere of iodine, (ii) fusion of equimolar amounts of UI_4 and UCl_4 in the presence of small amount of iodine, (iii) fusion of UCl_4 and either UI_3 (at 600°C) or UI_4, (iv) iodination of UBr_3 at 500°C, (v) iodination of UBr_2I at 500°C, or fusion of UBr_4 and UI_4 at 520°C followed by sublimation in a stream of iodine, and (vi) fusion of a 1:3 mole ratio of UBr_4 and UI_4, followed by sublimation at a low pressure of iodine. The compounds are dark-brown or black and undergo rapid hydrolysis in a humid atmosphere. Their melting points range from 478 and 490°C for UBr_3I and UCl_3I, respectively, to somewhat less than 500°C for the remaining mixed halides. All compounds readily lose iodine on heating *in vacuo*, except of $UBrI_3$, which can be sublimed without decomposition. A number of thermodynamic data are available for these compounds (see Table 5.26). The stability of the chloride iodides increases with increasing iodide content. A reverse stability trend is reported for the bromide iodides.

The preparation of uranium(IV) mixed halgeno-compounds by fusion methods and mixed halgeno compounds with donor ligand have been also reported, e.g. $M^I_2UX_2Y_2$ (where M^I = Na, K or Cs, X = Cl, and Y = Br), $K_2UCl_4I_2$, $K_2UBr_4I_2$, $UCl_3I \cdot 8CO(NH_2)_2$, $UI_2Cl_2 \cdot 5DMA$ (DMA = *N*,*N*-dimethylacetamide), and $UClI_3 \cdot 5DMA$ (Gregory, 1958; Brown, 1968).

(*xi*) *Nitrogen-containing uranium halides*

Uranium nitride chlorides, bromides, and iodides

High-temperature ammonolysis of UCl_4, UBr_4, or UI_4 leads to the corresponding uranium nitride chloride, bromide, and iodide. The formation of UNCl and UNBr proceeds via a number of intermediates such as $U(NH_2)Cl_3$, $U(NH)_2Cl_2$, or UNCl. Other routes to UNCl involve high-temperature interaction of UCl_4 and $UN_{1.33}$ as well as solid-state reactions between UCl_4 and aluminium or silicium at about 800°C in a nitrogen atmosphere. Crystallographic data for UNCl (Juza and Sievers, 1965; Juza and Meyer, 1969) are listed in Table 5.26.

A dark brown compound of the formula $UN_{1.03}Br_{1.03}$ was obtained on heating uranium tetrabromide ammoniates in gaseous ammonia for 48–60 h. The compound may also be prepared by heating uranium nitride and the tetrabromide at 600–900°C (Juza and Meyer, 1969). It is insoluble in water but dissolves slowly in 2 M H_2SO_4 with the formation of a green solution. UNBr is converted to uranium nitride in gaseous ammonia at temperatures over 750°C. The compound crystallizes in the BiOCl-type of structure, space group $P4/nmm$, D^7_{4h}, the same as the corresponding UNCl and UNI compounds (see Table 5.26).

The preparation of UNI can be achieved by ammonolysis of uranium tetraiodide at about 350°C or by heating uranium nitride with UI_4. The compound has the BiOCl-type structure and is isostructural with the chloride and bromide analogs (Juza and Meyer, 1969; see Table 5.26).

(c) Pentavalent halides and complex halides

Uranium halides in the pentavalent oxidation state exhibit a tendency to hydrolysis and disproportionation into U(IV) and U(VI) species. However, in the absence of substances that cause hydrolysis, diproportionation does not occur spontaneously (Bacher and Jacob, 1980). Stable solutions of uranium(V) have been obtained, for example, by heating a mixture of UO_3 with thionyl chloride under prolonged refluxing, or by dissolving UF_5 in methyl cyanide, dimethylformamide or Me_2SO as well as of UCl_5 and UBr_5 in some organic solvents (Selbin and Ortego, 1969; Brown, 1979; Halstead *et al.*, 1979). Uranium hexachloride decomposes easily in solvents like carbon tetrachloride, methylene dichloride, or 1,2-dichlorethane and is therefore a suitable starting material for the preparation of uranium(V) compounds on a laboratory scale. The synthesis and properties of various uranium(V) compounds and complexes have been reviewed by Selbin and Ortego (1969). The preparation of UX_6^- (X = F, Cl, Br or I) complexes and the oxohalide complexes $[UOF_5]^{2-}$, $[UOCl_5]^{2-}$, and $[UOBr_5]^{2-}$ has been reported by Ryan (1971). The chemical properties of the compounds, their stability against disproportionation in various non-aqueous halide solutions as well as some aspects of their absorption spectra are also discussed. The halides and complex halides have a variety of colors – from pale blue and red brown to yellow (Table 5.28). The coordination geometry of uranium(V) halides are: octahedral (α-UF_5), pentagonal bipyramidal (β-UF_5), and edge-sharing octahedral (U_2Cl_{10} units).

Uranium(V) has a [Rn]$5f^1$ electronic configuration with the $^4F_{5/2}$ (Γ_7) ground state. A number of spectra in solutions, solids, and gas phase are available (Ryan, 1971; Edelstein *et al.*, 1974; Leung and Poon, 1977; Bacher and Jacob, 1980; Eichberger and Lux, 1980; Carnall and Crosswhite, 1985). The analysis of the spectra has been based on a strong ligand-field model. The site symmetry of the U^{5+} ion is frequently found to be octahedral or distorted octahedral (Carnall and Crosswhite, 1985). The combined ligand field and spin–orbit interaction split the parent ^2F state into the Γ_7, Γ_8, Γ_7', Γ_8', and Γ_6 components. The spectra of U^{5+} in the approximate octahedral sites of the different compounds have very similar f–f band energy and relative intensities, e.g. the spectra of $[N(C_2H_5)_4]_2UOCl_5$ (Selbin *et al.*, 1972a), UCl_5 single crystals (Leung and Poon, 1977), UCl_5 in $SOCl_2$ (Karraker, 1964), and $(UCl_5)_2$ or $UCl_5 \cdot AlCl_3$ in the vapor phase (Gruen and McBeth, 1969). Spectroscopic studies and semi-empirical theoretical calculations of energy levels of UOX_5^{2-} species (X = F, Cl, or Br) in the corresponding tetraethylammonium oxopentahalide complexes reveal that each of the six electronic transitions is shifted to higher energy in the expected order: $Br^- < Cl^- < F^-$. The spin–orbit coupling constants obtained in the best fits also increase in this same order: 1750, 1770, and 1850 cm^{-1}. For a number of uranium(V) halides and complex halides, magnetic susceptibility measurements were carried out over wide temperature ranges. The paramagnetic constants from the Curie–Weiss law $\chi'_M = C/(T-\theta)$ and the effective

(*i*) *Uranium pentafluoride and uranium*(*V*) *complex fluorides*

Uranium pentafluoride

The pentafluoride exists in two crystalline modifications: a high-temperature α-UF_5 (over 150°C) and a low-temperature β-UF_5 form (below 125°C). The general preparation procedures involve either the oxidation of UF_4 or reduction of UF_6 (Bacher and Jacob, 1980). Halogen fluorides, some noble gas fluorides, and CoF_3, VF_3, and OF_2 may be used as oxidation reagents. The formation of α-UF_5 can be achieved by fluorine oxidation of UF_4 at 150°C, or the conversion of UCl_5 by gaseous HF at 300°C; the low-temperature form may be prepared by the reaction with anhydrous liquid HF (AHF) and UCl_6 or UCl_5. The β-form may be also obtained by reduction of UF_6 by silicium powder, NH_3, or $SOCl_2$. This compound is also formed in AHF in the presence of gold plates, by pyrolysis of NH_4UF_7, photolysis of UF_6 by UV light, and by reaction of $NOUF_6$ in a solution of AHF and BF_3. The reduction of UF_6 to UF_5 has also been achieved in hydrogen bromide and CF_3COOH. Some of the preparation methods are of little practical importance because of small yields, an impure product, or inconvenient starting materials. On laboratory scale the most convenient procedures involve photoreduction of UF_6 in the presence of H_2, CO, or SO_2. The reaction between UF_4 and UF_6 results in the formation of β-UF_5 below 125°C and α-UF_5 at 230–250°C. β-UF_5 is formed also in the following reaction at molar ratios 1.1 to 1 between UF_6 and $(CH_3)_3SiX$ (Brown *et al.*, 1983):

$$UF_6 + (CH_3)_3SiX \rightarrow (CH_3)_3SiF + 1/2X_2 + UF_5 \quad (X = \text{Cl or Br})$$

The pentafluoride is a hygroscopic crystalline solid, which disproportionates even in a humid atmosphere, according to reaction

$$2UF_5 + 3H_2O \rightarrow UF_4 + UO_2F_2 \cdot H_2O + 4HF$$

In aqueous solutions this reaction results in the precipitation of the hydrated tetrafluoride and the formation of a solution of uranyl fluoride. Above 150°C, UF_5 disproportionates slowly to U_2F_9(s) and UF_6(g). The disproportionation reaction can be limited by the presence of UF_6(g); the temperature dependence of the vapor pressure follows the equations (Wolf *et al.*, 1965):

$$\log p_{\text{solid}}(\text{mmHg}) = -8001\,T^{-1} + 13.99$$
$$\log p_{\text{liquid}}(\text{mmHg}) = -5388\,T^{-1} + 9.82$$

UF_5 can be reduced to UF_4 by H_2 or Ni (at 600°C) and by some covalent fluorides such as PF_3, AsF_3, or $AsCl_3$. Halide exchange reactions were observed with BCl_3, $TiCl_4$, and PCl_3, the products being respectively, BF_3, TiF_4, and PF_3, in addition to UF_4 and UCl_6.

Uranium pentafluoride dissolves without hydrolytic decomposition in 48–50% hydrofluoric acid, forming relatively stable blue solutions from which $(H_3O)UF_6 \cdot 1.5H_2O$ crystallizes; by addition of RbF or CsF, the blue MUF_6 salts (M = Rb or Cs) are formed. Uranium pentafluoride dissolves in acetonitrile and reacts with alkali fluorides and sodium ethoxide, NaOEt, to form $M[UF_4]$ and $U_2(OEt)_{10}$, respectively.

The structure of α-UF_5 consists of infinite chains of UF_6 octahedra, bridged by *trans*-fluorides to give a linear chain parallel to the *c*-axis. The remaining four fluorine atoms are single bonded to uranium. The low-temperature β-form is isostructural with PaF_5 and NpF_5 and consists of an eight-coordinate arrangement with a geometry intermediate between dodecahedral and square antiprismatic (Ryan *et al.*, 1976; Eller *et al.*, 1979). The crystal packing of β-UF_5 is shown on Fig. 5.43. Other crystallographic data are listed in Table 5.28.

Theoretical model calculations performed using the vibrational spectrum of monomeric UF_5 molecules isolated in an Ar-matrix indicate a square-pyramidal structure in which the U atoms are located above the equatorial plane formed by the fluorine atoms (Paine *et al.*, 1976).

In non-aqueous solvents such as nitriles, dimethyl sulfoxide, and dimethylformamide, uranium pentafluoride forms stable solutions containing UF_6^- anions and solvated UF_4^+ cations. From these solutions several adducts and complex

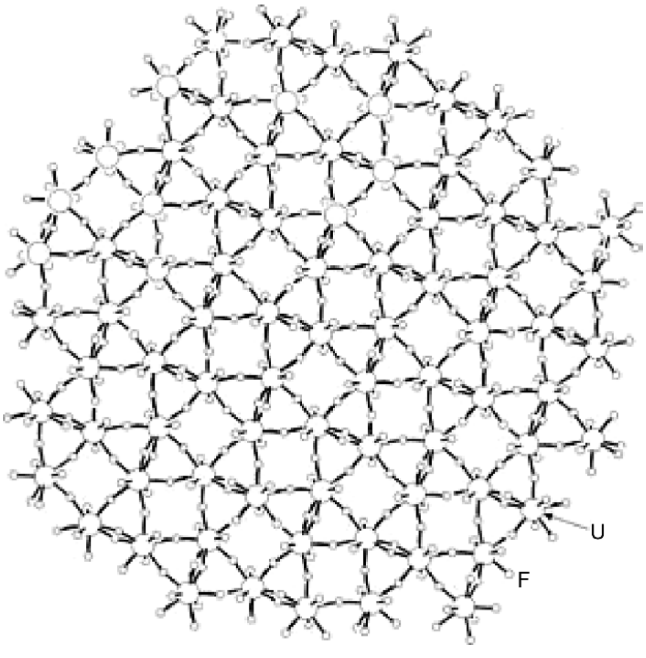

Fig. 5.43 *Crystal packing view of β-UF_5 (from Ryan* et al., 1976).

fluorides have been isolated, for example, $UF_5 \cdot CH_3CN$, $[UF_4(Me_2SO)_3][UF_6]$, $[UF_4(DMF)_3][UF_6]$, $[(C_6H_5N(CH_3)_3][UF_6]$, $[(C_6H_5)_3PNP(C_6H_5)_3][UF_6]$, Na $[UF_6]$, and $K[UF_6]$ (Berry *et al.*, 1977; Halstead *et al.*, 1979). The compounds and their solutions have been characterized by electronic, infrared, Raman, and EPR spectra.

*Complex uranium(*v*) fluoro compounds*

A number of fluorouranates(v) have been characterized by determination of their crystallographic data and their chemical and thermodynamic properties (see Table 5.28). Additional information in the reviews of Chatalet (1967), Penneman *et al.* (1967), Ryan (1971), Brown (1972), Bacher and Jacob (1980), and Freestone and Holloway (1991). Complex compounds identified in a number of selected fused salt systems are listed in Table 5.29.

The compounds may be prepared by a variety of methods (Bacher and Jacob, 1980; Freestone and Holloway, 1991): (i) solid state reactions between UF_5 and the appropriate alkali fluorides in an inert atmosphere at 300°C constitute a general route to most of the fluoro complexes; (ii) melting of mixtures of hexa- and octafluoro complexes leads to the formation of the heptafluoro complex compounds; (iii) solid state reactions or reduction of UF_6 with NH_3 yield ammonium fluorouranates; (iv) treatment of equimolar mixtures of UF_5 and the appropriate alkali fluoride with anhydrous HF yields the hexafluorouranates(v); (v) oxidation of UF_4–alkli fluoride mixtures with fluorine also leads to the hexafluoruranates; and (vi) $RbUF_6$ may be also obtained by crystallization from solutions of RbF and UF_5 in concentrated HF.

The pentafluoro uranates may disproportionate into U(iv) and U(vi). However, they are relatively stable in the absence of substances that cause hydrolysis. Ohwada (1976) and Soulié (1978) suggest that the U–F bonds in the fluorouranates(v) are partly covalent (68 to 77% as compared to 46.3 and 35%, respectively, in UF_4 and β-K_2UF_5). The bonds in UF_5 are assumed to have

Table 5.29 *Uranium(*v*) complex fluorides identified in molten salt systems.*

System	*Complex fluorides*

a nearly 100% covalent character. The pentafluoro uranates of the M_2UF_7 type (M = K, Rb, Cs, or NH_4) have the same type of powder patterns ($P2_1/c$, C^5_{2h}, No. 14) as that of K_2NbF_7 where the coordination polyhedon is a monocapped trigonal prism (Brown and Walker, 1966). The analysis of the spectral data for $CsUF_6$ (Carnall and Crosswhite, 1985) made it possible to assign the electronic transitions from the Γ_7 ground state to the excited levels Γ_8, $\Gamma_{7'}$, $\Gamma_{8'}$ and Γ_6 of the $5f^1$ electronic configuration. The spin–orbit coupling parameter ς_{5f} and the B^2_0, B^4_0, and B^6_0 crystal-field parameters determined for the D_{3d} site symmetry are equal to 1910.2(13), 534.2(139), –14866(66) and 3305(78) cm^{-1}, respectively.

Pentavalent oxide fluorides and oxide fluoride complexes

White U_2OF_8 oxide fluoride has been obtained by heating of UF_4 in an intermittent oxygen flow at 850°C (Kirslis *et al.*, 1950; Freestone and Holloway, 1991). The compound disproportionates in vacuo at 300°C to form a mixture of uranyl fluoride and uranium hexa and tetrafluoride. The existence of this compound has not been confirmed by other authors (Ekstrom *et al.*, 1974). A series of uranium oxide fluoride phases, UO_xF_y, containing uranium in the oxidation state 5+ ($UO_{2.33}F_{0.33}$ to $UO_{2.00}F_{1.00}$), a mixture of 5+ and 6+ ($UO_{2.58}F_{0.17}$ to $UO_{2.17}F_{0.83}$) and a mixture of 4+ and 5+ ($UO_{2.00}F_{0.25}$) have been obtained by heating UF_4 with UO_3 or U_3O_8 at 400–500°C *in vacuo* (Kemmler-Sack, 1967, 1969). The possible structures of these phases have been discussed on the basis of X-ray powder, magnetic, and spectral data.

A number of complexes of the $M^IM^{II}U_2O_6F$-type (where M^I = Na, K, Rb, or Tl and M^{II} = Ba, Sr, or Pb) were obtained by heating appropriate mixtures of the component fluorides and oxide fluorides at 500–900°C *in vacuo*, e.g. (i) M^IF with $M^{II}UO_4$, and UO_2; (ii) $M^{II}F_2$ with $M_2{}^IUO_4$, $M^{II}UO_4$, and UO_2, and (iii) M^IUO_2 with $M^{II}O$, UO_3, UO_2, and UF_4 (Kemmler-Sack, 1968a). All complexes have cubic symmetry (Kemmler-Sack, 1968b,c) with similar lattice parameters (Table 5.28). Reflectance spectra of the compound have been analyzed on the basis of the $5f^1$ configuration of the U(v) ion in an octahedral field.

Two additional complex oxide fluoride compounds, $[N(C_2H_5)_4]_2UOF_5$ and $[N(C_2H_5)_4]_2UOF_5 \cdot 2H_2O$, have also been isolated. The hydrated compound is formed by hydrolysis of the corresponding UCl_6 salt in a saturated solution of $[N(C_2H_5)_4]F \cdot nH_2O$ in an ethanol–acetone mixture. The complex is easily dehydrated in vacuum (Ryan, 1971). Both compounds are pink colored and oxygen-sensitive. UOF_5^{2-} solutions may be stabilized by an excess of $[N(C_2H_5)_4]F$. Addition of water results in a rapid disproportionation of UOF_6^{2-} to U^{IV} and U^{VI} species. An analysis of the absorption spectra of $[N(C_2H_5)_4]_2UOF_5$ in solid state and in an acetonitrile solution made it possible to make an assignment of the six electronic transitions based on a D_4 ligand field model (Selbin and Sherrill, 1974).

(*ii*) *Uranium pentachloride and uranium*(*v*) *complex chlorides*

Uranium pentachloride

Uranium pentachloride may be prepared by a number of methods, but only a few of them result in high yields and high purity due to the instability of the compound towards thermal decomposition and disproportionation; these reactions take place below 100°C at pressures between 10^5 Pa (1 atm) and 133×10^{-4} Pa, respectively:

$$UCl_5 \xrightarrow{10^5 Pa} UCl_4 + 1/2Cl_2 \text{ and}$$

$$2UCl_5 \xrightarrow{133 \times 10^{-4} Pa} UCl_4 + UCl_6$$

At normal pressure, the disproportionation is complete in the range 100 to 175°C.

One of the most satisfactory preparative methods is to use liquid phase chlorination of UO_3 or U_3O_8 with carbon tetrachloride at 80–250°C under pressure and UCl_5 as catalyst (Brown, 1979). The most convenient laboratory method involves decomposition of UCl_6 at room temperatures in carbon tetrachloride, methylene dichloride, or 1,2-dichloroethane. Another relatively simple method is the reduction of UO_3 by silicon tetrachloride at 400°C followed by vacuum removal of the excess of reagent from the resulting solution of UCl_5 in $SiCl_4$ (Selbin *et al.*, 1968).

Uranium pentachloride is obtained as dark brown crystals, which exist in two crystal modifications. The more often encountered α-UCl_5 is obtained by recrystallization from CCl_4 and the β-UCl_5 is formed by crystallization of UCl_6 from carbon tetrachloride or methylene dichloride (Kolitsch and Müller, 1974). UCl_5 is very hygroscopic and immediately disproportionates into U(IV) and U(VI) in aqueous solutions. It reacts instantly with a number of organic solvents such as alcohols, acetone, dimethyl ether, diethyl ether, ethyl acetate, formamide, or dioxane. In some anhydrous organic solvents such as carbon tetrachloride, carbon disulfide, and thionyl chloride, it forms relatively stable solutions; it is insoluble in benzene, xylene, or isopropyl ether. Impure samples may be recrystallized from carbon tetrachloride and separated from UCl_4 by dissolution and recrystallization from liquid chlorine. Hydrogen reduces UCl_5 to UCl_4 at 250–300°C. Anhydrous gaseous or liquid hydrogen fluoride converts it to UF_5 and fluorine oxidizes it to UF_6. The reactions of UCl_5 with some univalent chlorides yield $N(CH_3)_4UCl_6$, $As(C_6H_5)_4UCl_6$, or $N(CH_3)_2H_2UCl_6$ (Bagnall *et al.*, 1964).

The structures of the monoclinic α-UCl_5 (space group $P2_1/n$) and triclinic β-UCl_5 (space group $P\bar{1}$) are based on a cubic or hexagonal close packing of the chlorine atoms. In the first one, the uranium atoms occupy one-fifth of the octahedral holes and two octahedra are forming a dimeric U_2Cl_{10} unit by sharing a common edge. The structure of the β phase contains the same

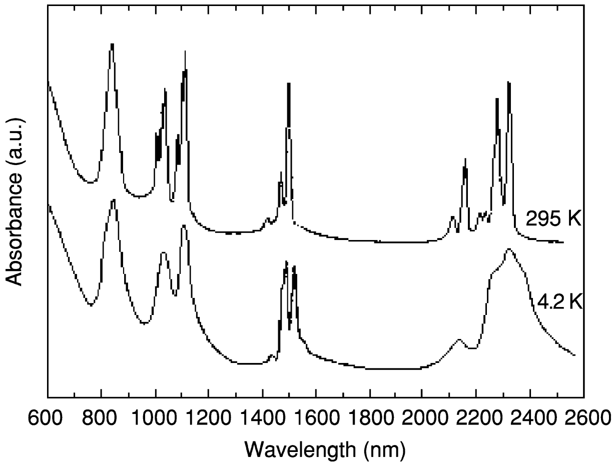

Fig. 5.44 *Absorption spectrum of* UCl_5 *single crystals at* 4.2 *and* 295 K (*partially adapted from Leung and Poon*, 1977). *Reproduced with the permission of Copyright Clearance on Government of Canada Works.*

U_2Cl_{10} units (Table 5.28). The following ligand-field parameters have been reported from an analysis of the UCl_5 spectrum: $\varsigma_{5f} = 1559(115)$, $B_0^4 = 13479$ (1125) and $B_0^6 = -158.6(745)$ (Leung and Poon, 1977). The electronic absorption spectra of the two UCl_5 crystal modifications (see Fig. 5.44) are identical and similar to those of the hexachlorouranates(v).

The magnetic susceptibility follows the Curie–Weiss law in the 14–300 K temperature range. Different effective magnetic moments were reported: according to Rüdorff and Menzer (1957), they range from 1.05 B.M. at 77 K to 1.42 B.M. at 398 K, while Handler and Hutchison (1956) report $\mu_{eff} = 2.00$ B. M. at 300 K with $\Theta = -99$ K.

Complex uranium(v) *chloride compounds*

The isolation of numerous pentavalent uranium complexes with ligands containing N, P, As, S, Se, and Te donor atoms has been reported (Selbin and Ortego, 1969; Brown,1972, 1979). Thus, complexes of UCl_5L-type are formed with triphenylphosphine oxide, thionyl chloride, phenazine, 2,2′-bipyridyl, ethylene bis(diphenylphosphine), triphenylphosphine, trioctylphosphine, diarsine, anthrone, benzanthrone, methyleneanthrone, triphenylbismuthine, diphenyldisulphide, Ph_2Se_2, and Ph_2Te_2; those of the $UCl_5{\cdot}2L$-type – with pyrazine, phthalazine, methyl cyanide, pyridine, 1,10-phenanthroline, 2-mercaptopyridine, ethylene bis-salicylaldiamine, 8-hydroxyquinoline, anthrone, benzil, benzanthrone, and triphenylphosphine oxide, while $UCl_5{\cdot}3L$ complexes are formed with dioxane and tetramethyl amine.

The preparation of $[N(CH_3)_4]_3UCl_8$ and a number of $MUCl_6$ complexes (where M = $N(CH_3)_4$, $N(CH_3)_2H_2$, $N(C_2H_5)_4$, $N(C_3H_7)_4$, $N(C_3H_9)_4$,

$N(C_4H_9)_4$, $P(C_6H_5)_4$, $As(C_6H_5)_4$, NH_4, K, Rb, etc.) has been achieved by addition of carbon disulfide to thionyl chloride solutions of U(v) using the appropriate MCl compound (Bagnall *et al.*, 1964; Brown, 1979). A convenient alternative method to prepare $MUCl_6$ complexes (where M = $N(C_2H_5)_4$, As $(C_6H_5)_4$, or $N(CH_3)_4$) employs chlorine oxidation in nitromethane solutions (Ryan, 1974). UCl_5tcac (tcac is the acronym for $Cl_2C{=}CClCOCl$) has been reported (Fuji *et al.*, 1979) to be a useful starting material for the preparation of $RbUCl_5$, $(n\text{-}C_3H_7)_4NUCl_5$, and a number of UCl_5 adducts with different donor ligands. Other convenient routes to the U(v) complexes involve the addition of MCl (where M = NH_4, $As(C_6H_5)_4$, or $N(CH_3)_4$) to uranium hexachloride in methylene dichloride (Brown, 1979). The reactions between UO_3, $SOCl_2$, and MCl (M = Na, K, Rb, Cs, NH_4, Ag, Ba, or Tl) in sealed vessels at 180–200°C also lead to uranium(v) hexachloro complexes (Stumpp, 1969); the reaction between UO_3 and PCl_5 results in the formation of $UCl_5 \cdot PCl_5$. The last compound should be formulated as $[PCl_4]^+[UCl_6]^-$ (Brown, 1969). Gruen and McBeth (1969) have reported the formation of a uranium(v) chloro complexes in the vapor phase according to the reaction

$$UCl_4 + \frac{1}{2}Cl_2 + AlCl_3 \rightarrow UCl_5 \cdot AlCl_3$$

The analysis of the high-temperature electronic spectrum indicates that the compound should be formulated as $[AlCl_4]^+[UCl_6]^-$.

The hexachlorouranates(v) are very hygroscopic. On exposure to air they are hydrolyzed with disproportionation to U(iv) and U(vi). With the exception of those containing alkali metal cations, they are soluble in numerous organic solvents such as methyl cyanide, diethyl ether, acetone, nitromethane, or phosphorous oxytrichloride. $CsUCl_6$ is reported to react in inert solvents with oxygen donor ligands forming $UCl_5 \cdot L$ adducts. Structure data and references to heats of formation determinations of several uranium(v) chloro-complexes are listed in Table 5.28. Spin–orbit and crystal field parameters, $\varsigma_{5f} = (1913)$, $B^4_0 = 12209(710)$, and $B^6_0 = -39(776)$, were determined for $N(C_2H_5)_4UCl_6$ by Edelstein *et al.* (1974). The magnetic susceptibility of $CsUCl_4$, $[(CH_3)_2H_2]UCl_6$, $[N(CH_3)_4]UCl_6$, and $[As(C_2H_5)_4]UCl_6$ exhibits a Curie–Weiss dependence in two temperture ranges: 140–205 K and 210–310 K. The effective magnetic moments and Weiss constants (in brackets) range between 1.71 (161 K) and 2.14 B.M. (280 K) (Bagnall *et al.*, 1964; Brown, 1979). In the 250–310 K range $[N(CH_3)_4]_3UCl_8$ has a temperature-independent paramagnetism ($\chi_{mole} = 1100 \times 10^{-6}\ cm^3\ mol^{-1}$).

(*iii*) *Uranium*(*v*) *and mixed valence oxide chlorides*

The most convenient methods for the preparation of $UOCl_3$ involve heating of stoichiometric amounts of (i) UO_3 and $MoCl_5$ at 200–220°C *in vacuo*, (ii) UCl_4 and UO_2Cl_2 at about 370°C, or (iii) UO_2Cl_2 with WCl_5, $ReCl_5$, or $MoOCl_3$ at about 200°C (Brown, 1979). The mechanism of the first reaction is:

$$UO_3 + MoCl_5 \rightarrow UO_2Cl_2 + MoOCl_3$$
$$UO_2Cl_2 + MoOCl_3 \rightarrow UOCl_3 + \uparrow MoO_2Cl_2$$

The brown, moisture-sensitive solid is insoluble in non-polar organic solvents like carbon tetrachloride and benzene, but dissolves without decomposition in anhydrous ethanol. In the latter, it reacts with $C_6H_5N \cdot HCl$ to give $[C_6H_5NH]_2UOCl_5$. In other alcohols, acetone, and water, the compound dissolves with decomposition. Hydrolysis of $UOCl_3$ results in the formation of polymeric –U–O–U–O– chains. The reduction with $MoOCl_3$, $MoCl_5$, or $ReCl_5$ *in vacuo* around 200°C leads to UCl_4.

The preparation of UO_2Cl can be achieved by heating equimolar quantities of UO_2Cl_2 and UO_2 at 590°C *in vacuo* (Levet, 1969) or by reduction of UO_3 with $MoCl_3$ (Eliseev *et al.*, 1972). Uranium(v) dioxide monochloride is a brown-violet, air-sensitive solid. It is insoluble in organic solvents and decomposes to UO_2 and Cl_2 at 600°C in an inert atmosphere. UO_2Cl is reduced to UCl_4 by $MoCl_5$ at about 200°C and to $UOCl_2$ when heated with $MoOCl_3$. It exhibits Curie–Weiss dependence between 86 and 295 K with $\mu_{eff} = 1.86$ B.M. and $\Theta = -95$ K (Levet, 1969).

There is also a mixed valence state oxide chloride, $(UO_2)_2Cl_3$, which may be obtained by thermal decomposition of UO_2Cl_2 in high vacuum at 400–500°C, or by heating UO_2 and $UOCl_2$ in the molar ratio of 1:3 at 500°C; at higher temperature (500–650°C), UO_2Cl is formed. The black-brown solid has orthorhombic symmetry (Table 5.28) and dissolves slowly in water and in dilute mineral acids (Cordfunke *et al.*, 1977, Brown, 1979). On exposure to the atmosphere, the compound converts into the heptahydrate $(UO_2)_2Cl_3 \cdot 7H_2O$.

(*iv*) *Complex uranium*(*v*) *oxochlorides*

Brown (1979) has described methods for the preparation and characterization of a number of uranium(v) oxochloro-compounds, such as M_2UOCl_5 (where M = $N(C_2H_5)_4$, $N(C_2H_5)_3H$, $As(C_6H_5)_4$, or C_5H_5NH), $[N(C_2H_5)_4]UOCl_5{\cdot}L$ (where L = phtalazine or 1,10-phenantroline), $[LH]_2UOCl_5{\cdot}L$ (where L = pyridine, quinoline, isoquinoline, α- and β-picoline), and $[C_5H_5NH]_2UOCl_5 \cdot 2.5C_5H_5NHCl$. The complex $[C_5H_5NH]_2UOCl_5$ may be obtained by the addition of pyridine to an ethanolic solution of $UCl_5 \cdot SOCl_2$ saturated with hydrogen chloride; $[N(C_2H_5)_3H]_2UOCl_5$ by photolysis of $UO_2Cl_2 \cdot 2C_5H_5N$ in dry ethanol; and $[N(C_2H_5)_4]_2UOCl_5$ or $[As(C_2H_5)_4]_2UOCl_5$ by controlled hydrolysis in nitromethane of the corresponding hexachloro complexes. They are slightly soluble in nitromethane where they may react with other species to yield different uranium(IV), (V), or (VI) complexes. The oxopentachloro compounds are moisture-sensitive and undergo rapid disproportionation in water-containing solvents with the exception of $[N(C_2H_5)_4]_2UOCl_5$ and $[As(C_2H_5)_4]_2UOCl_5$ that are moderately stable on exposure to air. Reactions between $[N(C_2H_5)_4]_2UOCl_5$ and nitrogen heterocyclic compounds in nitromethane or nitrobenzene yield complexes of uranyl(VI) or U(IV) (Selbin *et al.*, 1972b, 1973; Brown, 1979).

The electronic absorption spectra of $[UOCl_5]^{2-}$ in solid state and non-aqueous solvents are essentially identical (Ryan, 1971). A good agreement between observed and calculated energy levels of $[N(C_2H_5)_4]_2UOCl_5$ is obtained assuming D_4 symmetry and using the following crystal field parameters: $\tau = 700\ \text{cm}^{-1}$ and $\varsigma_{5f} = 1770\ \text{cm}^{-1}$, where τ is a parameter which depends on the radial function and ς_{5f} is the spin–orbit coupling parameter (Selbin *et al.*, 1972a).

(*v*) *Uranium pentabromide and uranium*(*V*) *complex bromides*

Uranium pentabromide

The most convenient method for the preparation of UBr_5 is bromination of either uranium metal or uranium tetrabromide at 55°C, or at room temperatures in the presence of catalytic amounts of methyl cyanide (Brown, 1979). The compound is a dark brown solid and is extremely sensitive to moisture. It disproportionates rapidly on dissolution in water and in various organic solvents like ethanol, acetone, dioxane, and ethylacetate. In chloroform and bromoform, the rate of disproportionation is much slower. Stable solutions may be obtained on dissolution in anhydrous, oxygen-free methyl cyanide and methylene dichloride. A number of stable $UBr_5 \cdot L$ complexes with oxygen donors like $L = (C_6H_5)_3PO$ or $[(CH_3)_2N]_3PO$ have been prepared by bromine oxidation of UBr_4 in the presence of the ligand. Interactions with univalent bromides in thionyl bromide result in the formation of hexabromourantes(V), $MUBr_6$. Uranium pentabromide crystallizes with triclinic symmetry, space group $P\bar{1}$ and is isostructural with β-UCl_5 (see Table 5.28).

Ternary and polynary bromides and bromo compounds of uranium(*V*)

Hexabromouranates(V) of the formula $MUBr_6$ (where M = Na, K, Rb, Cs, NH_4, $N(CH_3)_4$, $N(C_2H_5)_4$, $N(C_4H_9)_4$, $As(C_6H_5)_4$, $P(C_6H_5)_4$, etc.) have been prepared by a variety of methods (Brown, 1979): (i) bromine oxidation of the appropriate tetravalent M_2UBr_6 compounds in non-aqueous solutions, e.g. nitromethane; (ii) halogen exchange reactions between the chloro complexes and an excess of liquid boron tribromide; (iii) reactions between thionyl bromide solutions of pentavalent uranium (prepared by dissolution of UO_3 in the solvent under refluxing) and the appropriate MBr; and (iv) reaction of UBr_6^{2-} and $UO_2Br_4^{2-}$ in nitromethane or methyl cyanide in the presence of anhydrous HBr according to the reaction

$$UBr_6^{2-} + UO_2Br_4^{2-} + 10HBr \rightarrow 2UBr_6^- + 2H_3O^+ + 4HBr_2^-$$

The hexabromouranates have a brown-black color and are rapidly decomposed on dissolution in water or in the presence of moisture. $[As(C_6H_5)_4]UBr_6$ and $[N(C_2H_5)_4]UBr_6$ form stable solutions in anhydrous methylene dichloride and nitromethane. In the last solvent, the presence of bromine is required to avoid reduction to uranium(IV). The complexes with M = $N(CH_3)_4$, $N(C_2H_5)_4$, and $N(C_4H_9)_4$ dissolve also in methylene dibromide and dibromoethane.

Vibronic side-bands dominate in the solid state and solution spectra of the bromo complexes, which indicates an octahedral or close to octahedral stereochemistry. An assignment of the electronic transitions in $[N(C_2H_5)_4]UBr_6$ from the Γ_7 ground level to the Γ_6, Γ_7, and Γ_8 excited levels of the $5f^1$ electronic configuration has been made (Edelstein *et al.*, 1974). The spin–orbit coupling parameter ς_{5f} and the B_0^4 and B_0^6 crystal-field parameters determined from the fitting procedure are 1761(31), 10953(350) and –1058(274) cm^{-1}, respectively (Ryan, 1971; Eichberger and Lux, 1980). There are IR vibronic frequencies at 215 (ν_3) and 87 (ν_4) and at 61 cm^{-1} (ν_6); the identification of the infrared (IR) and Raman inactive (ν_6) vibration has been made by Brown *et al.* (1970). The first electron transfer band in a solution of anhydrous nitromethane has been registered at 17400 cm^{-1}, from which a value of 2.22 for the uncorrected optical electronegativity was deduced (Ryan, 1971).

(*vi*) *Uranium*(V) *oxide bromides*

Uranium(V) *oxide tribromide*

Uranium(V) oxide tribromide, $UOBr_3$, may be conveniently prepared by heating UO_3 in a stream of nitrogen and carbon tetrabromide vapour at 110°C. $UOBr_3$ is a moisture-sensitive and thermally unstable compound, slowly evolving bromine even at room temperatures. It is converted to UO_2Br_2 or UBr_4 by heating in oxygen at 148°C and with CBr_4 at 165°C, respectively. When heated at 200–300°C in a nitrogen atmosphere $UOBr_3$ converts to $UOBr_2$. In water and ethanol, acetone, ethyl acetate, and dioxan, it disproportionates to U(IV) and U(VI) species. The compound is insoluble in non-polar organic solvents like CCl_4 or CS_2.

Uranium(V) *dioxide monobromide*

The preparation of UO_2Br can be achieved by thermal decomposition of UO_2Br_2 in a sealed evacuated glass tube (Levet *et al.*, 1977) or by heating the latter compound in a nitrogen–bromine mixture around 320°C (Gueguin, 1964). It may also be prepared by heating UO_3 at 250°C in a mixture of H_2 and HBr, or by treating UO_2Cl_2 with HBr (Levet, 1965). UO_2Br is a moisture-sensitive black-brown solid. When heated in an inert atmosphere (400–500°C), it decomposes to UO_2 and Br_2. It reacts with chorine (400°C) and oxygen (300°C) to yield UO_2Cl_2 and UO_3, respectively.

The compound has an orthorhombic symmetry in the space group *Cmcm* (No. 63). The coordination polyhedron is a pentagonal bipyramid with two bromine and three oxygen atoms in the equatorial plane and two oxygen atoms at the apices. The uranium atoms are linked in double chains by the sharing of three coordinated oxygen atoms. The structural arrangement is similar to those in $PaOBr_3$, U_3O_8 and $PaCl_5$ and the compound is isostructural with PaO_2Br, NbO_2Br, TaO_2Br, NbO_2I and TaO_2I (Levet *et al.*, 1977). Crystallographic data are listed in Table 5.28. Magnetic susceptibility data are reported by Levet (1969) and the effective magnetic moment is 1.76 B.M. with $\Theta = -200$ K.

(*vii*) *Ternary and polynary uranium*(*v*) *oxide bromides and oxobromo compounds*

Green oxybromo complexes of the formulas $[As(C_6H_5)_4]_2UOBr_5$, $[N(C_2H_5)_4]_2UOBr_6 \cdot 2.5N(C_2H_5)_4Br$, etc. have been obtained by controlled hydrolysis of hexabromouranates(v) in acetone or acetone–nitromethane mixtures at –75°C (Ryan, 1971; Brown, 1979). The complexes are significantly less stable than their fluoro and chloro analogs. They are moisture-sensitive and rapidly disproportionate in numerous anhydrous solvents, such as nitromethane.

Selbin *et al.* (1972a) and Selbin and Sherrill (1974) have presented an interpretation of the electronic spectra of UBr_6^- and $UOBr_5^{2-}$ and have shown the effect of perturbing the $5f^1$ orbital energy levels successively by a tetragonal distortion of the octahedral field and spin–orbit coupling. Semi-empirical theoretical calculations of energy levels of UBr_6^- and $UOBr_5^{2-}$ have been performed in order to locate and assign all electronic transitions in these $5f^1$ species. The first electron transfer transition was observed at 26 700 cm^{-1}. As compared with UBr_6^- species it is shifted by 9300 cm^{-1} to higher frequencies, equivalent to 0.3 eV. This change is reported to result from the pronounced anisotropic nature of the $UOBr_5^{2-}$ complex (Ryan, 1971).

(*viii*) *Intermediate uranium halides*

The reaction of solid UF_4 with gaseous UF_6 results in a gradual formation of intermediate fluorides with a composition between UF_4 and $UF_{4.5}$, depending on the temperature used and the partial pressure of uranium hexafluoride: U_2F_9 (= $UF_{4.5}$), U_4F_{17} (= $UF_{4.25}$), and U_5F_{22} (= $UF_{4.2}$) (Eller *et al.*, 1979; Bacher and Jacob, 1980).

$$3UF_4 + UF_6 \rightleftharpoons 2U_2F_9 \quad (200\,^\circ C)$$

$$7UF_4 + UF_6 \rightleftharpoons 2U_4F_{17} \quad (300\,^\circ C)$$

Agron (1958) has studied the chemical equilibria in these systems; the forward reactions take place at temperatures between 225–300 and 270–350°C, respectively. Agron (1958) has also reported the conditions of formation, equilibrium, dissociation, and the thermodynamics of the disproportionation reactions.

Intermediate uranium fluorides may also be prepared by reduction of UF_6 with HBr by a careful control of the reactant stoichiometry in reactions between

UF_3 and iodine, SiH_4 or PF_3. There are only two oxidation states, U(IV) and U(V), in U_2F_9 as shown by spectroscopic analyses. U_4F_{17} and U_2F_9 are slowly hydrolyzed, in water with the formation of $UF_4 \cdot nH_2O$, UO_2^{2+}, and F^-, and in moist air with the formation of $UO_2F_2 \cdot xHF \cdot yH_2O$. Organic solvents such as C_6H_6, $CHCl_3$, or CCl_4 react with U_2F_9 with reduction to UF_4.

U_4F_{17} has a monoclinic structure that is a distorted version of that of UF_4 (Chatalet, 1967). In U_2F_9 the uranium atoms are nine-coordinated with a tricapped trigonal prismatic arrangement (Zachariasen, 1949d; Taylor, 1976a,b).

Investigation of the UCl_3–UF_4 phase diagram identified mixed valence phases $2UCl_3 \cdot UF_4$ and $UCl_3 \cdot 7UF_4$ that melt incongruently at 625 and 760°C, respectively.

The preparation and characterization of a mixed-valence oxide chloride of the composition $(UO_2)_2Cl_3$ has been reported by Cordfunke *et al.* (1977). The compound is formed by thermal decomposition of anhydrous UO_2Cl_2 at 400–500°C in high vacuum, or by the reaction of UO_2 and UO_2Cl_2 in evacuated quartz tubes at temperatures between 400 and 800°C. On the basis of comparable uranium compounds, such as U_3O_8, the authors have assumed that uranium is present in both oxidation states 6+ and 5+. Structure data of the intermediate halides are given in Table 5.28.

(d) Hexavalent halides and complex halides

Uranium hexahalides and complex halides have been the most extensively investigated uranium compounds due to their commercial applications. The stability of the halides decreases with increasing atomic number of the halide anion, e.g. UCl_6 is much more prone to thermal decomposition than UF_6, and no simple halides are formed with iodine or bromine in this oxidation state. The hexahalides react violently with water at room temperatures to form soluble uranyl halides; they are also readily soluble in polar organic solvents, in many cases with formation of complexes. The uranyl ion (UO_2^{2+}) forms weak complexes with halide ions, with the exception of fluoride cf. Table 5.34, p.349. Hexavalent halides and complex halides are typically yellow and in a few cases colorless (e.g. UF_6) or green (e.g. UCl_6) (see Table 5.30).

Hexavalent uranium has the $[Rn]5f^0$ electronic configuration. The ground state is formally $^1S_0$. There are numerous reports on absorption and fluorescence spectra of hexavalent halides and uranyl halogeno complexes in the solid state, aqueous solutions, and organic solvents that are discussed in a review article by Carnall (1982). The spectra of UO_2^{2+} compounds exhibit a characteristic vibrational fine structure in the visible–ultraviolet region due to coupling with the stretch modes in the linear UO_2 unit. The absorption spectrum of UF_6 displays a similar complex vibronic structure, which is observed to be superimposed on broad and intense charge transfer bands centered near 26670 and 38460 cm^{-1}. An analysis of the spectrum (Lewis *et al.*, 1976) has

Table 5.30 *Properties of selected uranium(VI) halides and complex halides.*[a]

shown the existence of several progressions in the symmetric stretching frequency (ν_1) coupled with other modes. Two non-phonon transitions, originating at 24564 and 25265 cm^{-1}, are associated with the first band and four other with origins at 30331, 31032 (observed directly), 32120, and 32821 cm^{-1} with the second one; they could be located in the low-temperature spectra of the compound. The observed fine structure has been explained in terms of electric–dipole forbidden transitions from the t_{1u} $(\pi+\sigma)$ orbitals of the fluorine atoms to the empty 5f orbitals of the uranium atoms. A strong absorption band without vibronic structure, observed at about 46730 cm^{-1}, has been assigned as a charge transfer transition.

Since the ground state of UO_2^{2+} does not contain unpaired electrons the uranyl compounds are either diamagnetic or weakly paramagnetic. The octahedral hexahalides exhibit a weak, almost temperature-independent, paramagnetism.

(*i*) *Uranium hexafluoride and uranium*(VI) *complex fluorides*

Uranium hexafluoride

Uranium hexafluoride is the only uranium compound that is readily volatilized and is therefore used for uranium isotope separation by gas diffusion, gas centrifugation, liquid thermal diffusion, or in mixtures with a light auxiliary gas like H_2 or He (separation nozzle). The uranium enrichment technologies have been surveyed by Becker (1979) and Ehrfeld and Ehrfeld (1980), for example. Due to the importance of UF_6, the physical and chemical properties of UF_6, including commercial syntheses, have been extensively studied. The literature is covered in a number of reviews (Caillat, 1961; Brown, 1968; Bacher and Jacob, 1980, 1982, 1986; Hellberg and Schneider, 1981; Freestone and Holloway, 1991). A scheme of reactions leading to UF_6 is shown in Fig. 5.45.

Some important preparative procedures are based on the following reagents (Bacher and Jacob, 1980; Freestone and Holloway, 1991):

(1) reaction of elemental fluorine with U, UF_4 (at 340°C), U_4F_{17}, U_2F_9 (at 300°C), UF_5 (at 270°C), $NaUF_5$ (at 340°C), UO_2 (at 500°C), UO_3 (at 400°C), U_3O_8 (at 360°C), UO_2F_2 (at 340°C), $Na_2U_2O_7$, CaU_2O_7, UCl_5 (at –20 to 30°C), UO_2HPO_4 (at 370°C), UC_2 (at 350°C); e.g.

$$U_3O_8 + 17F_2 \xrightarrow{360^\circ C} 3UF_6 + 8F_2O$$
$$CaU_2O_7 + 7F_2 \rightarrow 2UF_6 + CaF_2 + 7/2O_2$$

(2) reaction of bromine trifluoride with U (at 50–125°C), U_2F_9 (at 170°C, leading to UF_4), UO_2, UO_3, U_3O_8, UO_2F_2; e.g.

$$U_3O_8 + 6BrF_3 \rightarrow 3UF_6 + 3Br_2 + 4O_2$$

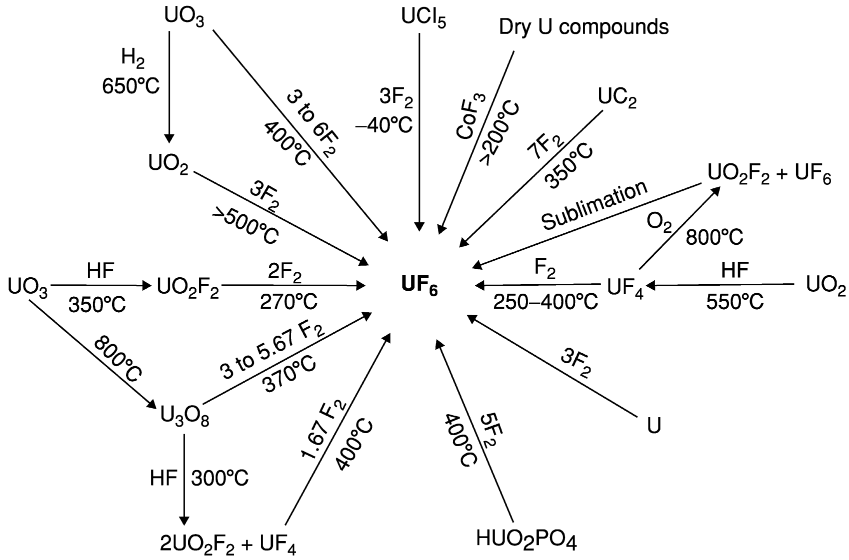

Fig. 5.45 *Reactions leading to UF_6 (adapted from Katz and Rabinowitch,* 1951).

(3) reaction of hydrogen fluoride with UO_2 (at 550°C), $Na_2U_2O_7$, UCl_5; e.g.

$$UCl_5 + 5HF \rightarrow UF_5 + 5HCl$$

followed by reactions (6b) and (6c) below;

(4) reaction with low temperature fluorinating agents: O_2F_2 with U_3O_8; KrF_2 with UF_4, and UO_2 and U_3O_8 in the gaseous phase or at room temperatures in HF solutions;

(5) reaction with other reagents:

(a) $O_2 + 2UF_4$ (at 660–800°C) $\rightarrow UF_6 + UO_2F_2$
(b) $3BrF_5 + U$ (at 50–125°C) $\rightarrow UF_6 + 3BrF_3$
(c) $3ClF_3 + U$ (at 25–75°C) $\rightarrow UF_6 + 3ClF$
(d) $2CoF_3 + UF_4$ (at 250°C) $\rightarrow UF_6 + 2CoF_2$

(6) decomposition reactions with disproportionation:

(a) $2U_4F_{17}$ (at 270–350°C) $\rightarrow 7UF_4 + UF_6$
(b) $3UF_5$ (at 170°C) $\rightarrow U_2F_9 + UF_6$
(c) $2U_2F_9$ (at >500°C) $\rightarrow 3UF_4 + UF_6$
(d) $9UO_2F_2$ (at >700°C) $\rightarrow 3UF_6 + 2U_3O_8 + O_2$.

As indicated above, the fluoride obtained by means of the reaction given in (3) can be converted to UF_6, using double decomposition with subsequent disproportionation (reactions 6b and 6c). The separation from UF_4 and an excess of HF can be achieved by heating, followed by fractional distillation. The method based on reaction (5a) is also a convenient route, not involving the use of gaseous fluorine; UO_2F_2 is formed as a by-product, but can be converted to UF_4 by reduction and to UF_6 by hydrofluorination. An attractive method on laboratory scale uses reactions (5d) (Weigel, 1958). The by-product CoF_2 can easily be separated from UF_6 and regenerated with fluorine. The general route for purification of UF_6 employs trap-to-trap distillation followed by condensing the hexafluoride at about –80°C.

The production of UF_6 on an industrial scale is achieved mainly by oxidative fluorination of uranium oxides or lower fluorides by fluorine at elevated temperatures. A uranium ore concentrate is first purified by solvent extraction or by ion exchange methods. From this concentrate, $(NH_4)_2U_2O_7$ (ammonium diuranate, ADU, yellow cake) or $UO_2(NO_3)_2 \cdot 6H_2O$ (UNH) is then precipitated. ADU is converted to UO_2 by calcination in the presence of H_2 whereas UNH is first pyrolyzed to UO_3 and then reduced by H_2 to UO_2.

A detailed description of the commonly applied direct fluorination technology of UF_4

$$UF_4(s) + F_2(g) \rightarrow UF_6(g)$$

has been published by Smiley and Brater (1956) and Brater and Smiley (1958). In the conversion flow sheet shown in Fig. 5.46, the fluorination reactor used is either a flame reactor or a fluidized-bed reactor (Harrington and Ruehle, 1959). In the first one UF_4 is fed to the top of the reactor having a length of 3.60 m, diameter of 20 cm, and a capacity of 380 kg per hour. The highly exothermic fluorination reaction takes place over a length of $\sim$1 m at the top of the reactor where a flame with temperatures up to 1100°C is formed. In order to suppress corrosion, the temperature of the reactor walls is maintained below 540°C. For a maximum yield of UF_6 a temperature limit of 450°C, which eliminates the formation of intermediate fluorides, is required. The off-gases contain $\sim$75% UF_6 and have their outlet at the lower part of the reactor. All unreacted solids are collected, powdered, mixed with fresh UF_4 and transmitted again to the feed.

In the second method, UF_4 is fluorinated with F_2 at 500°C in a Monel fluidized-bed reactor with an annual production capacity of 4400 to 7400 tons of UF_6. The UF_4 feed material and fluorine gas are mixed continuously by means of a conveyor screw and a gas distributor (6–20 $cm^3\ s^{-1}$), respectively. For stabilization of the fluidized bed CaF_2 is added to the feed. It serves also to prevent sintering of UF_4 and as a heat transfer material. The product obtained in both types of reactors is passed through Monel filters in order to remove UF_4 dust and is then condensed, first at +4 to –15°C and finally at –40°C. The condensers are then heated to 80°C and UF_6, which liquefies at that temperature under its own pressure, is drained into transport cylinders, which have a volume of up to about 4 m^3, weigh around 2.36 tons, and have a capacity

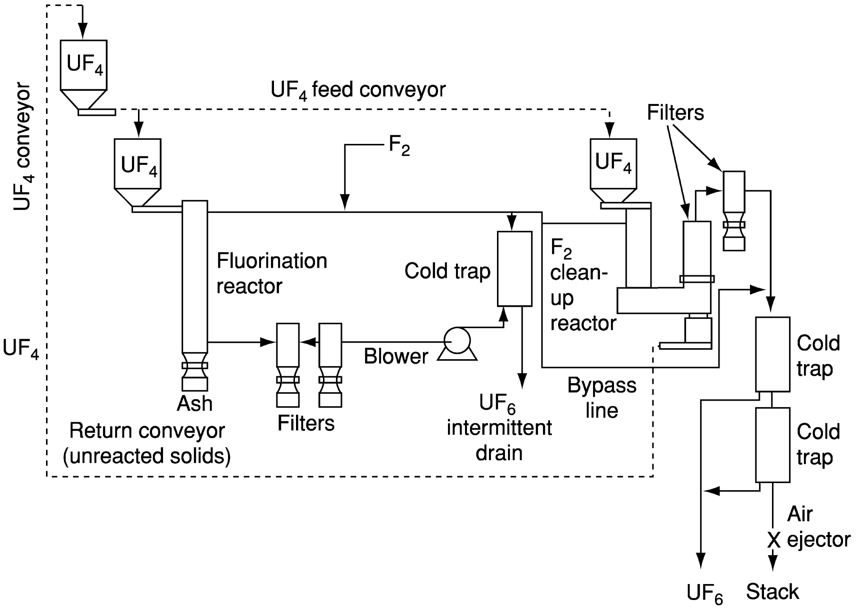

Fig. 5.46. *Schematic flow diagram for uranium hexafluoride production* (*Harrington and Ruehle*, 1959).

of 12.5–14 tons (Keller, 1956). The crude product usually contains numerous volatile impurities such as SiF_6, CF_4, SF_4, MoF_6, CrO_2F_2, or VF_5 as well as some less volatile compounds like MoF_4, VOF_3, and other transition metal fluorides. Since stringent purity specifications are required of commercial UF_6 for isotope separations, the impurities are removed by fractionation at temperatures and pressures above the triple point and by absorption–desorption techniques. At room temperature, UF_6 has a pressure of ca. 120 mmHg; it is thus possible to handle it as a gas in the separation of ^{235}U from natural uranium. For large-scale applications, solid UF_6 is delivered to isotope separation plants in containers, which are then placed into a steam-heated autoclave in which UF_6 builds up a high enough pressure to flow as a gas into the attached diffusion cascade for the separation process (Arendt *et al.*, 1957).

Uranium hexafluoride forms low-melting orthorhombic (space group *Pnma*) colorless crystals which sublime at 56.5°C at atmospheric pressure. The compound has a triple point at 64.02°C and a pressure of 1137 mmHg (Hoard and Stroupe, 1959; Rigny, 1965, 1966; Levy *et al.*, 1976). The structure of solid UF_6 was first determined by Hoard and Stroupe (1959) and later in a number of X-ray and neutron diffraction studies (Levy *et al.*, 1976; Jacob and Bacher, 1980). It consists of hexagonal close-packed fluorine ions with uranium atoms in octahedral holes. The crystallographic data of UF_6 are listed in Table 5.30 together with selected physical data.

The structure of UF_6 in the liquid and gaseous states is perfectly octahedral (point group O_h) with U–F bond lengths in solid UF_6 equal to 1.996 Å. The compound has a temperature-independent paramagnetism with a molar susceptibility of $\chi_{\text{mole}} = 43 \times 10^{-6}\ \text{cm}^3\ \text{mol}^{-1}$, after correction for a diamagnetic contribution of $\chi_{\text{mole}} = 106 \times 10^{-6}\ \text{cm}^3\ \text{mol}^{-1}$. Carnall (1982) has published extensive analyses of the absorption and fluorescence spectra of UF_6. The absorption spectrum of UF_6 in visible to the near-UV range is similar to that of the UO_2^{2+} ion; in the range 200–420 nm there is only one broad band at 375 nm.

The compound is highly reactive and extremely moisture-sensitive. It reacts with most elements but is relatively stable towards oxygen, chlorine, bromine, carbon dioxide, and noble gases even at elevated temperatures. UF_6 has a significant solubility in liquid chlorine and bromine. Thermodynamic calculations have shown that UF_6 is thermally stable below 1000 K; dissociation starts between 1100 and 1450 K. Since UF_6 is rapidly hydrolyzed by water with the formation of HF it is recommended to store the compound in teflon, Kel-F, nickel, or Monel containers.

$$\mathrm{UF_6 + 2\,H_2O \rightarrow UO_2F_2 + 4HF}$$

It can be also stored in quartz or Pyrex tubes by using NaF and KF as HF 'getters'.

Uranium hexafluoride is a powerful fluorinating agent with a vapor pressure of 115 mm at 25°C. Bacher and Jacob (1982) have classified, as discussed below, a number of reactions of UF_6.

Oxidative fluorination results in a simultaneous formation of lower uranium fluorides. UF_6 oxidizes elements or their fluorides in low oxidation states to yields fluorides in higher oxidation state, e.g. with alkali, alkaline earth metals, B, Al, Ga, In, C, Si, Ge, Sn, Pb, As, Sb, S, Se, and Te binary fluorides are formed; lower fluorides such as PF_3, SF_4, MoF_5, or WF_4 are oxidized to higher fluorides:

$$n\mathrm{UF_6 + M(s) \rightarrow} n\mathrm{UF_5(s) + MF}_n$$

Lower oxides are converted to oxyfluorides whereas chlorides and bromides yield fluorides in presence of an excess of UF_6 with formation of Cl_2 and Br_2, respectively:

$$n\mathrm{UF_6 + 2MX}_n \rightarrow n\mathrm{UF_4 + 2MF}_n + n\mathrm{X_2} \quad (\mathrm{X = Cl\,or\,Br})$$

The high fluorination efficiency of UF_6 is also demonstrated by interactions with SO_3 that leads to the formation of the peroxide $S_2O_6F_2$ (Wilson *et al.*, 1977; Masson *et al.*, 1978). The effective first bond dissociation energy of UF_6, according to the the reaction scheme

$$\mathrm{UF_6 \rightarrow (UF_5)_{solid} + F}$$

is equal to (134.0 ± 29.3) kJ mol^{-1}, and is of the same order of magnitude as the bond energy of elemental F_2 (153.2 kJ mol^{-1}, Jacob and Bacher, 1986).

Reaction of UF_6 with other highly electronegative groups may lead to a total or partial substitution of the fluorine atoms with retained oxidation state of uranium as in the vapor phase hydrolysis:

$$UF_6 + 3H_2O \rightarrow UO_2F_2 \cdot H_2O + 4HF$$

and the hydrolysis in liquid HF:

$$UF_6 + nH_2O \rightarrow UO_nF_{(6-2n)} + 2nHF \quad (\text{where } n = 1 \text{ or } 2)$$

or in exchange reactions where fluorine is replaced by groups such as Cl, OCH_3, and $OTeF_5$:

$UF_6 + 6BCl_3 \rightarrow UCl_6 + 6BCl_2F$ (with excess of BCl_3) (O'Donnell *et al.*, 1966)
$UF_6 + 6Si(OCH_3)_4 \rightarrow U(OCH_3)_6 + 6SiF(OCH_3)_3$ (with excess of $Si(OCH_3)_4$) (Jacob, 1982).

UF_6 is a strong Lewis acid that can bind fluoride from Lewis bases such as MF (where M = Na, K, Cs, Rb, NH_4, N_2H_5, NO, and NO_2) under the formation of the corresponding heptafluorouranates(VI), MUF_7 and octafluorouranates(VI), M_2UF_8. UF_6 can oxidize various metals, as well as NO, NO_2, and I_2 in other less common reactions. These reactions are due to the high electron affinity of UF_6 (5.2 eV) and to a favorable lattice energy when fluorouranates(V) are formed, e.g.:

$$NO \rightarrow NO^+ + e \quad +9.2\text{ eV}$$

$$UF_6 + e \rightarrow UF_6^- \quad -5.2\text{ eV}$$

$$NO^+ + UF_6^- \rightarrow NOUF_6 \quad -\text{lattice energy}$$

The hexafluoride is reduced to the tetravalent state by a number of reagents, e.g. HCl (250°C), PF_3, HBr (80°C), CCl_4, CS_2, H_2S, amorphous carbon as well as $SiCl_4$, $AsCl_3$, $SbCl_3$, PBr_5, and BBr_3, with the formation of the appropriate free halogen. Reduction with H_2 is slow and may be carried out at 650°C, or in pressurized systems at 300°C. Exposure of UF_6 to UV light or photocatalytic reduction with HBr, SO_2, or CO yield β-UF_5:

$$2UF_6 \xrightarrow{h\nu} (UF_5)_{\text{solid}} + 1/2F_2$$

$$2UF_6 + X \xrightarrow{h\nu} 2\beta\text{-}(UF_5)_{\text{solid}} + XF_2 \quad (X = H_2, CO, \text{ or } SO_2).$$

Alpha radiation from hexafluoride enriched with ^{235}U or ^{234}U results in significant reduction to lower fluorides.

A number of binary phase diagrams of uranium hexafluoride with fluorine and elements of the 7th main group have been reported (Bacher and Jacob, 1980). Simple eutectic types were observed in the UF_6–BrF_3, UF_6–BrF_5, and UF_6–BrF_2 systems. Some deviation from ideality was found for the UF_6–BrF_3, UF_6–BrF_5, UF_6–ClF_3, and UF_6–BrF_3 systems. In all of these systems, the solid phases are pure stoichiometric compounds. The UF_6–HF phase diagram investigated by Rutledge *et al.* (1953) has practical importance due to the common presence of HF in UF_6. In the phase diagram shown in Fig. 5.47 there is a complete miscibility above 100°C and above a pressure of 10 atm.

The system possesses an eutectic point at –85°C with less than 0.5 mol% of UF_6. The separation of HF from UF_6–HF solutions by distillation is limited due to the appearance of azeotropes.

Complex uranium(vi) *fluorides*

Bacher and Jacob (1980) and Freestone and Holloway (1991) have compiled data on the synthesis and characterisation of numerous fluorouranate(vi) compounds listed below in Table 5.31; some of their physical data are presented in Table 5.30.

NaF has found practical application in nuclear processing. It absorbs UF_6 quickly and has the largest absorption capacity of all alkali metal fluorides. The sodium fluorouranates(vi) formed in the process can easily be thermally dissociated to UF_6 (Bacher and Jacob, 1986).

Several methods have been applied for the preparation of the fluoro complexes (Bacher and Jacob, 1980; Freestone and Holloway, 1991), e.g.: (i) most of

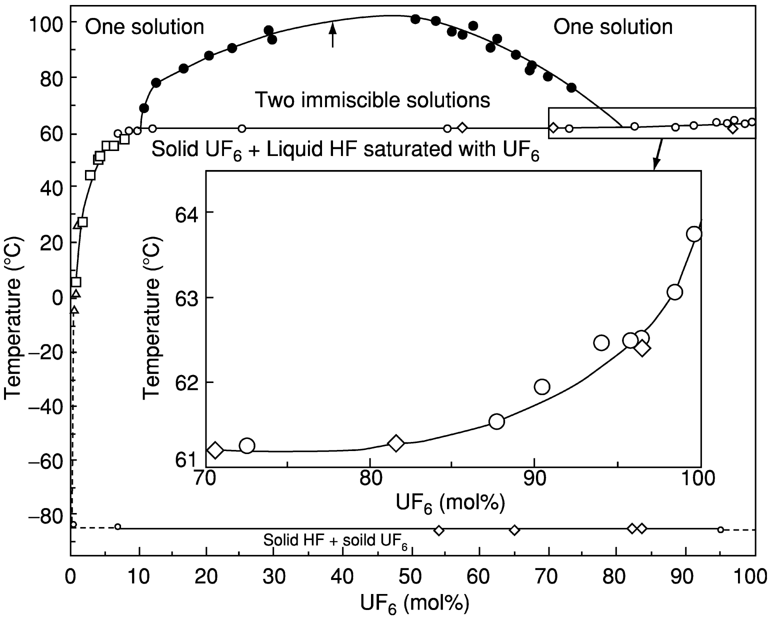

Fig. 5.47 *Phase diagram of the binary system UF_6-HF* (*Rutledge* et al., 1953). •, *Visual observation of disappearance of two liquid layers;* □, *visual observation of precipitation of solid UF_6;* Δ, *filter cell;* ○, *freezing point cell–K2 potentiometer;* ◇, *freezing point cell–white potentiometer. Table 5.31 *Identified uranium*(VI) *complex fluorides.*

System	*Complex fluorides*
$NaF–UF_6$	$NaUF_7$, Na_2UF_8, Na_3UF_9, $Na_3U_2F_{15}$
$KF–UF_6$	KUF_7, K_2UF_8, K_3UF_9, $K_3U_2F_{15}$
$RbF–UF_6$	$RbUF_7$, Rb_2UF_8, Rb_3UF_9
$CsF–UF_6$	$CsUF_7$, Cs_2UF_8, Cs_3UF_9
$NH_4F–UF_6$	NH_4UF_7, $(NH_4)_2UF_8$
$N_2H_5F–UF_6$	$N_2H_5UF_7$, $N_2H_6(UF_6)_2$
$NO_xF–UF_6$	$NOUF_7$, NO_2UF_7, $(NO)_2UF_8$

the compounds can be obtained by the reaction of gaseous UF_6 with solid MF (where M = Na, K, Rb, Cs, or NH_4). In some cases, the reactions are carried out at higher temperatures and pressures. The products may be however contaminated by unreacted solid fluorides; (ii) the interaction of a large excess of liquid UF_6 with solid MF yields MUF_7 (M = K, Rb, or Cs); (iii) complex fluorides of the formula MUF_7 or M_2UF_8 are formed by interaction of UF_6 with NaF, KF, RbF, CsF, AgF, or TlF_3 by using appropriate solutions or suspensions in perfluoroheptane, C_7F_{16}, C_8F_{16}, ClF_3, or anhydrous HF; (iv) fluorination of a M_2UF_6 (M = Rb or Cs) or a NaF–UF_4 mixture with F_2 results in the formation of M_2UF_8 and $NaUF_7$, respectively; (v) the M_2UF_8 octafluoro uranate(VI) may also be prepared by thermal decomposition of the corresponding sodium (at 60–145°C), potassium (at 130°C), rubidium (at 150°C), and cesium (180–200°C) heptafluoro uranates; (vi) the reaction between UF_6 and liquid or gaseous ammonia yields NH_4UF_5 and NH_4UF_6, respectively. In the latter case also, a mixture of NH_4UF_5 and UF_5 may be obtained; (vii) the condensing of UF_6 in a suspension of NH_4F in tetrachloroethane yields NH_4UF_7; (viii) the corresponding hydrazinium $N_2H_5UF_7$, nitrosonium $NOUF_7$, and nitronium NO_2UF_7 salts are prepared by direct reaction of the component fluorides, the former in anhydrous hydrofluoric acid.

The fluoro uranates(VI) are extremely moisture-sensitive solids, very susceptible to hydrolysis. With some exception (e.g. NH_4UF_7, which decomposes to UF_5 or UF_4, depending of the applied temperature) they decompose to UF_6 when heated. The UF_6–bromine fluorides and the UF_6–HF systems (HF removal) have also found application in the fluorination reactions in nuclear reprocessing.

(*ii*) *Uranium*(VI) *oxide fluorides and complex oxide fluorides*

Uranium(VI) *oxide tetrafluoride, UOF_4*

UOF_4 can most conveniently be prepared either by the interaction of an excess of UF_6 with quartz wool in liquid HF

$$3UF_6 + SiO_2 \overset{\text{HF (liquid)}}{\rightarrow} 3UOF_4 + SiF_4$$

or by reaction with an excess of B_2O_3

$$3UF_6 + B_2O_3 \rightarrow 3UOF_4 + 2BF_3$$

Uranium oxide tetrafluoride is an orange solid with a shade of red. It is nonvolatile and decomposes at 200–250°C without melting. At 250°C in vacuum UOF_4 decomposes spontaneously in an exothermic reaction to UF_6 and UO_2F_2. The reaction proceeds quantitatively and may be used for purity checking. UOF_4-hydrate is formed after some time in moist air, but liquid water results in a rapid hydrolysis. UOF_4 reacts with KF and NH_4F in liquid HF to form $MUOF_5$ type of salts. Fluorination of UOF_4 by ClF_5, ClF_3, or $ClOF_3$ at room temperature yields UF_6:

$$ClF_5 + 2UOF_4 \rightarrow ClO_2F + 2UF_6$$

UOF_4(cr) has trigonal symmetry in the space group $R3m$ and a pentagonal bipyramidal coordination geometry formed by the O and F atoms. Some physical data are given in Table 5.30.

Uranium(VI) oxide difluoride (uranyl fluoride), UO_2F_2

One of the simplest methods to prepare UO_2F_2 is by heating of UO_3 in gaseous HF at 300–500°C. Other satisfactory routes employ fluorination of uranium oxides at 350°C and oxidation of UF_4 with O_2 at 600–800°C. The compound is a pale yellow solid with a green hue, slightly soluble in water, methanol, and ethanol. Recrystallization from water results in the formation of $UO_2F_2 \cdot 2H_2O$. Controlled action of H_2O in a closed vessel yields hydrates $UO_2F_2 \cdot nH_2O$ ($n = 1$ to 4). The reaction of an excess of UF_6 with water vapour at 60°C leads to the formation of $UO_2F_2 \cdot 1.53H_2O$. Adducts of the $UO_2F_2 \cdot L(H_2O)$ and $UO_2F_2 \cdot nL$ ($n = 1$ to 4) type are formed by interactions with oxygen or nitrogen donor ligands (L) such as NH_3, pyridine (py), tributylphosphine oxide (tbpo), dimethylsulfoxide (dmso), antipyrine (antypy), 2,2′-dipyridyl (dipy), dimethylformamide (dmf), acetamide (aa), dimethylacetamide (dma), urea (ur), dimethylurea (dmur), and tetramethylurea (tmur) (Shchelokov *et al.*, 1977; Bagnall, 1979, 1987; Mass, 1979). IR and Raman data are available for most of the compounds. The nature of the uranium–oxygen bonds in UO_2^{2+} depends on the electron donor properties of the ligands, which result in variations of the UO_2^{2+} ν_1 and ν_2 frequencies that provide valuable structural information. The k_{UO} force constants, determined from both of these frequencies, decrease in the series (Shchelokov *et al.*, 1977) $H_2O >$ aa $>$ dma $>$ dmur $>$ dmso $>$ dmf $>$ tmur$\sim$antipy $>$ ur.

The total energy, molar entropy, heat capacity, and vibration frequencies of the compound in the gas phase have been calculated by *ab initio* methods to obtain thermodynamic data for reactions. They agree well with experimental values and previous results (Privalov *et al.*, 2002).

UOF_2 is converted to UF_6 by gaseous fluorides such as XeF_6 (25°C), BrF_3 (25°C), ClF_3 (50–160°C), ClF (64–150°C), ClO_2F (100–150°C), ClF_5 (>120°C)

F_2 (>300°C), BrF_5 (250°C), SF_4 (>300°C), and VF_5 (100°C). The reactions proceed with much greater difficulty than oxidative fluorination of UF_4 or UF_5 (Bacher and Jacob, 1980). The compound crystallizes with a rhombohedric structure in the space group $R\overline{3}m$. Selected crystallographic data are given in Table 5.30. Besides, Otey and LeDoux (1967) have identified an oxide fluoride of the composition $U_3O_5F_8$ and suggested the existence of an intermediate, $U_2O_3F_6$ compound.

Hexavalent oxide fluoride complexes

There is a large variability in the stoichiometry of the very large number of reported hexavalent oxide fluorides: M^IUOF_5, $M^I(UO_2)_2F_5$, $M^IUO_2F_3$, $M^I_2UO_2F_4$, $M^I_3UO_2F_5$, $M^I_3(UO_2)F_3$, $M^I_3(UO_2)_2F_7$, $M^I_4(UO_2)_2F_8$, $M^I_5(UO_2)F_9$ (where M^I is usually an alkali metal ion), $M^{II}(UO_2)F_4$ (where M^{II} = Ca, Pb, Cu, Zn, or Cd) and $M^{II}(UO_2)_2F_6$ (where M^{II} = Sr, Ba, or Mg) (Freestone and Holloway, 1991). Many of the compounds were identified from phase diagram investigations. The complexes of the M^IUOF_5-type (M = K, Rb, Cs, NH_4) have been prepared by interaction of UOF_4 with the appropriate MF fluoride in liquid sulfur dioxide or anhydrous HF (Joubert and Bougon, 1975; Joubert *et al.*, 1978a,b). Hydrated complexes of the $M^{II}(UO_2)F_4 \cdot 4H_2O$ (M^{II} = Zn, Cd, Cu, Mn, Co, or Ni) were obtained by crystallization from aqueous solutions. A number of fluoro-oxalato compounds of the $[UO_2F(C_2O_4)_2(H_2O)]^{3-}$ and $[UO_2F_3(C_2O_4)(H_2O)]^{3-}$ types with alkali metals, ammonium, and guanidinium have been reported by Chernyayev (1966) and Shchelokov and Belomestnykh (1968a,b). Fluoro-oxalato compounds of the types $M_2[UO_2F_2(C_2O_4)]$, $M_4[UO_2F_2(C_2O_4)_2]$, and $M_2[(UO_2)_2F_4(C_2O_4)]$ (where M = Rb or K) are obtained by mixing of saturated solutions of $H[UO_2F_3] \cdot H_2O$ with alkali metal oxalates in different mole ratios (Chakravorti *et al.*, 1978). Some crystallographic data and IR spectral bands are collected in Table 5.30.

Numerous hydrated and anhydrous uranyl fluoro compounds have been obtained from aqueous solutions by varying the preparation conditions with a given alkali metal or organic base cation (Brown, 1968; Bacher and Jacob, 1980), e.g. $CsUO_2F_3$, $CsUO_2F_3 \cdot H_2O$, $NaUO_2F_3 \cdot xH_2O$ (x = 2 and 4), $CsUO_2F_4 \cdot H_2O$, $M_3UO_2F_5$ (M = Na, K, Rb, Cs, NH_4), $M_4(UO)_2F_5 \cdot 2H_2O$ (M = K, R, Cs), $M^I(UO_2)_2F_5 \cdot xH_2O$, $M^IUO_2F_3 \cdot xH_2O$ and $M^I(UO_2)_3F_7 \cdot xH_2O$ (where M^I is an organic base and x varies from 0 to 6). The MF/UO_2F_2 ratio in aqueous solutions has a significant influence on the stoichiometry of the complexes obtained. With a large excess of MF one usually obtains the $M_3UO_2F_5$ type of complexes. When the ratio is less than 3 one obtains di- or polynuclear complexes. The compounds obtained using the preparative methods described above can be rationalized from information on the equilibrium constants of the complexes present (cf. Section 5.9).

In $CsUOF_5$, the fluorine and oxygen atoms form a pseudo-octahedral surrounding of the uranium atom. In the other $MUOF_5$ (M = NH_4, K or Rb) oxide fluorides, uranium is eight coordinated with dodecahedral coordination geometry. The structure consists of chains formed by surface sharing of individual dodecahedra through bridging fluoride ligands. (Joubert *et al.*, 1978a,b). Some structural details are also available for other hexavalent oxide fluoride complexes (see Table 5.30).

(*iii*) *Uranium hexachloride*

Uranium hexachloride may be obtained by thermal decomposition of UCl_5 at 120–150°C *in vacuo*. The green UCl_6 crystals are collected on a cold finger and purified from contaminating UCl_5 by sublimation in vacuum at 75–100°C or distillation in a stream of an inert gas at a low pressure. On laboratory scale it is best prepared by condensing an excess of BCl_3 onto UF_6 at –196°C and allowing the vessel with the compounds to warm up slowly. It is not necessary to purify the product by sublimation since the by-products are volatile at room temperatures (Brown, 1979).

UCl_6 is an extremely moisture-sensitive, black to dark green crystalline solid. The compound is reported to melt at (177.5 ± 2.5)°C, but it readily liberates chlorine at temperatures higher than $\approx$120°C. It reacts violently with water to form uranyl(VI) solutions. Hydrogen reduces UCl_6 to UCl_4 at 250°C. Reaction of UCl_6 with anhydrous liquid hydrogen fluoride or UF_6 converts it to UF_4 and UF_5, respectively. The hexachloride is slightly soluble in carbon tetrachloride, liquid chlorine, methyl chloride, isobutyl bromide, and thionyl chloride. On prolonged storage in carbon tetrachloride, it decomposes forming crystalline red-brown, volatile U_2Cl_{10}. The decomposition reaction proceeds much faster in 1,2-dichloroethane and methylene dichloride. The reduction in the last solvent appears to be photochemically mediated. Interaction with chlorides such as NH_4Cl, $(C_6H_5)_4AsCl$, and $(CH_3)_4NCl$ yields the appropriate $MUCl_6$ hexachloorouranate(V) compounds.

UCl_6 has hexagonal symmetry, space group D^3_{3d}; $P\bar{3}m1$ (Zachariasen, 1948f). The structure has been refined with neutron and X-ray powder diffraction data by Taylor and Wilson (1974b) and can be described as a hexagonal close packing of chlorine atoms with uranium atoms in one-sixth of the octahedral holes. The chlorine atoms form an almost regular octahedron around the U(1) located at 0,0,0 while the geometry around U(2) at 1/3, 2/3, 0.518 is slightly distorted (Fig. 5.48).

The absorption spectra for UCl_6 in the solid state, vapor phase, and solutions in perfluoroheptane in the UV–Vis range have been reported and analyzed (Brown, 1979). Charge transfer bands were observed at 17000 and 20800 cm^{-1} for solid UCl_6 and at 21000 and 20800 cm^{-1} in the vapor phase. Some X-ray and physical data of the compound are summarized in Table 5.30.

(*iv*) *Uranium*(*VI*) *dioxide dichloride, UO_2Cl_2, and related compounds*

Uranium(*VI*) *dioxide dichloride* (*uranyl chloride*)

Since the literature on uranium(VI) dioxide dichloride is very extensive (Brown, 1979), the results of investigations presented in this section must necessarily be incomplete. The most attractive methods for the preparation of UO_2Cl_2 involve

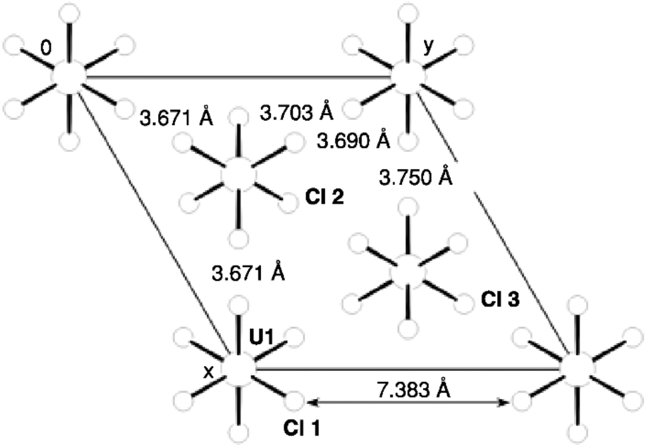

Fig. 5.48 *View of the crystal packing of* UCl_6 (*distances are taken from Taylor and Wilson*, 1974*b*).

the oxidation of UCl_4 at temperatures between 300 to about 350°C or the dehydration of $UO_2Cl_2 \cdot H_2O$. The last method may readily be performed by heating in a stream of gaseous HCl or HCl + Cl_2 mixtures at 400–450°C. UO_2Cl_2 may be also obtained by electrochemical oxidation of uranium in an acetonitrile solution of Cl_2 in the presence of oxygen. This solution of UO_2Cl_2 may be used for the preparation of numerous adducts, e.g. $(Et_4N)_2UO_2Cl_4$ (Kumar and Tuck, 1984).

The anhydrous compound is a yellow, hygroscopic solid, readily soluble in a number of organic solvents, in many cases with complex formation. It is not soluble in non-polar organic solvents. Thermal decomposition in air leads to formation of a mixture of α-UO_3 and $UO_{2.9}$ at 460°C and to U_3O_8 at higher temperature. The compound decomposes to UO_2 and Cl_2 on heating in a nitrogen atmosphere. Vacuum thermal decomposition results first in the formation of an intermediate state $(UO_2)_2Cl_3$ and next, at 450°C, of a mixture of UO_3 and U_3O_8. UO_2Cl_2 may be converted to $UOCl_3$ by reaction with UCl_4 *in vacuo* at 370°C.

The reaction of UO_2Cl_2 solutions with a variety of ligands in both aqueous and non-aqueous media results in the formation of a large number of stable compounds of different UO_2Cl_2:ligand stoichiometry, e.g.:

- (1:1): with methyl cyanide, methylmalonamide, benzophenone; acetyl chloride, 1,10-phenantroline and *N*,*N*,*N*′,*N*′- teramethyl-α,α-dimethylmalonamide;
- (1:1,5): with *N*,*N*,*N*′,*N*′-tetramethylmalonamide, *N*,*N*,*N*′,*N*′-tetramethylglutaramide;
- (1:2): aniline, pyridine, ethanol, acetic anhydride, diethyl ether, acet-*p*-phenetidine, 1,10-phenantroline, dimethylurea, tetramethylurea,

trialkyl-phosphine, triaryl-phosphine, 2,2′-bipyridine, and 4-methoxoy-pyridine-*N*-oxide;
- (1:3): with 4-methylpyridine-*N*-oxide, *N*,*N*-dimethylformamide, ethylurea, diethylurea;
- (1:4): hydrazine, urea, 1,3-dimethylurea and 4-chloropyridine-*N*-oxide etc.

A number of uranyl chloro-complexes have been identified during investigations of the MCl–UO_2Cl_2, $CuCl_2$–UO_2Cl_2, and NaCl–KCl–UO_2Cl_2 phase diagrams (where M = Li, Na, K, Rb, or Cs) (Brown, 1979).

UO_2Cl_2 has orthorhombic symmetry, space group *Pnma* (see Table 5.30). Uranium has pentagonal bipyramidal coordination geometry with two uranyl oxygen atoms at the apices; there are four chlorine atoms and one oxygen atom in the equatorial plane, the latter an "yl" oxygen atom from neighbouring uranium. The pentagons form chains parallel to the *b* axis by sharing Cl–Cl edges (Taylor and Wilson, 1973b). Electronic absorption spectra in the solid state and solutions in non-aqueous media and luminescence spectra have been discussed in numerous papers (Brown, 1979; Wells, 1990). Some physical data are listed in Table 5.30.

Uranyl(VI) chloride hydrates and hydroxide chlorides

The following compounds have been identified $UO_2Cl_2 \cdot 3H_2O$, $UO_2Cl_2 \cdot H_2O$, $[(UO_2)_2(OH)_2Cl_2(H_2O)_4]$, $[(UO_2)_4O_2(OH)_2Cl_2(H_2O)_6]$, and $4UO_3 \cdot HCl \cdot 8H_2O$ (Brown, 1979). The tri- and monohydrate are most conveniently prepared by slow evaporation from concentrated uranyl(VI) hydrochloric acid solutions over KOH and P_2O_5, or from an aqueous solution in dry air at room temperature; they form yellow hygroscopic powders. The hydrates are readily soluble in water and in various organic solvents such as ether, acetone, ethyl acetate, and a number of alcohols. The trihydrate may be dehydrated to $UO_2Cl_2 \cdot H_2O$ and then readily converted to the anhydrous salt by heating in a stream of dry hydrogen chloride or a HCl + Cl_2 mixture. When heated in an inert atmosphere, it is converted at about 220°C to impure UO_2Cl_2 and at temperatures above 400°C to U_3O_8 (Brown, 1979). $UO_2Cl_2 \cdot H_2O$ reacts with $P(C_6H_5)_4Cl$ by refluxing in a thionyl chloride solution to give $[P(C_6H_5)_4]UOCl_5$ on cooling. With smaller cations reductive chlorination to hexachlorouranates(V) occurs.

$UO_2Cl_2 \cdot H_2O$ and $UO_2Cl_2 \cdot 3H_2O$ have monoclinic ($P2_1/m$) and orthorhombic ($Pn2_1a$) symmetry, respectively. Neutron diffraction studies of $UO_2Cl_2 \cdot H_2O$ (Taylor and Wilson, 1974c) show that uranium has the common pentagonal bipyramidal coordination geometry with four chlorine and one water oxygen atoms in the equatorial plane. Infinite chains similar to those in UO_2Cl_2 are formed by sharing two Cl–Cl edges (Table 5.30).

Three basic hydroxide chlorides are observed in the UO_3–HCl–H_2O phase diagram at 25°C, but only one, $[(UO_2)_2(OH)_2Cl_2(H_2O)_4]$, is reported to be congruently soluble (Prins and Cordfunke, 1975). The compound may be easily obtained as hydrolysis product of a UO_2Cl_2 solution prepared by dissolution of

UO_3 in concentrated HCl (Åberg, 1969). Thermal decomposition of the compound in air leads first to the hemi-hydrate $UO_2(OH)Cl \cdot 0.5H_2O$ at 80–120°C, from which the nearly anhydrous salt, $UO_2(OH)Cl$ is formed at about 250°C. The compound crystallizes with monoclinic symmetry (see Table 5.30) and has a structure in which two linear uranyl units are linked through a double OH bridge, the remaining coordination sites are occupied by one Cl atom and four O atoms from two H_2O molecules, resulting in an irregular planar pentagon (Åberg, 1969).

(*v*) *Uranium*(*VI*) *oxochloro complexes*

The typical representatives of this group have the composition: M^IUOCl_5 (e.g. $M = P(C_6H_5)_4$, $M^I_2UO_2Cl_4$ (e.g. M = Li, Na, K, Rb Cs, NH_4, $P(C_6H_5)_4$, $N(C_2H_5)_4$, and others), $M^I_2UO_2Cl_4 \cdot 2H_2O$ (M = Li, Na, K, Rb, or NH_4), $M^{II}UO_2Cl_4 \cdot 2H_2O$ (M = Mg, Ca, Sr, Ba, Zn, Zn, Cd, and others), $M^IUO_2Cl_3$ (e.g. $M = P(C_6H_5)_4$, $N(C_{10}H_{21})_4$, and others), $M^I(UO_2)_2Cl_5$ (e.g. M = Na, K, Rb, Cs, or NH_4), $M^I_2U_2O_5Cl_4$ (M = Na, K, Rb, or Cs), $M^I_2U_2O_5Cl_4 \cdot xH_2O$ (M = Na, K, Rb or Cs), $KNa_2(UO_2)_2Cl_7$, KUO_3Cl, $K_2U_3O_8Cl_4$, and $K_2(UO_2)_xCl_{2x+2}$ ($x = 2$, 3, or 4). The compounds have been prepared by variety of methods (Brown, 1979), most commonly by crystallization from organic solvents (methyl cyanide or ethanol solutions) or aqueous hydrochloric acid solutions of the corresponding chlorides, as well as by solid-state reactions. Some of them are air-sensitive (e.g. $[P(C_6H_5)_4]UOCl_6$) or are hydrated on exposure to moist air ($M^I_2UO_2Cl_4$ where M = Li to Rb and NH_4); they are soluble in some organic solvents.

Structure data (Brown, 1979) are available for a number of the compounds (see Table 5.30). In $M^I_2UO_2Cl_4$ there are discrete $UO_2Cl_4^{2-}$ units with linear O–U–O groups. The structure of $M_2U_2O_5Cl_4 \cdot 2H_2O$ (M = Rb or Cs) consists of discrete planar tetranuclear anions, $[(UO_2)_4O_2Cl_8(H_2O)_2]^{4-}$, in which the uranyl groups in the equatorial plane are linked by oxygen and chloride bridges. In the structure of $[N(C_6H_5CH_2)(CH_3)_3]_4[UO_2Cl_3O]_2$ there are puckered sheets of binuclear $[Cl_3O_2U\text{-}(\mu\text{-}O_2)\text{-}UO_2Cl_3]^{4-}$ anions parallel to (001), which are interleaved by the cations. The anion is built of two identical, distorted pentagonal bipyramides sharing the peroxo-group as a common edge. Oxochlorouranates of the formula $Ln_3UO_6Cl_3$ (Ln = La, Pr, or Nd) were prepared by heating stoichiometric amounts of $LnOCl/Ln_2O_3/U_3O_8$ (Ln = La or Nd) or $PrOCl/Pr_6O_{11}/U_3O_8$ in silica ampoules at 800–1000°C in an excess of chlorine (Henche *et al.*, 1993). The crystals were investigated by X-ray diffraction methods (see Table 5.30) and high-resolution electron microscopy.

(*vi*) *Uranium*(*VI*) *perchlorates and related compounds*

The synthesis and characterization of uranyl(VI) perchlorate, $UO_2(ClO_4)_2$ and its hydrates $UO_2(ClO_4)_2 \cdot xH_2O$ ($x = 0$, 1, 3, 5, or 7) have been investigated by a number of authors (Brown, 1979). The heptahydrate has been obtained by crystallization from aqueous solution at room temperatures. Vacuum drying of the compound at that temperature leads to the pentahydrate, and vacuum dehydration over sulfuric acid to the trihydrate. Further vacuum drying converts the latter to the monohydrate; in the temperature range 100–140°C anhydrous perchlorate $UO_2(ClO_4)_2$ is formed (Vdovenko *et al.*, 1963). All of the compounds are readily soluble in water and polar organic solvents, in many cases with the formation of stable uranyl(VI) perchlorate complexes. The interaction with oxygen and nitrogen donor ligands leads to the formation of the following types of complexes:

$UO_2(ClO_4)_2 5L$: where L = pyridine, pyridine-*N*-oxide, antipyrene, dimethylsulfoxide, dimethylselenoxide, dimethylformamide, diphenylsulfoxide, thioxane oxide, urea, 1,3-dimethylurea, 1,3-diethylurea, hexamethylphosphoramide.

$UO_2(ClO_4)_2 4L$: where L = trimethylphosphine oxide, triphenylphosphine oxide, tripropylphosphine oxide.

$UO_2(ClO_4)_2 3L$: where L = octamethylphosphoramide, camphor, methyl cyanide, nonamethylimido-diphosphoramide.

$UO_2(ClO_4)_2 2L$: where L = tributylphosphate, tributylphosphine oxide, nitromethane, dibutyl ether.

$UO_2(ClO_4)_4 \cdot 7H_2O$ crystallizes in the orthorhombic space group $Pca2_1$ The structure consists of $[UO_2(OH_2)_5]^{2+}$ and ClO_4^- ions, with two additional water of solvation. The crystal structure is held together by an extensive network of hydrogen bonds.The coordination polyhedron is a distorted pentagonal bipyramid (Alcock and Esperas, 1977). Some crystallographic and infrared data are are listed in Table 5.30.

(*vii*) *Uranium*(*VI*) *oxide bromides and complex oxobromo compounds*

Uranyl(*VI*) *bromide and related complexes*

One of the most convenient methods for the preparation of UO_2Br_2 is the reaction of anhydrous UBr_4 with oxygen at a carefully controlled temperature in the range 150–160°C; at higher temperature, U_3O_8 is formed (Brown, 1979). An alternative method involves the electrochemical anodic oxidation of uranium in CH_3CN/Br_2 solution in the presence of dry oxygen. The resulting solution of UO_2Br_2 may also be used for the preparation of adducts by adding a two-fold excess of the appropriate ligand (Kumar and Tuck, 1984).

The compound is a bright red, hygroscopic solid which turns yellow on exposure to moisture. It is thermally unstable and appears to lose bromine slowly even at room temperature. The decomposition is complete within 48 h in an inert atmosphere at 350°C. UO_2Br_2 is extremely soluble in water and polar organic solvents. Numerous complex compounds have been prepared by reactions with a variety of ligands in anhydrous solvents, for example, of the following types: UO_2Br_2L (L = methyl cyanide), $UO_2Br_2 2L$ (L = acetic anhydride, ether, *N*,*N*–dimethylacetamide, antipyrine, *N*-methylacetanilide,

$(CH_3)_3PO$, $(C_2H_5)_3PO$, $(C_6H_5)_3PO$, etc), UO_2Br_23L (L = dimethylformamide), UO_2Br_24L (L = dimethylsulfoxide) $UO_2Br_2 \cdot xNH_3$ ($x = 2$, 3, and 4), $UO_2Br_4 \cdot (LH)_2$ (L = 2,2′-dipyridine,1,10-phenanthroline) and $(Et_4N)_2UO_2Br_4$. In addition, a number of oxo-tetrabromo complexes of the $M_2UO_2Br_4$ (M = Cs, $P(C_6H_5)_3CH_3$, $P(C_6H_5)_3H$, $P(CH_3)_3H$, $P(C_6H_5)_3C_6H_5CH_2$, etc.) and $M_2UO_2Br_4 \cdot 2H_2O$ (M = NH_4, K, or Rb) types have been obtained by reaction of UO_2Br_2 with the appropriate ligands in HBr or in anhydrous organic solvents (Brown, 1979, Kumar and Tuck, 1984).

Uranyl(VI) hydroxide bromide and bromide hydrates

A stable hydrate of the formula $UO_2Br_2 \cdot 3H_2O$ is obtained in the form of dark yellow needles by crystallization from an aqueous solution of HBr and UO_2Br_2, followed by vacuum drying (Peterson, 1961). The dehydration of the trihydrate over phosphoric acid leads to the formation of the monohydrate $UO_2Br_2 \cdot H_2O$. The hydrates may be also obtained by other methods (Brown, 1979). Crystallization of UO_2Br_2 from acid-deficient solutions leads to the formation of $UO_2(OH)Br \cdot 2H_2O$ (alternative formulations are: $[U_2O_5(H_2O)]Br_2 \cdot 4H_2O$ or $[UO_2(OH)_2UO_2]Br_2 \cdot 4H_2O$). The compound is isostructural with its chloride analog $[UO_2(OH)_2UO_2]Cl_2 \cdot 4H_2O$; it is converted to $UO_2(OH)Br$ when heated at 200°C.

The hydrates are readily soluble in water and numerous organic solvents like ethanol, ether, amyl alcohol, etc. $M_2UO_3Br_2$ (M = NH_3 or K) is formed by reacting the monohydrate with ammonia gas or a stiochiometric quantity of KOH (Brown, 1979). According to Peterson (1961) the trihydrate is stable in dry air and may lose one molecule of water at 60°C without decomposition.

Uranium(VI) oxobromo complexes

The synthesis and characterization of a large number of complex oxobromo compounds containing uranium(VI) have been summarized by Brown (1979). Oxo-tetrabromo complexes of the $M_2UO_2Br_4 \cdot 2H_2O$ type (M = NH_4, Na, K, or Rb) were prepared from aqueous or alcoholic HBr solutions of uranyl bromide by precipitation with appropriate MBr. The anhydrous analogs were obtained by heating at 120°C in an inert atmosphere. With large cations, for example Cs^+ or pyridinium, only anhydrous complexes of the $M_2UO_2Br_4$-type are formed.

Other anhydrous complexes of this type were prepared by reactions of uranyl bromide solutions in ethanol or methyl cyanide with various phosphonium bromides (e.g. $P(C_6H_5)_3C_4H_9Br$, $P(C_6H_5)_3HBr$, $P(C_6H_5)_3C_6H_5CH_2)Br$, $P(C_2H_5)_3HBr$, and $P(C_3H_7)_3HBr$) as well as with $N(C_2H_5)_4Br$ (in ethanol), $N(CH_3)_4Br$ (in a C_2H_5OH–HBr mixture), choline bromide, $(C_5H_{14}NO)Br$ (in methanol), and acetylcholine bromide, $(C_7H_{16}NO_2)Br$ (in methanol). The reaction of UO_2Br_2 with tetradecylammonium bromide in anhydrous benzene results in the formation of a viscous liquid of the $[N(C_{10}H_{21})_4]UO_2Br_3$. In the presence of traces of water in benzene compound converts into the oxo-tetrabromo complex.

The oxobromo complexes are yellow and readily soluble in aqueous solutions; those with organic cations also in anhydrous solvents such as acetone, benzene, methyl cyanide, and nitromethane. Structure investigations reveal a distorted octahedral geometry in complexes with M = Cs, $N(CH_3)_4$, $N(C_3H_7)_4$, and $C_7H_{16}NO_2$, where the U–O and U–Br bond distances range from 1.70 to 1.90 and 2.78 to 2.86 Å, respectively. For structural data, see Table 5.30. Extensive information on the infrared and Raman spectra is also available (Brown, 1979). On the basis of these data the observed frequencies for various oxotetrabromo complexes can be assigned as follows:

IR (cm^{-1}): ν(U–O, asym. stretch.) = 895–934; ν(O–U–O deformation) = 243–263; ν(U–Br stetch.) = 160–180; Raman (cm^{-1}): ν(U–O sym. stretch.) = 826–835, ν(U–O–Br bend.) = 190–198, ν(U–Br stretch.) = 167–172 ν(U–Br bending mode) = 81–83. The fluorescence spectrum of $Cs_2UO_2Br_4$ measured at 14.3 K reveals the existence of two sites of different symmetry, which has been supported by the observed differences in the fluorescence relaxation time. The solution spectra of $[N(C_{10}H_{21})_4]UO_2Br_3$ and $[N(C_{10}H_{21})_4]UO_2Br_4$ in anhydrous benzene have absorption bands at 508, 491, 483, 447, and 431 nm and at 497, 480, 464, and 449 nm, respectively. For $[P(C_6H_5)_3H]_2 \cdot UO_2Br_3$ in methyl cyanide solution these bands appear at 19800, 20080, 20790, 21550, 20220, and 22880 cm^{-1}. As one should expect, the absorption bands of the solid state reflectance spectra of $[C_5H_{14}NO]_2UO_2Br_4$ and $[C_7H_{16}NO_2]UO_2Br_4$ are somewhat shifted towards longer wavelengths as compared to their chloro analogs.

The reactions of uranyl bromide with various metal bromides in aqueous HBr lead to the formation of the following hydrated bromo compounds:

$MUO_2Br_4 \cdot xH_2O$ (M = Sr, $x = 3$; M = Zn, Mg, $x = 4$; M = Ca, $x = 8$);
$MUO_2Br_5 \cdot xH_2O$ (M = La, $x = 3$; M = Y, $x = 5$);
$MUO_2Br_6 \cdot 4H_2O$ (M = Ce or Th);
$MU_3O_8Br_5 \cdot xH_2O$ (M = Co, $x = 12$; M = Sc, $x = 8$), and
$Be_2UO_2Br_6 \cdot 8H_2O$, $Mn_3UO_2Br_8 \cdot 11H_2O$, and $HgU_3O_8Br_4 \cdot 4H_2O$

The complexes may be dehydrated in an oxygen atmosphere at about 200°C. $LaUO_2Br_5$, YUO_2Br_5, and $CeUO_2Br_5$ are converted to $LaUO_2(O_2)Br$, $YUO_2(O_2)Br$, and $LaUO_2(O_2)Br$, respectively, at 290–305°C. Decomposition at high temperature results in the formation of appropriate uranates, $CaUO_4$, Mn_3UO_6, $Co_2U_6O_{21}$, and HgU_3O_{10}, etc. The heating of $K_2UO_2Br_4$ at 250°C and $(NH_4)_2K_2UO_2Br_4$ at 250–350°C in an oxygen atmosphere results in the formation of $K_2UO_3Br_2$ and $(NH_4)_2UO_3Br_2$, respectively. $K_2UO_3Br_2$ may be also prepared by interaction of uranyl bromide monohydrate with KOH, or by heating K_2UO_4 with gaseous hydrogen bromide, whereas $(NH_4)_2UO_3Br_2$ is obtained by action of gaseous NH_3 on $UO_2Br_2 \cdot H_2O$. Compounds of the composition $K_2U_2O_6Br_2$ and $K_2U_3O_9Br_2$ have been prepared by heating K_2UO_4 or $K_2U_3O_{10}$ with gaseous HBr, respectively. A phase of the composition $K_xUO_3Br_x$ ($x = 0.9$) is obtained when UO_3 and KBr are heated at 300–550°C *in vacuo*. The compound is isostructural with $K_xUO_3Cl_x$ (see Table 5.30).

The interaction of $M_2UO_2Br_4 \cdot 2H_2O$ (M = K or Rb) with $UO_2(OH)_2$ results in the formation of compounds containing the tetranuclear unit $M_2[(UO_2)_4O_2(OH)_2Br_4(H_2O)_4] \cdot 2H_2O$. The complexes lose four H_2O molecules in an inert atmosphere at 60°C and form $M_2U_4O_{11}Br_4$ at ≈200°C. The compounds are triclinic ($P\bar{1}$) and isostructural with the chloro analogs (see Table 5.30).

(*viii*) *Uranium*(*VI*) *compounds with iodine*

$UI_4 \cdot 4$dmf is obtained by electrochemical oxidation of uranium anodes in *N*,*N*-dimethylformamide (dmf) (Kumar and Tuck, 1984). The preparation of an extremely unstable UO_2I_2 has been reported in a number of papers (Brown, 1979; du Preez and Zeelie, 1989). The compound has not been obtained in a pure form but relatively stable compounds, such as $UO_2I_2 \cdot 4$dmf (yellow, m.p. = 156°C; dmf = dimethylformamide), $UO_2I_2 \cdot 2$tppo (orange red, m.p. = 268°C; tppo = triphenylphosphine oxide), $UO_2I_2 \cdot 2$tmu (orange, tmu = *N*,*N*,*N*′,*N*′-tetramethylurea), $UO_2I_2 \cdot 5CO(NH_2)_2 \cdot H_2O$ (orange-red), $UO_2I_2 \cdot 2$hmpa (orange, hmpa = hexamethylphosphoric triamide), $UO_2I_2 \cdot xNH_3$ ($x = 2$ or 3), $UO_2I_2 \cdot 2$tbso (yellow-green, tbso = di-*tert*-butyl sulfoxide), $UO_2I_2 \cdot 2$dmeu (dmeu = *N*,*N*′-dimethylethylene urea), $(PPh_4)_2UO_2I_4$ (black), $UO_2I_2 \cdot 2Et_2O$ (decomposes at room temperature by evolving iodine), may be separated from solutions in water and various organic solvents (for example, ether, methanol, ethanol, amyl alcohol, methyl acetate, ethyl acetate, pyridine) (Brown, 1989; du Preez and Zeelie, 1989). A red uranyl(VI) iodo compound, $[P(C_6H_5)_3C_4H_9]_2UO_2I_4$, has been obtained by interaction of uranyl(VI) iodide with phosphonium iodide in a methyl cyanide solution (Day and Venanzi, 1966).

The addition of soluble iodides to uranyl nitrate solutions at room temperatures results in the formation of the uranyl(VI) iodide dihydrate, $UO_2(IO_3)_2 \cdot 2H_2O$. The compound is converted to α-$UO_2(IO_3)_2 \cdot H_2O$ when UO_2NO_3 and iodic acid are mixed in boiling nitric acid. β-$UO_2(IO_3)_2 \cdot H_2O$ is formed by recrystallization from water in the absence of acid. The compound $(UO_2)_2I_2O_9$ has been obtained by addition of potassium periodate to a cold solution of $UO_2(NO)_2$. The preparation of a number of uranium(VI) iodato and periodato complexes has also been reported: $KUO_2(IO_3)_3 \cdot 3H_2O$, $(KIO_4)_2(UO_2)_2O_2 \cdot 5H_2O$, $[Co(NH_3)_6][(UO_2)_2(IO_3)_7] \cdot 10H_2O$, $K_2I_2O_5(UO_2)_2$, $H(UO_2)_2IO_6 \cdot 8H_2O$, $NaH_2UO_2IO_6 \cdot 7H_2O$, $Ba(H_2UO_2IO_6)_2 \cdot xH_2O$ (Brown, 1979).

(*ix*) *Mixed halogeno-complexes*

Mixed uranyl(VI) halogeno-compounds $M^I_2UO_2Cl_2Br_2$ (M^I = NH_4, Na, K, or Cs), $Cs_2UO_2X_3Y$ (X and Y = Cl or Br), $[N(C_{10}H_{21})_4]_2[UO_2X_3I]$ (where X = Cl or Br), and $[P(C_6H_5)_3C_4H_9]_2[UO_2Cl_2Br_2]$, $[P(C_6H_5)_3C_4H_9]_2[UO_2Br_2I_2]$ have been obtained by interaction of uranyl halides with appropriate univalent bromides or iodides in aqueous HBr solutions, or in anhydrous organic solvents such as benzene and methyl cyanide. Alternative routes to these and similar mixed halogeno complexes have been also reported (Brown, 1968, 1979). $Cs_2UO_2BrCl_3$ and $Cs_2UO_2Br_3Cl$ (Ellert *et al.*, 1965) have been obtained by varying the HBr concentration in the interaction between CsBr and $UO_2Cl_2 \cdot H_2O$ The preparation of the dihydrate $K_2UO_2Br_2Cl_2 \cdot 2H_2O$ has been achieved by crystallization from 20% HCl containing KBr and UO_2Cl. Dehydration of the compound in an inert atmosphere at 110°C leads to $K_2UO_2Br_2Cl_2$ (Lucas, 1964). Dihydrates of the composition $M_2UO_2Br_{4-x}Cl_x$ ($M = NH_4$ or Rb; $x = 1$, 2, or 3) have also been isolated (Kharitonov *et al.*, 1967).

Complexes containing alkali metal cations are soluble in water and aqueous acetic acid solution; those containing phosphonium or tetralkylammonium cations are soluble in numerous non-aqueous solvents like methyl cyanide, benzene, and ethanol. In water, hydrolysis takes place. Dehydration of the compound in an inert atmosphere at $\approx$110°C leads to the anhydrous complexes (Lucas, 1964).

X-ray powder diffraction data are available for $Cs_2UO_2Cl_2Br_2$, $Cs_2UO_2BrCl_3$, $Cs_2UO_2Br_3Cl$ (Ellert *et al.*, 1965), $K_2UO_2Cl_2Br_2$, $K_2UO_2Br_2Cl_2 \cdot 2H_2O$, and $K_2U_2O_5Cl_2Br_2$ (Lucas, 1964). The ν(U–O) asymmetric stretching vibrations occur at 905–910 cm^{-1} for $M_2UO_2Br_{4-x}Cl_x \cdot 2H_2O$ ($M = NH_4$, K or Rb) and at 907–922 cm^{-1} for various anhydrous complexes. In the IR spectrum of $[P(C_6H_5)_4]UOBr_4Cl$, they appear at 838 cm^{-1}.

The metal–halogen stretching frequencies have been reported for: $[P(C_6H_5)_3C_4H_9]_2UO_2Br_2Cl_2$, $\nu(U\text{–}Cl) = 260\ cm^{-1}$; $[N(C_{10}H_{21})_4]_2UO_2BrCl_3$, $\nu(U\text{–}Cl) = 255\ cm^{-1}$, $\nu(U\text{–}Br) = 165\ cm^{-1}$; $[N(C_{10}H_{21})_4]_2UO_2Cl_3I$, $\nu(U\text{–}Cl) = 236\ cm^{-1}$, and $\nu(U\text{–}I) = 135\ cm^{-1}$, with the uranyl deformation mode at 261 cm^{-1} (Brown, 1979). The first high-intensity bands in the visible spectra of $[N(C_{10}H_{21})_4]_2UO_2Cl_3I$, and $[N(C_{10}H_{21})_4]_2UO_2BrCl_2I$ in benzene solutions, were recorded at about 20000 cm^{-1} (Vdovenko *et al.*, 1969).

5.8 CHEMICAL BONDING IN URANIUM COMPOUNDS

5.8.1 U(III) and U(IV) compounds

In general, the discussion of chemical bonding in U(III) and U(IV) compounds is related to metal–organic complexes as discussed in Chapters 25 and 26. A recent review of the organometallic chemistry of lanthanides and actinides has been given by Hyeon *et al.* (2005). An early example is given in a study by Bursten and Strittmatter (1987) that discussed the bonding in $[Cp_3UCO]$ and $[Cp_3UCO]^+$, where Cp is cyclopentadiene, $\eta^5\text{-}C_5H_5$. They suggested an extensive U(III) 5f–CO π-back-bonding, an effect that decreases significantly on oxidation to U(IV). The coordination of dinitrogen in $[\{U(NN'_3)\}_2(\mu_2\text{–}\eta^2:\eta^2\text{–}N_2)]$, where NN'_3 is $N(CH_2CH_2NSiBu^tMe_2)_3$, was studied by Roussel and Scott (1998). The end-on coordination is consistent with U → N back-bonding, but the authors suggest that the effect is minor. The role of the 5f orbitals in back-bonding has also been studied by comparison with the bonding in lanthanide compounds in oxidation states 3+ and 4+. A typical example is given in a study by Berthet *et al.* (2002) of the selective complexation of U(III) over Ce(III) and Nd(III) in 2,2′:6,2″-terpyridine complexes. This ligand forms much stronger complexes with uranium than cerium in solution. The authors probed the possible reasons behind this by determination of the X-ray crystal structure of the complexes $[MI_2(terpy)_2]I$, M = Ce, Nd, $[CeI_2(terpy)_2(H_2O)]I$, and $[UI_2(terpy)_2(pyridine)]I$. They suggest that the shortening of the average M–N distance by 0.05 Å in the uranium complex as compared to that of cerium might be a result of a stronger π back-bonding interaction between uranium and the terpyridyl ligand. The evidence for back-bonding is indirect and more direct information is necessary to draw definite conclusions, e.g. Di Bella *et al.* (1996) point out, based on electronic structure calculations and photoelectron spectroscopic data, that the bonding in isoleptic 4f and 5f M(III) bis-(cyclopentadienyl) is very similar. Experimental data and quantum chemical calculations on different model systems indicate 5f orbital participation in chemical bonding, but the extent of this and its chemical effects are far from clear. A detailed discussion of the quantum chemistry of uranium and other actinides is given in Chapter 17.

Roos and Gagliardi have used quantum chemical methods to explore the stability and possible existence of compounds with U–U bonds, similar to those found for some d-transition elements, e.g. Cr, Mo, W, Tc and Re. They predicted stable diatomic U_2 with a quintuple U–U bond and a bond distance of 2.43 Å (Gagliardi and Roos, 2005a). Gagliardi *et al.*, (2005) found that also U_2^{2+} is a stable ion with several low-lying electronic states, all with U–U bond distances around 2.30 Å.

Compounds containing U–U bonds have been identified by matrix isolation techniques; $H_2U–UH_2$ by Souter *et al.* (1997) and O-U–U-O by Gorokhov *et al.* (1974). In their most recent paper Gagliardi and Roos (2005b) have studied the stability and chemical bonding in U_2Cl_6, $U_2Cl_6^{2-}$, $U_2(OCHO)_4$, $U_2(OCHO)_6^{2-}$, and $U_2(OCHO)_4Cl_2^{2-}$. It seems unlikely that compounds where the formal oxidation state of uranium is +2 can be prepared, but those with the oxidation state of +3 seem more probable. $U_2Cl_6^{2-}$, has a similar structure and bonding as $Re_2Cl_6^{2-}$, with the eclipsed conformation as the most stable one. The weakest bond is found in $U_2(OCHO)_4Cl_2^{2-}$, where the U–U distance is 2.80 Å.

5.8.2 UF_5 and UF_6 compounds

The bonding in these compounds has been discussed by Rosén and Fricke (1979), Wadt and Hay, (1979), and Onoe *et al.* (1993, 1997); these compounds can presumably be used as models for the bonding also in other uranium(V) and uranium(VI) halides. The authors point out that there is extensive involvement of 5f, 6p, and 6d orbitals in the U–F bonds, the orbital population in the 7s and 7p orbitals is smaller, and relativistic effects are of great importance for the chemical bonding. The participation of the 5f orbitals in the bonding explains the fluxional geometry of UF_5 between C_{4v} and D_{3h} (Onoe *et al.*, 1997).

5.8.3 Uranyl(v) and uranyl(vi) compounds

The linear "yl"-ions in aqueous systems are unique for the actinide elements; in other "yl"-ions, such as VO_2^+, MoO_2^{2+}, and WO_2^{2+}, the oxygen atoms are mutually *cis*, thereby maximizing $(p_\pi) \rightarrow M(d_\pi)$ bonding. A linear MO_2^{2+} group is known in compounds of technetium, rhenium, ruthenium, and osmium, but the corresponding aqua-ions are unknown (a recent discussion of the electronic structure of these *trans*-dioxometal complexes is found in Hummel *et al.*, 2006). The short U(vi)–O_{yl} bond distance, approximately 1.75 Å, indicates a strong multiple uranium–oxygen bonding, one of σ and two of π character. The uranium–"yl" distance in UO_2^+ is somewhat longer due to the smaller effective charge of uranium (Vallet *et al.*, 2004a). The orbitals involved in the uranium–"yl"-oxygen bonds have been extensively discussed (see Denning, 1992; Kaltsyoannis, 2000; Matsika *et al.*, 2001 for a review); the MO diagram in Fig. 5.49 illustrates the bonding.

The bonding molecular orbitals are $\sigma_g^2\ \sigma_u^2\ \pi_g^4\ \pi_g^4$ with 5fδ and 5fφ as the lowest unoccupied orbitals. The bonding orbitals have mainly O 2p character and the uranyl(vi) ion can therefore be described as $O^{2-}{\equiv}U^{6+}{\equiv}O^{2-}$.

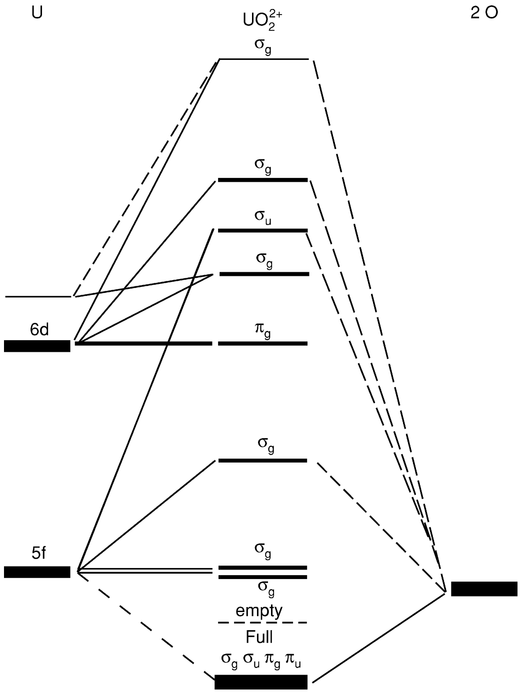

Fig. 5.49 *Schematic molecular orbital diagram for the uranyl(*vi*) ion.*

The nonbonding and antibonding orbitals have 5f and 6d character. The ordering of the bonding orbitals and the HOMO in UO_2^{2+} is not straightforward (de Jong *et al.*, 1999); Denning (1992) and later Kaltsyoannis (2000) suggested the order $\pi_g < \pi_u < \sigma_g << \sigma_u$, where σ_u is the highest occupied orbital. The significant energy gap between the σ_g and σ_u orbitals is traced to the filled–filled interactions between the semi-core 6p orbitals and the σ_u valence level, the 'pushing from below' mechanism. Triatomic UN_2 and UON^+ are isoelectronic with UO_2^{2+} and Pyykkö *et al.* (1994) suggested that these and other triatomic groups could have a significant stability. This was confirmed in experimental studies by Brown and Denning (1996) who prepared a number of stable compounds containing the linear –N≡U=N– and O=U=N– groups and discussed their chemical bonding. Kaltsyoannis (2000) made a more detailed study using density functional methods and concluded that the U–N bond is significantly more covalent than the U–O bond in UON^+ and UO_2^{2+} and that the uranium f-orbitals play a more important role than the d-orbitals in the metal to ligand bonding. He also pointed out that the U–N bond in iminato complexes is best described as a triple bond.

The previous correlation diagram can also be used to describe the bonding in UO_2^+, where the single 5f electron is located in one of the nonbonding 5fδ or 5fφ orbitals.

Tatsumi and Hoffmann (1980) and Wadt (1981) have discussed the electronic reasons for the change from the linear geometry in UO_2^{2+} to the *cis*-geometry in MoO_2^{2+}. Dyall (1999) and Straka *et al.* (2001) have discussed the bonding in actinyl ions and showed that the 5f character in the M–O bond increases steadily through the actinide series, while the 6d population remains nearly constant. The nonlinear O–M–O bonds are a result of an increased 6d population. As a result of the strong covalent U–O_{yl} bonding, the formal charge of uranium is much lower than +6, +2.43 for $UO_2(H_2O)_5^{2+}$ in gas phase (Vallet *et al.*, 2004a); the charge of the 'yl' oxygen atoms is –0.43. Because of their negative charge, the 'yl' oxygen atoms in UO_2^{2+} and UO_2^+ are Lewis bases, resulting in the formation of 'cation–cation' complexes of type O=U=O- - - M (Section 5.10.2f). The negative charge on the 'yl'-oxygen atoms varies with the nature of the ligands in the equatorial plane and by proper ligand choice, the Lewis basicity of the 'yl'-oxygen atoms can be significantly increased, resulting in coordination of strong Lewis acids such as $B(C_6F_5)_3$ (Sarsfield and Helliwell, 2003). The charges on U and oxygen in $UO_2(H_2O)_5^+$ are 2.19 and –0.66, respectively (Vallet *et al.*, 2004a), making the uranyl(v) oxygen atoms even stronger Lewis bases than in uranyl(vi). A more detailed discussion of the electronic structure and energy levels of the other oxidation states of uranium is given in Chapter 16. The slight variations in the effective charge of uranium in different compounds result in small differences in the U–O_{yl} bond distance and the effect is also noticeable as small changes in the vibrational stretch frequencies of the UO_2 group in infrared and Raman spectra. In the same way the 'yl'-stretch frequency is lower in UO_2^+ than in UO_2^{2+}, indicating a weaker bond in the former ion.

5.9 STRUCTURE AND COORDINATION CHEMISTRY OF URANIUM COMPLEXES IN SOLUTION AND THE SOLID STATE

The structure of complexes in solution is characterized by their coordination geometry, coordination number, and bond distances. The coordination geometry in solid-state structures is also influenced by additional factors, such as the efficiency of packing, the charge distribution in the structure, and the formation of hydrogen bond networks. The solid-state structures are often good models for bond distances and coordination geometry in solution. The structure in solution refers to discrete ions and molecules, more or less solvated, depending on the nature of the solvent and the charge of the complex. In some cases solid-state structures may contain discrete ions and molecules, but in general, the solid is better regarded as a 'polymer'. For example, $UO_2CO_3(s)$ is a layer structure that does not contain isolated UO_2CO_3 units (see Fig. 5.54), while $Na_4UO_2(CO_3)_3(s)$ contains discrete complexes of $UO_2(CO_3)_3^{4-}$ (Fig. 5.53).

The three-dimensional structures can be described using polyhedra and nets, and for simple structures, using packing of spheres (Chapters 3 and 4 in Wells, 1990). Polynuclear complexes are more common in the solid state than in solution, presumably as a result of the stronger electrostatic interactions in the solid phase. The water solvent with its high dielectric constant and strong hydrogen bond donor/acceptor properties reduces the stability of polynuclear complexes, except those involving hydroxide and oxide donors. Polynuclear fluoride complexes are very common in the solid state (Allen *et al.*, 2000), but are not formed in significant amounts in aqueous solution. This is presumably a result of the strong hydrogen bond acceptor properties of fluoride that makes hydrogen bonding to the water more favored than fluoride bridge formation between uranium atoms.

The stoichiometry, coordination number, and the number of available donor atoms per uranium atom indicate whether a certain compound contains isolated complexes, or if chains, layer structures, or three-dimensional networks are formed. Networks are common in oxide, uranate, phosphate, arsenate, and silicate compounds where they are a result of the sharing of oxygen donor atoms between two or more metal ions. These compounds are sparingly soluble and have a variable stoichiometry, (*cf.* Section 5.7.2).

The structure principles are demonstrated in the structure models of uranium compounds in oxidation states 3+, 4+, and 6+ described in the following sections. The largest number of structures are found for uranium(VI) compounds, many of which can be prepared from aqueous solution. In these compounds, the linear UO_2 unit is inert and the additional ligands in the coordination sphere are located in, or close to the plane through uranium and perpendicular to the UO_2 axis; the number of coordinated ligands in the plane varies between four and six; in solution, these ligands are labile, i.e. they can rapidly exchange with free ligand or in ligand substitution reactions as discussed in Section 5.10.3.

5.9.1 Uranyl(VI) compounds

The coordination chemistry of U(VI) differs from that of the d-transition and main-group elements. The common coordination geometry in UO_2^{2+} complexes with small ligands is a pentagonal bipyramid, with all labile ligands in the plane perpendicular to the linear UO_2 unit. Other coordination geometries are possible; a number of oxides and uranates have distorted octahedral or pentagonal bipyramidal structure, (Section 5.7.2.2, Fig. 5.25). Isolated ions of $UO_2(OH)_4^{2-}$ are found in the compound $[Co(NH_3)_6]_2[UO_2(OH)_4]_3 \cdot xH_2O$, the X-ray structure of which was determined by Clark *et al.* (1999) (Fig. 5.50), $UO_2(OH)_4^{2-}$ has a square bipyramidal geometry also in solution (Clark *et al.*, 1999; Wahlgren *et al.*, 1999; Moll *et al.*, 2000a); this geometry may also occur in complexes where there is a strong steric interference between coordinated organic ligands. The tetra-hydroxide complex has also been studied using quantum chemical methods (Schreckenbach *et al.*, 1998; Wahlgren *et al.*, 1999; Vallet *et al.*, 2001).

The structure of $K_2UO_2(SO_4)_2 \cdot 2H_2O$ is an example of pentagonal bipyramidal coordination consisting of uranium(VI) bipyramids linked in three dimensions by bridging sulfate groups (Niinistö *et al.*, 1979). Each sulfate acts as a bridge between two uranium atoms, leaving two non-coordinated sulfate oxygen atoms. The remaining coordination site on uranium is occupied by one of the two water molecules (Fig. 5.51).

A different structure (Burns and Hayden, 2002) still with pentagonal bipyramidal coordination is found in $Na_{10}[UO_2(SO_4)_4](SO_4)_2 \cdot 3H_2O$, shown in Fig. 5.52. This structure contains discrete complexes where the five-coordination in the equatorial plane is achieved by one chelating and three monodentate sulfate ions.

A hexagonal bipyramidal geometry with six ligands in the equatorial plane is in general obtained with ligands that can form chelates that have a small distance between their donor atoms. Examples are nitrates, $M[UO_2(NO_3)_3]$, where M = NH_4, K, Rb, Cs, and Tl (Zalkin *et al.*, 1989), carbonates such as $K_4UO_2(CO_3)_3$ (Anderson *et al.*, 1980), and acetates (Navaza *et al.*, 1991); these

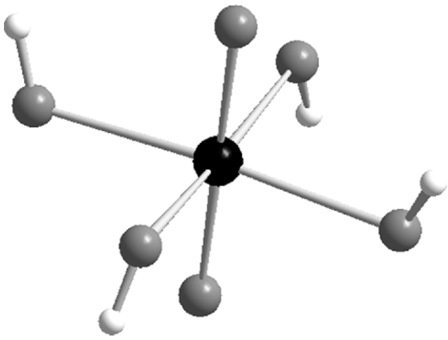

Fig. 5.50 *The structure of* $UO_2(OH)_4^{2-}$ (*from Clark* et al., 1999).

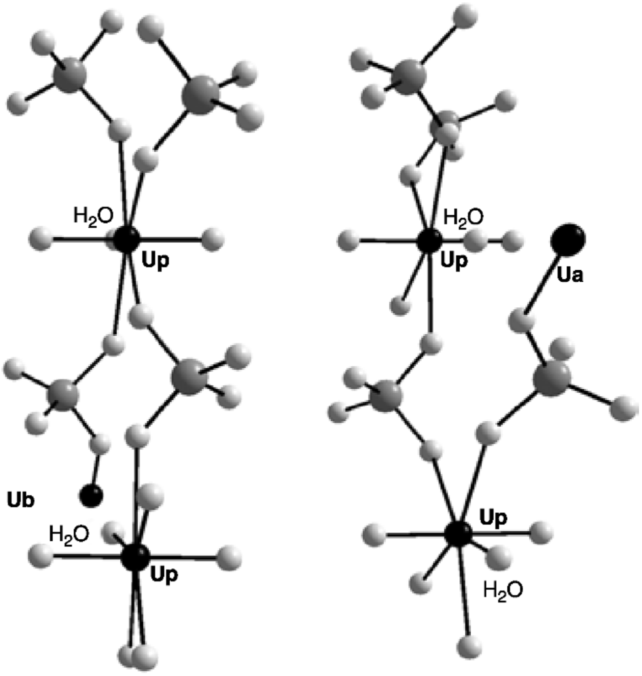

Fig. 5.51 *Coordination geometry and the three-dimensional linking in* $K_2UO_2(SO_4)_2 \cdot 2H_2O$ *(from Niinistö* et al., 1979). *The uranium atoms denoted* U_p *are located in the same plane and those denoted* U_a *and* U_b *in planes above and below this. The potassium atoms and one of the water molecules (not shown in the figure) provide additional links between the coordination polyhedra through coordination to the back end of the sulfate ions and through hydrogen bonding.*

compounds contain nine oxygen donors per uranium and from the geometry of the ligand, it is obvious that at most two per ligand can be coordinated to the same uranium atom. The donor atoms form hexagonal bipyramidal coordination together with the 'yl'-oxygen atoms. This results in structures that are composed of discrete complexes (Fig. 5.53). However, it is also feasible to have isomers; isolated pentagonal bipyramidal geometry is obtained if one of the ligands is coordinated through a single oxygen atom as in $UO_2(\text{oxalate})_3^{4-}$, discussed by Vallet *et al.* (2003). The only way to distinguish between these alternatives is through a structure determination or by using quantum chemical methods.

In UO_2CO_3(s), there are three oxygen donors per uranium and therefore the structure cannot contain isolated complexes; it turns out to be a layer structure where each oxygen donor is shared between two adjacent uranium atoms giving rise to hexagonal bipyramidal coordination (Fig. 5.54). This coordination geometry is very similar to that in the tris-carbonato complex (Fig. 5.53), but the three-dimensional structure of the latter is very different.

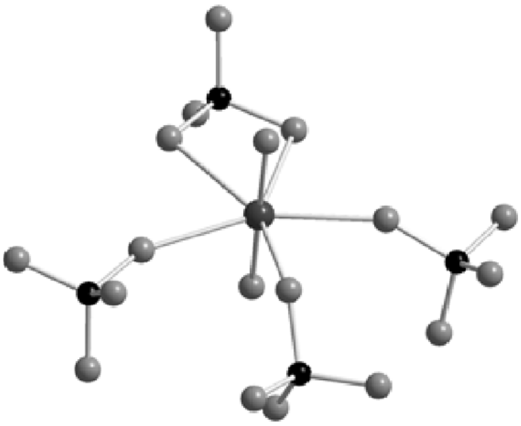

Fig. 5.52 *The coordination geometry of the* $UO_2(SO_4)_4^{6-}$ *ion in* $Na_{10}[UO_2(SO_4)_4](SO_4)_2 \cdot 3H_2O$ (*Burns and Hayden,* 2002). *One sulfate ion forms a chelate while the other three sulfate ions are monodentate.*

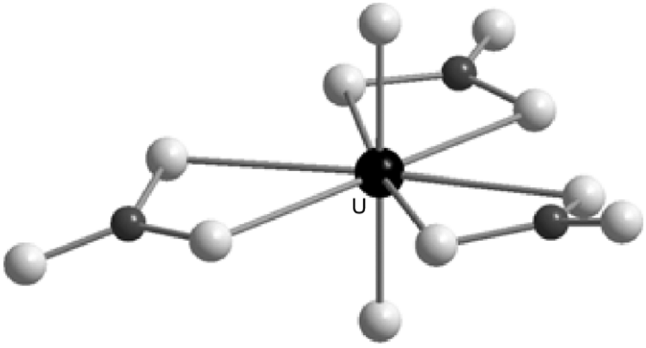

Fig. 5.53 *The coordination geometry, a hexagonal bipyramid, in* $K_4UO_2(CO_3)_3$ (*from the X-ray structure of Anderson* et al., 1980). *The ion* $[UO_2(CO_3)_3]^{4-}$ *occurs as discrete units in the structure; these units are linked through coordination to the counter ion* K^+.

Rare examples of six-coordination are also known in compounds containing organic ligands, e.g. $[UO_2(OTf)_2(bipy)_2]$ and $[UO_2(phen)_3][OTf]_2$, where bpy and phen denote bipyridine and phenantroline, respectively, and OTf^- the weakly coordinating triflate ion. Berthet *et al.* (2003) have determined the structure (Fig. 5.55) of these compounds, where the six nitrogen donors in the ligands are separated into two parallel and staggered equilateral triangles, (N2, N4, N6) and (N1, N3, N5) with the UO_2-axis perpendicular to the triangles. The uranium atom is equidistant, about 0.6 Å from these planes. The distortion is a result of geometric constraints in the chelating ligands.

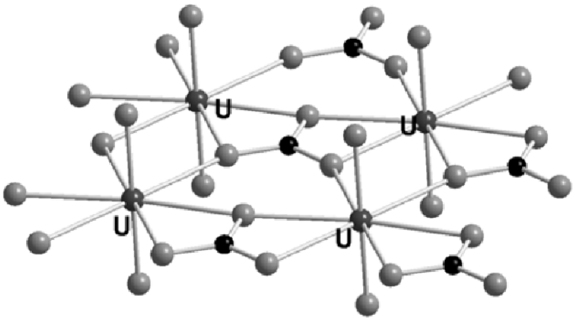

Fig. 5.54 *Part of the layer structure in $UO_2CO_3(s)$ showing the hexagonal bipyramidal coordination geometry of U(VI). By sharing each of the carbonate oxygens between two adjacent uranium atoms, six coordination in the plane perpendicular to the linear UO_2^{2+} ion is achieved. The structure is based on the X-ray study of Christ* et al. (1955).

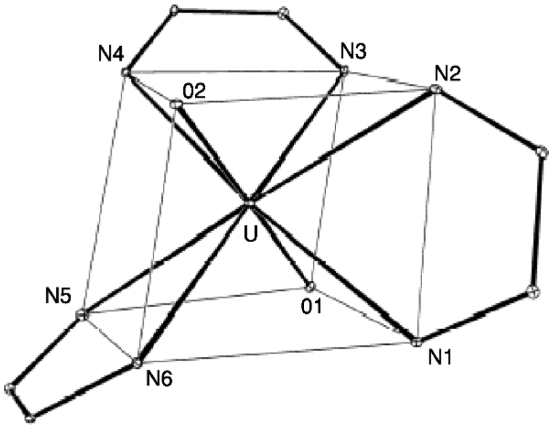

Fig. 5.55 *The coordination geometry for the six-coordinated U(VI) in $[UO_2(OTf)_2(bipy)_2]$ and $[UO_2(phen)_3][OTf]_2$; bpy denotes bipyridine, phen denotes phenantroline, and OTf the weakly coordinating triflate ion (from Berthet* et al., 2003, *reproduced by the permission of Royal Society of Chemistry).*

Uranium(VI) forms a number of peroxide complexes both in solution and in the solid state where the peroxide ligand is bonded 'side-on' to uranium as shown in Fig. 5.56a and b. The first one is the very rare mineral studtite, $UO_2(O_2)(H_2O)_2$ (Burns *et al.*, 2003); this compound has also been identified as a corrosion product on $UO_2(s)$ formed as a result of α-radiolysis (Sattonnay *et al.*, 2001); the second one is the structure of $Na_4[UO_2(O_3)_2](H_2O)_9$ from Alcock (1968). A number of other peroxide compounds and complexes in solution have been prepared by adding hydrogen peroxide to uranyl(VI) solutions; the sulfate and malonate systems were studied by Gurevich *et al.* (1971a,b);

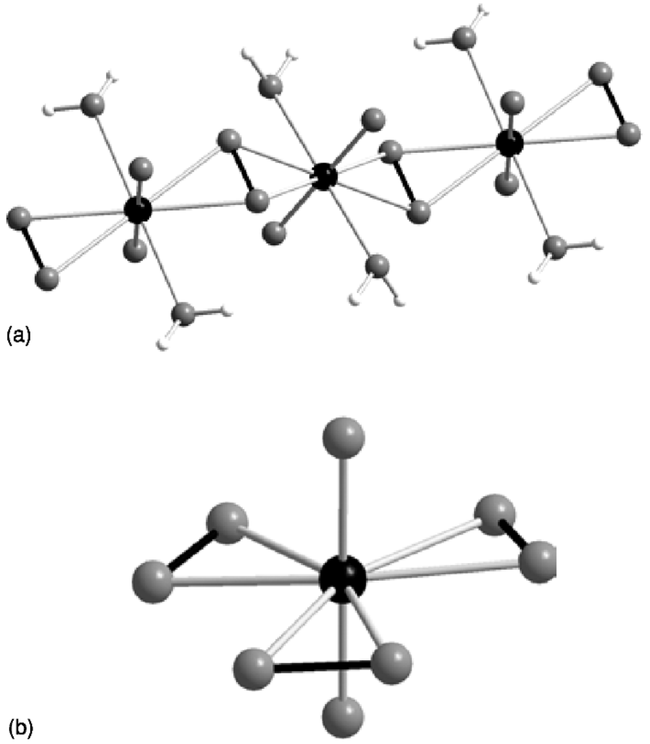

Fig. 5.56 (*a*) *The structure of studtite* (*from Burns* et al., 2003). *The peroxide group* (*black bond*) *is bridging two uranyl*(*vi*) *ions and forms a hexagonal bipyramidal coordination geometry around uranium together with two coordinated water molecules.* (*b*) *The structure of* $Na_4[UO_2(O_2)_3](H_2O)_9$ (*from Alcock,* 1968). *The structure contains discrete complexes with hexagonal bipyramidal coordination geometry.*

the oxalate system by Moskvin (1968); the uranyl(vi)-monoperoxo species was characterized by Djogic and Branica (1992). Self-assembled uranyl peroxide nanosphere clusters of 24, 28, and 32 polyhedra (some containing neptunyl) that crystallize from alkaline solution have been characterized (Burns *et al.*, 2005).

5.9.2 Uranium(iii) compounds

The structures of U(iii) complexes are expected to be very similar to those of the other trivalent actinides; the coordination chemistry of which has been extensively studied as they are chemically more stable than the corresponding U(iii) compounds. A point of interest is if there are differences in bonding between trivalent lanthanides and their actinide homologs. A comparison of equilibrium constants indicates that the actinide complexes are somewhat more stable, but the difference is not large. In the same way there are no large differences in bond distances and coordination geometry; the differences that do exist may be due to the larger ionic radius of the actinide homologs as compared to the corresponding lanthanides. Uranium(III) compounds are characterized by high coordination numbers, eight and nine coordination are predominating as in the corresponding lanthanide(III) compounds. There are no structure determinations of uranium(III) complexes of simple inorganic ligands in solution, but it is reasonable to assume that their coordination geometry is similar to those of the trivalent lanthanides and transuranium elements (Allen *et al.*, 2000). Examples of solid uranium(III) compounds are given by Chernyayev (1966) and Mehdoui *et al.* (2004), the latter also provides comparisons between U(III) and lanthanide(III) compounds.

Fig. 5.57 shows the structure of $K_3U(SO_4)_3 \cdot 3H_2O$ from Barnard *et al.* (1972a); it contains nine-coordinated U(III) through two chelating and two mono-dentate sulfate ions and three coordinated water molecules that form a strongly distorted trigonal prism around uranium.

5.9.3 Uranium(IV) compounds

Uranium(IV) forms both normal and basic salts with most inorganic ligands. The formation of basic salts is the result of the strong hydrolysis of U(IV) and these compounds contain coordinated hydroxide and/or oxide in addition to donor atoms from the other ligand. The relatively large ionic radius, 0.93 Å (eight coordination), and the high charge of U^{4+} results in high and often variable coordination numbers in different compounds, eight, nine and ten are

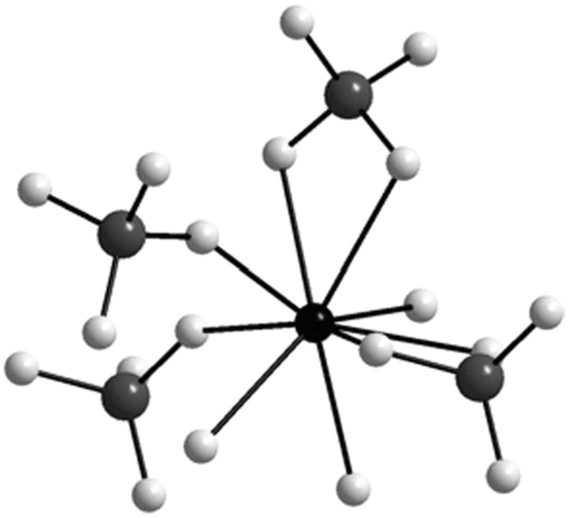

Fig. 5.57 *The coordination geometry of U(III) in $K_3U(SO_4)_3 \cdot 3H_2O$ (Barnard* et al.*, 1972a); uranium is nine-coordinated through two chelating and two monodentate sulfate ligands and three coordinated water molecules. The coordination polyhedron is strongly distorted from all the ideal geometries.*

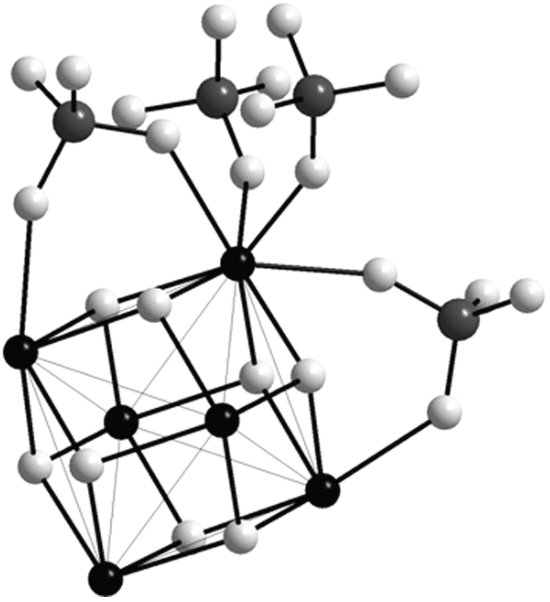

Fig. 5.58 *Structure of* $U_6(SO_4)_6O_4(OH)_4(s)$. *The characteristic structure element is an octahedron of six uranium(IV) ions (black) shown in the lower part of the figure. The oxide and hydroxide ions (light gray) are placed outside the eight triangular faces of this octahedron. The sulfate ions (sulfur is dark gray) are coordinated outside the octahedron and act as bridges between the U(IV) ions within the octahedron and between adjacent octahedra (not shown in the figure). Uranium(IV) is eight-coordinated in this compound. The structure is based on the X-ray study of Lundgren* (1952).

the most common ones. Uranium(IV) is in this respect similar to the elements in the lanthanide group, notably Ce(IV). Two examples of the coordination geometry of uranium(IV) in solid compounds are given in Figs. 5.58 and 5.59.

Fig. 5.59, based on an X-ray study of Fuchs and Gebert (1958), shows the structure of the mineral coffinite, $USiO_4$. A coordination number of eight can only be achieved by sharing all oxygen atoms in the silicate between two U(IV) atoms. The coordination geometry is best described as a triangular dodecahedron (Kepert, 1982, p. 153), the two 'arms' of which are indicated by the black full drawn lines.

The coordination number of the U(IV) and Th(IV) aqua ions in solution has been discussed based on data from Large-Angle X-ray Scattering (LAXS) and Extended X-ray Absorption Fine structure Spectroscopy (EXAFS). These methods provide accurate bond distances, while the determination of the coordination number is more uncertain, (9 ± 1). The high coordination number is retained in $UF^{3+}(aq)$, as indicated by EXAFS data (Moll *et al.*, 1999); these data demonstrate a pronounced difference in bond distance between coordinated fluoride and water; the U–F distance is 2.15 Å and the $U–H_2O$ distance 2.45 Å. The large variability of the coordination geometry in complexes of tetravalent actinides is demonstrated also by the structure of

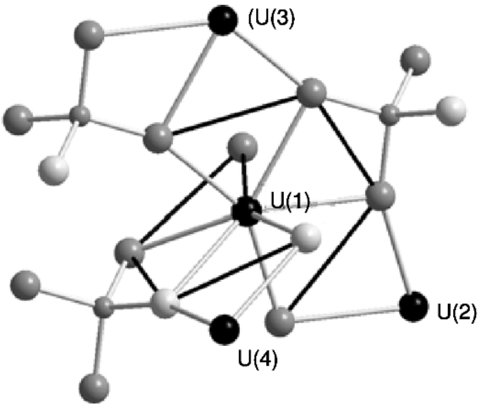

Fig. 5.59 *The structure of* $USiO_4$ *from Fuchs and Gebert* (1958). *The silicate group forms both a chelate and acts as a bridge between adjacent uranium atoms U*(2–4). *The chelate bonding is shown in the figure; the two remaining oxygen atoms in the silicate group are coordinated to adjacent uranium*(IV) *atoms not shown in the figure. The black full-drawn lines connect the atoms in the 'arms' of the dodecahedral coordination polyhedron. Each arm is approximately planar and the two planes are perpendicular.*

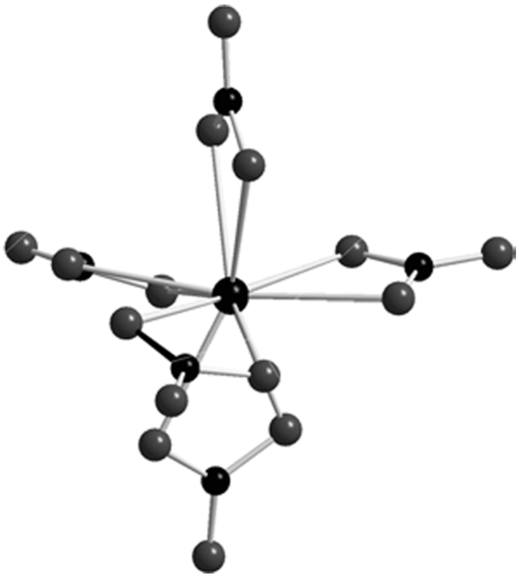

Fig. 5.60 *The structure of* $Th(CO_3)_5^{6-}$ *and the isostructural* $U(CO_3)_5^{6-}$ *from Voliotis and Rimsky* (1975).

$Na_6[Th(CO_3)_5] \cdot 12H_2O$ from Voliotis and Rimsky (1975), shown in Fig. 5.60; the corresponding uranium compound is isostructural. The carbonate ligands are arranged in an approximately trigonal bipyramidal arrangement around the central actinide ion; this geometry is very different from the common ones for ten-coordination, as discussed by Kepert (1982, p. 188). We may describe each carbonate ligand with one 'effective' charge because of its small ligand bite, resulting in a trigonal bipyramidal charge distribution in a geometry that minimizes the electrostatic repulsion between the ligands.

Another example of the variable coordination geometry is given by the structure of tetra(glycolato)uranium(IV) dihydrate, $[U(HOCH_2COO)_4] \cdot 2H_2O$ where uranium is ten-coordinated as indicated by Fig. 5.61, based on the structure data of Alcock *et al.* (1980). A recent example of the variable coordination geometry of U(IV) is the structure of the azide complex $U(N_3)_7^{3-}$, with an approximately pentagonal bipyramidal coordination geometry (Crawford *et al.*, 2005). The azide ion is linear, but the angle U–N–N–N is highly variable (from 120° to 180°).

5.9.4 Uranyl(V) compounds

There are few experimental data on the structure and bonding of uranyl(V) complexes, the only example is the structure of the uranyl(V) triscarbonate complex studied in solution using EXAFS (Docrat *et al.*, 1999). The complex has

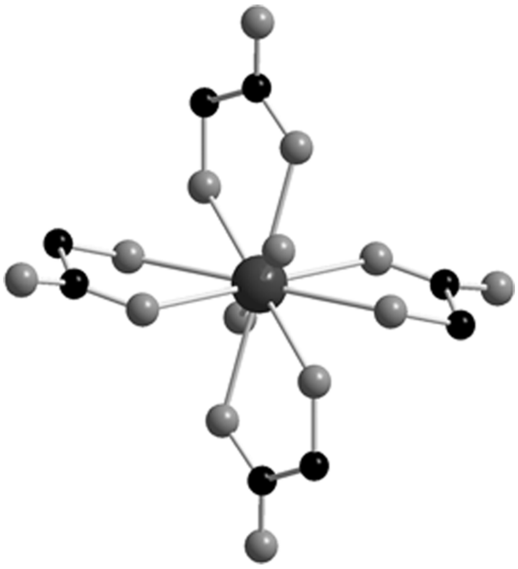

Fig. 5.61 *The coordination geometry in tetra(glycolato)uranium(IV) dihydrate from Alcock* et al. (1980). *The structure contains discrete ten-coordinated complexes* $[U(HOCH_2COO)_4(OH_2)_2]$ *with zero charge.*

hexagonal bipyramidal geometry similar to that of the uranyl(VI) triscarbonate complex, *cf*. Fig. 5.53. The corresponding information on neptunyl(V) complexes should provide good models also for the corresponding U(V) species. The geometry of the uranyl(V) and -(VI) carbonate complexes are supported by quantum chemical calculations by Gagliardi *et al.* (2001). The predominant coordination geometry is presumably a pentagonal or hexagonal bipyramid, with the labile ligands in the plane perpendicular to the linear UO_2 unit. The lower charge of the central atom results in the formation of weaker complexes and somewhat longer U–L distances than for the corresponding U(VI) complexes.

5.9.5 Uranium compounds of organic ligands

There is an abundance of organic ligands that form solid uranium complexes and we will restrict the examples to simple carboxylates, α-hydroxy and amino carboxylates.

The same structural principles as observed with the inorganic ligands are found also among the organic ones; the main difference between the two groups is that the geometry of the organic ligands puts additional constraints on the availability of the various donor atoms for bonding to uranium. In addition, the larger versatility of many organic ligands also opens up the possibility to form structural and bonding isomers.

Stoichiometric information on the constitution of complexes in solution can be obtained by an array of experimental methods (Rossotti and Rossotti, 1961), but this rarely gives information on structure and bonding. As is the case of inorganic ligands, the important methods to obtain structural information from solution are LAXS or EXAFS methods. However, both of them provide only limited structural information in the form of radial distribution functions, i.e. the distance from the central uranium atom to the atoms in the first and second coordination spheres and the number of such distances. In the case of LAXS one can also obtain information on the distances between the coordinated donor atoms. Allen *et al.* (1996b) give examples of the use of EXAFS for the deduction of structure models of uranyl(VI) tartrate, citrate, and malate complexes. Jiang *et al.* (2002) have investigated the structure and bonding of uranyl(VI) imino- and oxy-diacetate compounds and identified different modes of coordination of the ligands, an example that the stoichiometry of a complex does not provide sufficient information to identify the mode of coordination. In order to obtain more precise structure data it is often necessary to obtain additional structural information, such as provided by NMR spectroscopy (Szabó *et al.*, 1997, 2000; Moll *et al.*, 2000a,b) or by quantum chemical methods (Schreckenbach *et al.*, 1998; Tsushima *et al.*, 2001; Vallet *et al.*, 2001, 2004b; Yang *et al.*, 2003). The uranyl(VI) oxalate system provides a good example of different modes of bonding of the oxalate ligand in solid compounds and the structure of $UO_2(\text{oxalate})_3^{4-}$ complex in solution (Vallet *et al.*, 2003). The ground state structure predicted by the quantum chemical methods is the one that is found experimentally (Fig. 5.62a–c).

The stoichiometry and the value of the stability constants of the complexes given in Tables 5.33–5.37 give some indications of the mode of bonding of the ligands, in particular whether a certain ligand forms a chelate or not. A comparison between acetate and glycolate is instructive: acetate can only coordinate through the carboxylate group, either using one oxygen donor or both. In the latter case a four-membered chelate ring is formed. Glycolate can bind in the same way if only the carboxylate group is involved and one then expects a stability constant of the same magnitude for both ligands. However, glycolate can also form a chelate by using one donor atom from each of the carboxylate and the α-OH groups, in which case a five-membered chelate ring is formed. Chelate formation results in a large increase in the stability constant, *cf.* the $\log\beta_n$ values for the acetate and glycolate complexes of U(IV) in Table 5.36. The stability constants, with the exception of $\log\beta_1$, are slightly larger for the U(VI) acetate than those for the glycolate complexes, which strongly indicates the same mode of bonding of acetate and glycolate in the U(VI) complexes (Beck and Nagypál, 1990; Grenthe *et al.*, 1997). The stepwise equilibrium constants for the formation of $UO_2(ox)$ ($\log\beta_1 = 5.99$), $UO_2(ox)_2^{2-}$ ($\log K_2 = 4.65$ for the reaction $UO_2(ox) + ox^{2-} \rightleftharpoons UO_2(ox)_2^{2-}$) are large compared to the value for the formation of $UO_2(ox)_3^{4-}$ ($\log K_3 = 0.36$ for the reaction $UO_2(ox)_2^{2-} + ox^{2-} \rightleftharpoons UO_2(ox)_3^{4-}$), indicating that the third oxalate does not form a chelate. This assumption has been verified both by experimental EXAFS data from solution and by quantum chemical calculations (Vallet *et al.*, 2003) as shown in Fig. 5.62a–c. These data also illustrate the possible occurrence of isomers.

5.10 URANIUM CHEMISTRY IN SOLUTION

5.10.1 The uranium aqua ions

The most stable oxidation state of uranium in aqueous solution is 6+, with the linear uranyl(VI) ion, UO_2^{2+}, as the stable entity. The only known uranium ion in the 5+ oxidation state in aqueous solution is the linear dioxouranium(V) ion, UO_2^+. Aqueous solutions containing U^{4+} are stable in the absence of oxidation agents like dissolved oxygen. Aqueous solutions containing U^{3+} are rapidly oxidized under evolution of hydrogen. The relative stability of the various oxidation states is strongly depending on the pH of the solution and on the presence of complexing ligands as indicated in Fig. 5.63. The rate of the redox transformations between the different oxidation states of uranium is rapid when there is no change in chemical composition between the oxidized and reduced forms, otherwise it is very slow. This means that the reactions $UO_2^{2+} + e^- \rightleftharpoons UO_2^+$ and $U^{4+} + e^- \rightleftharpoons U^{3+}$ are fast, while $UO_2^{2+} + 4H^+ + 2e^- \rightleftharpoons U^{4+} + 2H_2O$ is slow.

The kinetics of the redox transformations in aqueous actinide systems has been described in a report by Newton (1975) (Section 5.10.3i). The structures and chemical properties of actinide aqua ions are discussed and compared in

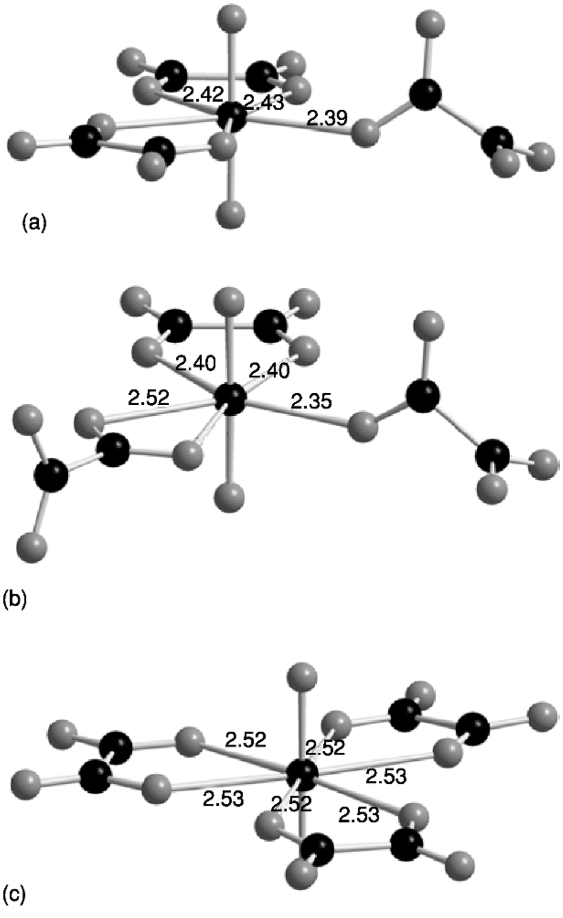

Fig. 5.62 (*a–c*) *Perspective views of three* $[UO_2(oxalate)_3]^{4-}$ *isomers, where* (*a*) *is the most stable one from Vallet* et al. (2003). *By using quantum chemical methods one can estimate the relative stability of the different isomers. The uranium atom and the carbon atoms are black and the oxygen atoms gray; distances are in ångströms. The bond distances for the ground state isomer a obtained from quantum chemical calculations agree with those obtained from EXAFS data in solution within* 0.03 Å. *The same mode of bonding has also been found in solid-state structures, but here there are no discrete complexes as the oxalate ligands act as bridges between adjacent uranium atoms.*

Chapter 23, section 2; a comparison of the complex formation properties of actinides is given in Chapter 23, sections 3–8. The kinetics of actinide reactions are compared and discussed in Chapter 23, sections 10 and 11.

Aqueous solutions of UO_2^+ are prone to disproportionation and the range of stability of U(v) is therefore small, a fact that makes it difficult to study its solution chemistry.

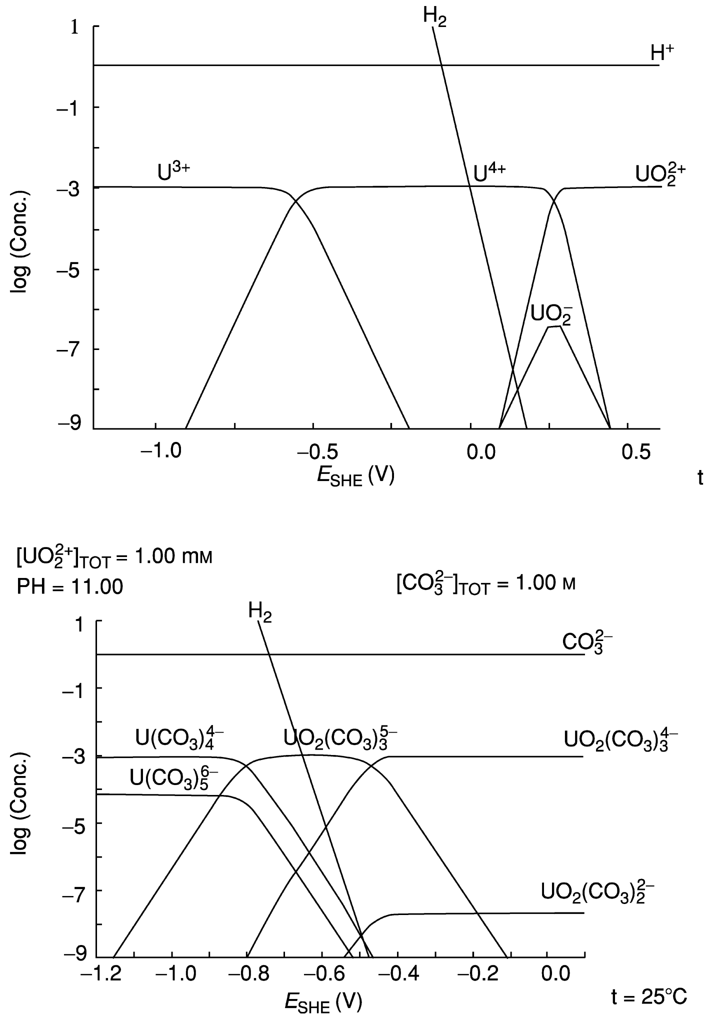

Fig. 5.63 *Logarithmic diagrams showing the distribution of U^{3+}, U^{4+}, UO_2^+ and UO_2^{2+} as a function of the redox potential in* 1 M *perchloric acid* (*the first diagram*), *and in* 1 M *Na_2CO_3* (*the second diagram*). *U*(*V*) *is predominant between* –0.7 *and* –0.4 V *in the second diagram.*

The oxygen atoms in UO_2^{2+} and UO_2^+ are kinetically inert and their rate of exchange with oxygen from water is slow, with a half-life of approximately 5×10^4 h in 1 M perchloric acid for the former (Gordon and Taube, 1961a), but much faster for the latter as indicated by the fact that UO_2^+ catalyzes the oxygen exchange between UO_2^{2+} and water (Gordon and Taube, 1961b).

However no exchange rate has been determined for UO_2^+ alone. The rate of exchange of the 'yl' oxygen atoms with the water solvent is strongly catalyzed by light in the near UV/visible region and varies with the chemical composition of the complexes present in solution as discussed in Section 5.10.3, where also some spectroscopic characteristics of the various species are described.

Solutions of U^{3+}, U^{4+}, and UO_2^{2+} can be used to prepare complexes in solution and various solid compounds using standard techniques. A treatise by Chernyayev (1966) gives an excellent account of the compounds prepared from aqueous media.

(a) Tripositive uranium, U^{3+}

Aqueous solutions of U^{3+} can be prepared by dissolving uranium trichloride in water. Alternatively, solutions of U(IV) or U(VI) can be reduced by electrolysis at a mercury cathode (Barnard *et al.*, 1967, 1972b; Weigel, 1958). The course of the reduction can conveniently be observed by the colour of the solutions in *incandescent* light: Solutions of U(VI) are yellow, while those of U(IV) and U(III) are green and wine red, respectively. These colors cannot be observed in fluorescent light. There are only few studies of the chemical properties of U^{3+} and its complexes in solution (Section 5.8.6); however the properties can often be estimated from those of the trivalent lanthanides. The standard redox potential of the U^{4+}/U^{3+} redox couple and the Gibbs energy and enthalpy of formation, entropy and heat capacity of U^{3+}(aq) have been reviewed by Grenthe *et al.* (1992) and Guillaumont *et al.* (2003). These data are reported in Table 5.32.

There is no structural information available on the U^{3+}(aq) ion, however the structure of Pu^{3+}(aq) has been determined (Matonic *et al.*, 2001) by a single-crystal X-ray diffraction study of $[Pu(H_2O)_9][CF_3SO_3]_3$. In addition, the structures of trivalent lanthanides and Am(III) and Cm(III) have been determined in solution using EXAFS (Allen *et al.*, 2000). The solid Pu(III) compound contains discrete nine-coordinated complexes that are very similar to those found among the trivalent lanthanides, in the same way the bond distances and coordination number determined from the EXAFS data are close to those in lanthanide(III) and actinide(III) complexes, indicating an aqua-ion of the composition $U(H_2O)_9^{3+}$ for trivalent uranium.

(b) Tetrapositive uranium, U^{4+}

U(IV) in the form of U^{4+}(aq) is a very strong acid and accordingly hydrolyzed except in solutions with a hydrogen ion concentration larger than 0.5 M. The hydrolysis will be discussed in Section 5.10.2b. Uranium(IV) species can be prepared by electrolysis of corresponding uranium(VI) solutions at low pH using a two-compartment cell and a mercury cathode, U(III) is formed simultaneously, but is rapidly oxidized by blowing air through the cathode

Table 5.32 *The redox potentials, Gibbs energy and enthalpy of formation, molar entropy, and heat capacity for the different uranium aqua ions under standard state conditions* (298.15 K, 0.1 MPa) *in pure water solvent at zero ionic strength* (*Grenthe* et al., 1992; *Guillaumont* et al., 2003).

compartment. Acid solutions of U(IV) are only slowly oxidized by oxygen but the situation is very different in the presence of strong complexing agents where the oxidation is very rapid and great experimental care has to be taken in order to keep the 4+ oxidation state. Uranium(IV) in acid solution can also be obtained by reduction of U(VI) with hydrogen using platinum black as a catalyst. The coordination number of the U^{4+}(aq) in solution has been studied by LAXS (Johansson, 1992) and by EXAFS (Moll *et al.*, 1999); the U–O distance is (2.42 ± 0.01) Å and the coordination number (9 ± 1). The coordination number is not well defined and the energy difference between isomers with different geometries is probably small (Kepert, 1982), an assumption supported by quantum chemical data on Th^{4+}(aq) by Yang *et al.* (2001, 2003). The rate constant for the exchange between coordinated and bulk water has been determined using ^{17}O NMR spectroscopy as discussed in section 5.10.3 (b). Experimental data for the redox potential and other thermodynamic quantities for U^{4+}(aq) have been reviewed (Grenthe *et al.*, 1992; Guillaumont *et al.*, 2003) and selected values are given in Table 5.32.

(c) Dioxouranium(V), UO_2^+

The 5+ oxidation state of uranium has a very narrow range of existence in aqueous solution, (Fig. 5.63). Millimolar solutions of UO_2^+ can be prepared by reduction of UO_2^{2+} with zinc amalgam or hydrogen, or by dissolving UCl_5 in water. A more convenient method is to irradiate a 0.5 M 2-propanol–0.2 M $LiClO_4$ solution of uranium(VI) at a pH between 1.7 and 2.7, with UV radiation from a Hg lamp (Howes *et al.*, 1988). The uranium(V) solution formed is not thermodynamically stable, but the rate of oxidation is so slow that there is little decomposition during 1 h.

There is no experimental information on the structure of UO_2^+(aq) and the number of coordinated water molecules. However, as judged by the chemical similarity between U(V) and Np(V) complexes, it is reasonable to assume that they also have a similar coordination geometry, as exemplified by the coordination geometry of different Np(V) carbonate complexes in solution is given by Clark *et al.* (1996); these structures are also very similar to those of the corresponding U(VI) system (Docrat *et al.*, 1999; Gagliardi *et al.*, 2001). Vallet *et al.* (2004a) have used quantum chemical models to predict that the most probable constitution of UO_2^+(aq) is $UO_2(H_2O)_5^+$, with pentagonal bipyramidal geometry. The thermodynamics of UO_2^+(aq) has been reviewed (Grenthe *et al.*, 1992; Guillaumont *et al.*, 2003) and the redox potential for the reaction: $UO_2^{2+}(aq) + e^- \rightleftharpoons UO_2^+(aq)$, and other thermodynamic data for UO_2^+(aq) from these reviews are given in Table 5.32. U(V) is an intermediate in the photochemical reduction of uranium(VI) (Heidt and Moon, 1953).

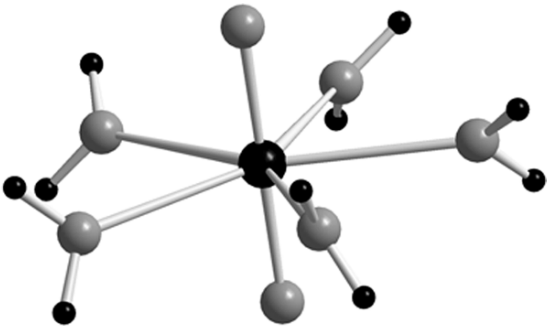

Fig. 5.64 *The coordination geometry of* $UO_2(H_2O)_5^{2+}$ *and* $UO_2(H_2O)_5^{+}$, *deduced from quantum chemical calculations using a solvent model as discussed by Vallet* et al. (2001, 2004). *Only the bond distances differ between the two structures; the U–O water distances are* 2.47 Å *in the uranyl*(VI) *aqua ion and* 2.63 Å *in the corresponding uranyl*(V) *species. The U–*O_{yl} *distance is* 0.1 Å *longer in the uranyl*(V) *compound than in the corresponding uranyl* (VI) *compound.*

(d) Dioxouranium(VI), UO_2^{2+}

The 6+ state is the most stable of the oxidation states of uranium and has accordingly been extensively studied. A large number of different compounds have been prepared from aqueous solution both by simple crystallization, by using hydrothermal techniques and other methods; numerous examples are given in other parts of this chapter. Under certain circumstances, the oxo ligands can undergo ligand exchange, scrambling, and substitution reactions; the ligand exchange reactions are in general slow but are strongly photo-catalyzed and these reactions are discussed in Section 5.10.3. The structure of the aqua ion $UO_2(H_2O)_5^{2+}$ in solution has been determined using LAXS (Åberg *et al.*, 1983) and EXAFS techniques (Wahlgren *et al.*, 1999; Sémon *et al.*, 2001; Neuefeind *et al.*, 2004b); more detailed studies have been made using quantum chemical methods (Spencer *et al.*, 1999; Wahlgren *et al.*, 1999; Hay *et al.*, 2000; Vallet *et al.*, 2001). Guilbaud and Wipff (1993), Hagberg *et al.* (2005) have determined the structure by using molecular dynamics simulations, a method that also gives some information on the structure of the second hydration sphere. The structure of the aqua ion is shown in Fig. 5.64. The redox potentials for reactions involving UO_2^{2+}(aq), and the standard Gibbs energy and enthalpy of formation, the molar entropy, and heat capacity of UO_2^{2+}(aq) from the reviews by Grenthe *et al.* (1992) and Guillaumont *et al.* (2003) are given in Table 5.32. The rate of exchange between coordinated water and the pure water solvent has been studied using ^{17}O NMR (Farkas *et al.*, 2000a), and these data are discussed in section 5.10.3(b).

5.10.2 Aqueous uranium complexes

Uranium is a very strong Lewis acid and a hard electron acceptor in all its different oxidation states. This means that the donor–acceptor interactions follow the sequences:

$$F^- \gg Cl^- > Br^- \approx I^-; O \gg S > Se; N \gg P \approx As$$

where the donors are either simple ions like fluoride, or part of a larger ion/molecule like carbonate. These sequences are expected if the donor–acceptor interactions are dominated by electrostatic forces. There is extensive information in the literature on the chemical thermodynamics of uranium complexes. Most of these data are compiled in *Stability Constants, Special Publications* No. 6 (Bjerrum *et al.*, 1957), No. 7 (Bjerrum *et al.*, 1958), No. 17 (Sillén and Martell, 1964), No. 25 (Sillén and Martell, 1971), and in the International Union of Physical and Applied Chemistry (IUPAC) Chemical Data Series, *Stability Constants of Metal-Ion Complexes, Part A* (Högfeldt, 1982) and *Part B* (Perrin, 1979). There are several critical evaluations of the compiled data; the series *Critical Stability Constants*, Vols 1–6, by Martell and Smith, is now available in a computer database that also includes the necessary software, *NIST Standard Reference Database* 46 (NIST, 2004). Grenthe *et al.* (1992) and Guillaumont *et al.* (2003) have given a more detailed critical evaluation of thermodynamic data for uranium, including a discussion of many of the experimental investigations on which the selected data are based.

The high Lewis acidity results in extensive hydrolysis of uranium that decreases in the order U(IV) > U(VI) >> U(III) > U(V). Another effect of the high Lewis acidity is that coordinated uranium exerts a very strong inductive effect on coordinated ligands, e.g. the dissociation constant of the proton in the α-hydroxy group of coordinated α-hydroxy carboxylic acids can increase by more than 13 orders of magnitude (Szabó and Grenthe, 2000) on coordination to uranium(VI); a similar effect is also found in some Th(IV) complexes (Toraishi *et al.*, 2002) and therefore most likely also in U(IV) complexes:

$$HOCH_2COO^- \rightleftharpoons {}^-OCH_2COO^- + H^+; pK \approx 17$$
$$UO_2(HOCH_2COO^-) \rightleftharpoons UO_2({}^-OCH_2COO^-) + H^+; pK = 3.6.$$

A similar example is found in the structure of the complex $[UO_2L(MeO)(MeOH)]_2$ where L is a thiosemicarbazone (Santos and Abram, 2004); this complex contains one coordinated (MeOH) and one deprotonated (MeO^-) methanol ligand. The ‘inductive effect’ is an electron redistribution in the coordinated ligand; if this is an organic species it will result in a changed ligand reactivity, a fact that has been used in preparative chemistry (van Axeel Castelli *et al.*, 2000).

(a) Uranium(III) and uranyl(V) complexes

Uranium(III) is a very strong reducing agent that is oxidized by water, hence no stable complexes can be maintained in aqueous solution. However, the chemical properties of uranium(III) are expected to be very similar to those of trivalent lanthanides, actinium(III) and the transuranium elements in oxidation state 3+. Guidance on the magnitude of equilibrium constants for U(III) species can therefore be obtained from databases for lanthanide(III) and actinide(III) elements: examples are given in Tables 5.34 and 5.36. The differences in chemical properties between U(III) and other An(III) ions and the corresponding Ln(III) species can be exploited by proper choice of ligand. This is a useful strategy for the design of An(III)/Ln(III) separation processes (Karmazin *et al.*, 2002). The narrow range of existence of uranium(V) in aqueous solution results in very little quantitative information on equilibrium constants. In view of the large chemical similarity between actinides in the same oxidation state, one may use the equilibrium constants for Np(V) complexes as estimates for the corresponding U(V) complexes (Chapter 6, section 9).

(b) Hydrolysis of uranium

A summary of the stoichiometry and equilibrium constants of the various hydroxide complexes are given in Table 5.33: they refer to reactions of the type

$$p\mathrm{M} + q\mathrm{H_2O} \rightleftharpoons \mathrm{M}_p(\mathrm{OH})_q + q\mathrm{H}^+$$

where all charges except for H^+ have been omitted for simplicity, and where M denotes, UO_2^{2+} UO_2^+, U^{4+}, or U^{3+}; the equilibrium constants are taken from Grenthe *et al.* (1992), Guillaumont *et al.* (2003) and Baes and Mesmer (1976).

In most of the experimental determinations of hydrolytic equilibria it is not possible to decide if the species formed contain coordinated hydroxide and/or oxide; the reason being that $2OH^- \equiv O^{2-}$ in experiments where the equilibrium constants and the stoichiometry are deduced from measurements of the free hydrogen ion concentration; this is an example of the so-called 'proton ambiguity' (Rossotti and Rossotti, 1961). The following example illustrates the point:

$$3\mathrm{UO_2^{2+}} + 5\mathrm{H_2O} \rightleftharpoons (\mathrm{UO_2})_3(\mathrm{OH})_5^+ + 5\mathrm{H}^+$$
$$3\mathrm{UO_2^{2+}} + 5\mathrm{H_2O} \rightleftharpoons (\mathrm{UO_2})_3(\mathrm{O})(\mathrm{OH})_3^+ + 5\mathrm{H}^+ + \mathrm{H_2O}$$

Both reactions result in the formation of five H^+ and can therefore not be distinguished. As the activity of water is a constant, the stability constant is the same for both stoichiometric formulations. This tri-nuclear complex was originally formulated as $(UO_2)_3(OH)_5^+$, but when structural data became available the actual composition turned out to be $(UO_2)_3(O)(OH)_3^+$, with the structure given in Fig. 5.65 (Åberg, 1978).

Except at very low total concentrations of uranium, the polynuclear hydroxide complexes are predominant for all oxidation states, with the possible exception of U(v). There are no experimental data for U(iii), but its behavior can be estimated from the chemically analogous Cm(iii) ion, for which precise data are available.

The coordination chemistry of $U(OH)_4$(aq) and UF_4(aq) (Section 5.10.2c) deserves a comment. Because of the strong inductive effect of uranium on the dissociation of H^+ from coordinated water one would have expected the formation of anionic hydroxide complexes according to

$$U(OH)_4(H_2O)_n \rightleftharpoons U(OH)_5(H_2O)_{n-1}^- + H^+$$

if water is present in the first coordination sphere. However, there is no experimental indication of the formation of negatively charged hydroxide complexes even in 1 M hydroxide solutions. A coordination number of four is unlikely in view of the large ionic radius of U^{4+}. A possible resolution of this dilemma might be that the complex formulated as $U(OH)_4$(aq) is a polymer, e.g. a tetramer $U_4(OH)_{16}$ with one of the A_4X_{16}-type structures (Wells, 1990, p. 201), where the coordination number of A, in this case uranium(iv), is six. Hydroxide and fluoride ions have similar size and often replace one another in solid-state structures. One might therefore expect that their coordination geometry is similar also in aqueous solution. However, UF_4(aq) is not the limiting stoichiometry in aqueous solution where two negatively charged fluoride complexes UF_5^- and UF_6^{2-} have been identified (Table 5.34). This indicates a coordination number of at least six in the U(iv)–fluoride system, the same as the coordination number for $U(OH)_4$(aq) if this has an $U_4(OH)_{16}$ structure. Polynuclear complexes, e.g. U_4F_{16}(aq) do not form because of the poor bridging ability of fluoride in aqueous solution.

(c) Complexes between uranium and other inorganic ligands

Uranium(IV) and uranium(VI) form very strong fluoride complexes, while those formed with Cl^-, Br^-, and I^- are weak. There are no experimental data for halide complexes of U(V) and U(III); however, data from the chemically analogous Np(V) and Cm(III) indicate that they are all weak, the strongest being the fluoride complexes. The strength of complexes containing ligands with oxygen donors, such as sulfate, sulfite, phosphate, carbonate, silicate, and nitrate increases strongly with the charge and base strength of the ligand. However, complexes of the strongest bases such as $HSiO_4^{3-}$ and SiO_4^{4-} are difficult to study in aqueous solution because of competition from OH^- (and the formation of sparingly soluble hydrous oxides) at the high pH where these ions are present in significant amounts.

Strong complexes are also formed between UO_2^{2+} and the peroxide ion and the mode of coordination of the ligand is known from solid state structures (Fig. 5.56a and b). Examples of uranyl(VI) peroxide complex formation in solution have been given by Djogic and Branica (1992), Gurevich *et al.* (1971a,b), and

Moskvin (1968). However, most of the stability constants are uncertain (Sillén and Martell, 1971; NIST, 2004).

Ternary complexes of the type MA_qH_r may be formed when the ligand is the anion of a polyprotic acid.

The stoichiometry and equilibrium constants of uranium complexes of inorganic ligands are given in Table 5.34 where the data are taken from Grenthe *et al.* (1992) and Guillaumont *et al.* (2003). The structure of the complexes may be inferred from the known coordination geometry of the central uranium atom and from the structure of the ligand. However, quantitative information requires other methods, either X-ray or neutron diffraction data from solid compounds containing the ligands, or from EXAFS spectroscopy of solutions. It is interesting to note that the tetrahedral sulfate (Moll *et al.*, 2000b) and phosphate ions (Dusausoy *et al.*, 1996) rarely form chelates in solid compounds. In most cases the ligands are bonded either through a single oxygen donor, or act as a bridge between different uranium atoms (Figs. 5.51, 5.52, 5.57, and 5.58). In solution, however, EXAFS data indicate that the sulfate ion forms a bidentate chelate in $UO_2(SO_4)_2^{2-}$ and in ternary hydroxide–sulfate complexes (Moll *et al.*, 2000b) but not in $UO_2SO_4(aq)$ (Neuefeind *et al.*, 2004a). On the other hand, carbonate invariably forms complexes where the ligand is chelate-bonded to uranium via two oxygen atoms (Fig. 5.66).

The data in Table 5.34 provide the experimental basis for describing uranium as a strong Lewis acid, or as a hard acceptor. Uranium also forms complexes of moderate stability with inorganic nitrogen donors like azide, N_3^-, and thiocyanate, SCN^- (Table 5.35). Uranium does not form ammine complexes in aqueous solution; ammines are strong bases and under the conditions where complexes might form the pH is so high that the stronger uranium hydroxide complexes predominate. However, N-donor complexes are found in organic ligands of various types, some examples are given in Table 5.36.

(d) Complexes between uranium and some important organic ligands

Two groups of ligands will be discussed, those containing carboxylate functional groups alone and those containing in addition one or more hydroxy or amino/imino groups; the first group is exemplified by acetate and oxalate, and the second by glycolate, glycine, iminodiacetate, and ethylenediaminetetraacetate ($EDTA^{4-}$). The stoichiometry and stability constants for the corresponding UO_2^{2+} and U^{4+} complexes are listed in Table 5.36. There is no experimental information available for U(III) and the equilibrium constants have been estimated from corresponding data for trivalent lanthanides and other trivalent actinides. The first chemical issue to be discussed is the mode of bonding of the ligand; the stoichiometry and the magnitude of the stability constants provide some insight, but more precise information requires direct structure information, either from X-ray or neutron diffraction, EXAFS spectroscopy, or from quantum chemistry. The relative magnitude of the stepwise stability constants often gives indication of changes in the mode of bonding of the ligand and structural changes of the complexes. An example is the stepwise stability constants of oxalate complexes of U(VI) (Table 5.36). It is also tempting to relate the very small equilibrium constant for the reaction $U(CO_3)_4^{4-} + CO_3^{2-} \rightleftharpoons U(CO_3)_5^{6-}$ (Table 5.34) to a structural rearrangement from a trigonal bipyramid arrangement of the carbonate ligands in $U(CO_3)_5^{6-}$ with CN = 10, (Fig. 5.60), to a tetrahedral arrangement with CN = 8 in $U(CO_3)_4^{4-}$ (the carbonate ligand is modelled with a single point change). The small stability constant for $UO_2(Hgly)^{2+}$, where Hgly is the "zwitter-ion" form of glycine, $^+H_3NCH_2COO^-$ indicates that the ligand is bonded only at the carboxylate end.

The equilibrium constants for the glycine complexes also deserve a comment. The predominant form of glycine at pH < 8 is the zwitter-ion; this means that one has to take the possible formation of complex with the formally uncharged zwitter-ion into account, which has not always been done in the

Table 5.36 *Stability constants for complexes between U(VI), U(IV), and U(III), and some organic ligands; acetate (ac^-); glycolate/α-hydroxyactate (α-ac^-), oxalate (ox^{2-}), glycinate ($glyc^-$), iminodiacetate ($IMDA^{2-}$), ethylenediamine-tetraacetate ($EDTA^{4-}$). The equilibrium constants are taken from Smith and Martell* (1989). *For some of the reactions, we have tabulated the equilibrium constant for the corresponding Th(IV) and Ce(III) complexes that should be good models for U(IV) and U(III).*

[a] From Szabó and Grenthe (2000).

published studies. The corresponding complexes with gly$^-$ are strong as indicated by log $k = 13.0$ for the reaction $UO_2^{2+} + 2gly^- \rightleftharpoons UO_2(gly)_2(aq)$ (Szabó and Grenthe, 2000). Aliphatic nitrogen donors are strong bases and the competition between H^+ prevents coordination to uranium unless the pH is above 6. The interpretation of experimental results is then complicated by the possible formation of binary and ternary complexes containing hydroxide. Sessler *et al.* (2001) have reviewed complex formation between uranium and macrocyclic ligands; these complexes together with organometallic complexes of uranium are discussed in Chapter 25.

(e) Ternary uranium complexes

Most experimental studies of uranium complexes in aqueous solution have been made in two-component systems (metal ion and ligand). Accordingly, most of the published equilibrium constant data refer to binary M_pL_q complexes. However, in experimental studies performed in water one must also take the possibility of the formation of ternary $M_pL_q(OH)_r$ complexes into account. When the ligand is a polyprotic acid also species of the type $M_pL_qH_r$ may form (the phosphate complexes in Table 5.34). The 'proton ambiguity' referred to in the case of hydroxide complexes, cf. $(UO_2)_3(OH)_5^+$ vs. $(UO_2)_3(O)(OH)_3^+$), is also found in other cases, notably for polyprotic ligands. An example is the UO_2^{2+}–glycolate system where there is a large difference in the dissociation constants of the carboxylate and α-hydroxy group. When studying the complex formation with this ligand using potentiometric methods, it is not possible to distinguish between the following two reactions:

$$UO_2^{2+}(aq) + HOCH_2COO^- \rightleftharpoons UO_2(OCH_2COO) + H^+$$

and

$$UO_2^{2+}(aq) + HOCH_2COO^- + H_2O \rightleftharpoons UO_2(HOCH_2COO)(OH) + H^+$$

To decide on the stoichiometry of the complex formed, it is necessary to use other methods, e.g. NMR spectroscopy as discussed by Szabó *et al.* (2000) and Toraishi *et al.* (2003).

It is possible to use coordination chemical data to decide on the conditions where ternary complexes containing different ligands (except OH^- and protonated ligands) may form; Beck and Nagypál (1990) and Grenthe *et al.* (1997) have discussed this issue and point out that the strength of a ternary complex MA_qB_r depends strongly on the strength of the binary complexes MA_q and MB_r and the steric constraints imposed by metal ion and ligands. Hence, ternary complexes are not common even in multicomponent systems; most of them contain fluoride or hydroxide, both strong donors that do not impose large steric constraints on the second ligand. Table 5.37 gives examples of some ternary uranium(VI) complexes. Note that the presence of the strongly binding oxalate and carbonate ligands has only a moderate influence on the strength of

bonding of fluoride as compared to that in the binary fluoride system. Ternary uranium(IV) complexes containing hydroxide/oxide ligands are abundant both in solid state structures and in solution. An example of the latter is U(EDTA) $(OH)^-$, where the equilibrium constant for the reaction $U(EDTA)(aq) + H_2O \rightleftharpoons U(EDTA)(OH)^- + H^+$ is equal to $\log^*K = -9.3$ (Smith and Martell, 1989), indicating a very large decrease in the acid strength of coordinated water from that in U^{4+}(aq), where $\log^*K$ is equal to –0.54 (see Table 5.33).

(f) Complex formation between UO_2^+ and other cations

The lower effective nuclear charge on uranium (V) as compared to uranium(VI) in uranyl ions results in a correspondingly larger negative charge of the 'yl' oxygen atoms (Vallet *et al.* (2004a). Electrostatic interactions between the 'yl' oxygen in MO_2^+ and the high positive effective charge of M(VI) in MO_2^{2+} is probably the reason for the formation of weak cation–cation complexes between the two. Newton and Baker (1965) were first to identify these species for UO_2^+ and UO_2^{2+} and Sullivan *et al.* (1961) for NpO_2^+ and UO_2^{2+}; Frolov and Rykov (1979) have reviewed the field.

5.10.3 Reaction mechanisms of ligand substitution reactions

The analysis of the rate and mechanism of chemical reactions requires information on the experimental rate equation and the thermodynamics of the reaction studied; in addition the structure and coordination geometry of reactants, intermediates, and products provide important clues on the microscopic details of the reaction. The rate equation describes how the rate of reaction depends on the concentration of different chemical species in the reacting system, some of them may appear as reactants/products in the total (stoichiometric) reaction, but this is not always the case. The rate equation may be simple or complex depending on the mechanism; details on the analysis of rate equations are given in standard texts on chemical kinetics, e.g. Katakis and Gordon (1987), Wilkins (1991) and Espenson (1995). 'Mechanism' is defined as the sequence of elementary reactions that transform the reactant(s) to product(s); these different steps can rarely be studied in isolation, but have to be inferred from the experimental rate equation and the activation parameters $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta V^{\neq}$ of the reaction. The rate equation rarely provides a unique mechanistic model for a certain reaction: one reason is that it contains only stoichiometric information on the rate determining step and the fast equilibria preceding this, but no information on the fast reactions following the rate-determining step. The mechanism deduced from the rate equation is usually referred to as the *stoichiometric mechanism* of the reaction; the *intimate mechanism* describes the molecular details of a certain reaction, e.g. the timing of bond breaking and bond formation.

The information on rates and mechanisms of ligand substitution reactions in uranium complexes is limited and in general only includes information on rate equations, while the mechanistic discussions are much more speculative. Most experimental data refer to uranyl(VI) complexes where three reviews provide some details. Lincoln (1979) and Tomiyasu and Fukutomi (1982) have reviewed reactions that mostly take place in non-aqueous solvents, while Nash and Sullivan (1998) have reviewed the kinetics and mechanism of actinide redox and complexation reactions in aqueous solution. Vallet *et al.* (2004b) have discussed the combination of experimental and quantum chemical methods for the elucidation of the intimate mechanism of solvent exchange and ligand substitution in uranyl(VI) complexes.

Substitution reactions of simple unidentate ligands in uranium complexes are in general very fast and require special experimental methods (stopped-flow, temperature jump and other relaxation methods; NMR spectroscopy). Only the uranyl(VI) fluoride system has been studied in detail (Szabó *et al.*, 1996).

Most of the experimental studies of ligand substitution have been made using multidentate ligands. These reactions involve several elementary reactions, chelate ring opening/ring closure, and ligand dissociation/association steps. In addition, the ligands are often protolytes and the rate equation therefore depends on the hydrogen ion concentration. All these factors result in complicated rate equations from which it is difficult to deduce the reaction mechanism. The activation parameters, $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta V^{\neq}$ (of which only the first two are known for reactions involving uranium) provide additional mechanistic information that in some cases can be corroborated by quantum chemical methods as will be described later. The ligand substitution reactions with multidentate ligands are conveniently followed using conventional stopped-flow spectrophotometric methods. Experiments of this type start from a system that is not in equilibrium and its evolution is then followed until equilibrium has been attained. In many cases the reaction has to be followed by using a color indicator and this introduces additional complications when deducing the reaction mechanism (Friese *et al.*, 2001).

A more direct method to obtain mechanistic information on ligand exchange reactions is to use NMR equilibrium dynamics with ^{1}H, ^{13}C, ^{17}O, and ^{19}F as the NMR-active nuclei. The use of ^{17}O-enriched UO_2^{2+} and ternary complexes containing fluoride have been particularly useful as the high sensitivity and wide chemical shift scales of these nuclei makes it possible to study a very large range of exchange rates. A typical example is the exchange reaction

$$UO_2(H_2O)_5^{2+} + H_2O^* \rightleftharpoons UO_2(H_2O^*)_5^{2+} + H_2O$$

that was studied using proton-NMR in mixed water–acetone media by Ikeda *et al.* (1979a) and Bardin *et al.* (1998) and by ^{17}O-NMR in water by Farkas *et al.* (2000a). An analogous example is the exchange between dimethyl sulfoxide (DMSO) and $UO_2(DMSO)_5^{2+}$ in DMSO solvent that was studied by Ikeda *et al.* (1979b). It should be noted that the NMR methods give information on all reactions that contribute to the dynamics at the reaction center. Hence one can use one NMR-active ligand as a probe to provide information on the dynamics of other ligands that are not easily studied using NMR, an example is the use of ^{19}F-NMR to estimate of the rate of water exchange in $UO_2(oxalate)F(H_2O)_2^-$ and $UO_2(oxalate)F_2(H_2O)^{2-}$ (Szabó *et al.*, 1997).

The range of rates that can be studied using NMR depends on the magnitude of the chemical shift between the NMR-active nuclei located in different exchanging sites, the larger the chemical shift the faster processes can be studied. The NMR method can be used in different ways: (a) as an analytical tool where the concentration is measured as a function of time. This method can only be used if the rate of exchange is slow in comparison with the time for measurement; (b) using magnetization transfer, which is a method appropriate for reactions with half-lives of a few seconds; (c) by measurement of the line-broadening which is the method for study of the fastest reactions. The NMR-active nuclei may be located in different chemical surroundings in the same complex allowing studies of intramolecular exchange, or located in different species, e.g. a complex and free ligand, making studies of intermolecular exchange possible. In order to provide accurate data the different sites must have similar concentrations.

It is often difficult, or impossible to use the NMR method to study the rate and mechanism of the formation of the first complex in systems where strong complexes are formed (Szabó *et al.*, 1996) because the free ligand concentration is here very small. In these cases stopped-flow technique is a useful alternative; on the other hand, NMR spectroscopy is superior when studying the rate and mechanism of limiting complexes (Ikeda *et al.*, 1984; Szabó *et al.*, 1997). A summary of experimental kinetic data is given in Tables 5.38 and 5.39, and a general discussion of the mechanistic conclusions in the following section.

(a) Reaction mechanisms

The Eigen–Wilkins mechanism describes the stoichiometric mechanism for many ligand substitution reactions; it includes the following two steps where N denotes the coordination number:

$$[(H_2O)_N M]^{n+} + [(H_2O)L^-] \rightleftharpoons [(H_2O)_N M \ldots L]^{(n-1)} + H_2O \qquad (1)$$

$$[(H_2O)_N M \ldots L]^{(n-1)+} \rightarrow [M(H_2O)_{N-1}L]^{(n-1)+} + H_2O \qquad (2)$$

Reaction (1) describes the formation of an outer-sphere ion pair; this is a fast diffusion controlled equilibrium reaction with equilibrium constants K_{os}. The second reaction is rate-determining with the rate constant k_2 (unit s^{-1}); it involves the substitution of water in the first coordination sphere of the metal ion with a ligand from the second coordination sphere. This situation may arise when L is a unidentate ligand, but also for polydentate ligands, when the rate of chelate ring-closure is fast. The rate equation deduced from the two elementary reactions is often approximated by the expression

$$\frac{-\mathrm{d}[M(H_2O)]}{\mathrm{d}t} = \frac{k_2 K_{os}[M(H_2O)][L]}{1 + K_{os}[L]} \cong k_2 K_{os}[M(H_2O)][L]$$

K_{os} is usually estimated using the Fuoss equation (Fuoss, 1958).

For reactions where the experimental rate equation has the form

$$\frac{-\mathrm{d}[M(H_2O)]}{\mathrm{d}t} = k_{obs}[M(H_2O)][L]$$

we have $k_{obs} = k_2 K_{os}$. The analysis of experimental rate data using the Eigen–Wilkins mechanism is described by Katakis and Gordon (1987) and Wilkins (1991). The intimate mechanism of the water–ligand exchange can be associative, A, dissociative, D, or of interchange type, I. The assignment is based on the identification of intermediates (A and D); if no intermediates are identified the reaction is classified as interchange (I) (Langford and Gray, 1965). The A intermediate has a higher and the D intermediate a lower coordination number than that of the reactant; in both cases there are two transition states along the reaction pathway. As no intermediate is formed in the interchange mechanism there is only one transition state. A rate constant k_{obs}, that is largely independent on the chemical nature of the entering ligand, indicates that the reaction mechanism is of dissociative type; the rate constant that depends strongly on the entering ligand is a characteristic of an associative mechanism. Szabó *et al.* (1996) have discussed fluoride exchange reactions in $UO_2F_n^{2-n}$ complexes using the Eigen–Wilkins mechanism.

The accessible coordination number at the metal center is often an important indicator when selecting the reaction mechanism. The characteristic coordination number for U(VI) and U(V) is five, but complexes with coordination numbers four and six are not uncommon; also U(IV) and U(III) have variable coordination numbers (9 ± 1). Hence, the coordination number is of little value as a mechanistic indicator in these cases, as neither associative nor dissociative mechanisms can be excluded. The size and charge of the metal ion and the ligand are also important for the mechanism; large ligands cannot enter the first coordination sphere until room is available through the dissociation of water. If water dissociation is rate determining, the intimate mechanism of the ligand exchange is dissociative; if the entry of the ligand from the second coordination sphere is rate determining the mechanism is associative.The simplest and most fundamental of the exchange reactions takes place between the aqua ions and the water solvent and this rate is often an important indicator for the mechanism of ligand substitution reactions of the Eigen–Wilkins type.

(b) Rates and mechanism of water exchange

The rate of water exchange has been studied both by proton NMR line-broadening at low temperature in mixed water–acetone solvents and in water containing 1 M $NaClO_4$. A complicating factor in experiments of this type is that it is not possible to vary the concentration of water in a pure water solvent; this is possible in the mixed water–acetone solvent. In the latter case, however, the concentration changes are often so large that the interpretation of the experimental data is ambiguous. Rate constants and activation parameters for the water exchange reactions are given in Table 5.38.

Because of the fast rate of exchange it is not possible to identify intermediates in these reactions and the rate equation alone is not sufficient to make a mechanistic assignment. This can be obtained by comparing the experimental activation energy with those for the D, A, and I mechanisms (Scheme 5.1), obtained using quantum chemical methods to identify the pathway of lowest activation energy; this value can then can be compared with the experimental data (Vallet *et al.*, 2001, 2004b). The theoretical activation energy of the pathways D, A, and I are 74, 19, and 21 kJ mol^{-1}, respectively; the dissociative pathway can be ruled out because of its high activation energy, while both the A and I mechanisms are consistent with the experimental value,

Table 5.39 *Experimental rate constants and activation parameters for some ligand substitution and ligand exchange reactions in aqueous uranyl(*VI*) systems studied by NMR and stopped-flow methods. The NMR experiments have been made in equilibrium systems where the rates of the forward reaction and the reverse reaction are equal. The stopped-flow experiments have been made under non-equilibrium conditions. The reactions in the table are in some cases elementary reactions; in other cases the mechanism is more complex and involves consecutive and/or parallel reactions. The ligand notation is: acetate ≡ ac; oxalate ≡ ox; picolinate ≡ pic; i-pentyl- picolinate ≡ i-pent-pic; 5-nitro-picolinate ≡ NO*$_2$*-pic; dipicolinate ≡ dipic; oxydiacetate ≡ oda. The following notation is used for the different fluoride ligands:* [a] *central fluoride,* [b,c] *edge fluorides. The rate constant in the forward and reverse directions is denoted +1 and –1, respectively;* k_{ex} *denotes an exchange reaction without net chemical change.*

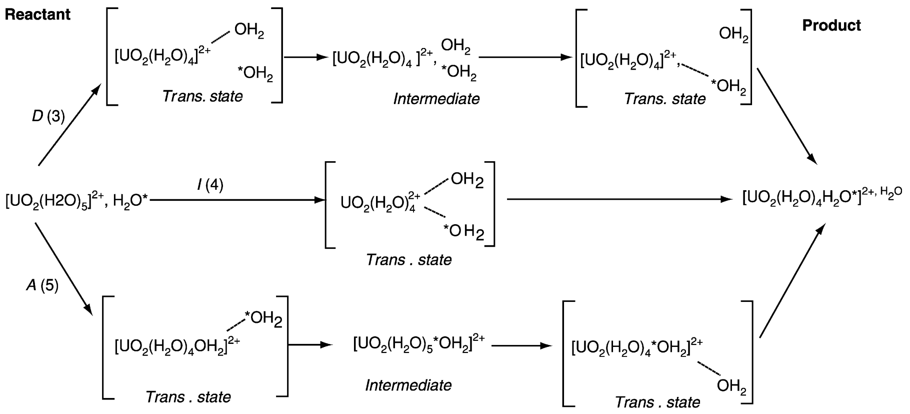

Scheme 5.1 *The scheme shows the dissociative (D), associative (A) and interchange (I) pathways for the water exchange between* $UO_2(OH_2)_5^{2+}$ *and water solvent from Vallet* et al. (2001) (*by permission of the American Chemical Society*).

$\Delta H^{\neq} = 26$ kJ mol^{-1}. The small difference in activation energy between these two pathways is understandable from the very similar structures of their transition states (Fig. 5.67a and b).

There are no experimental water exchange data for

$$UO_2(H_2O)_5^+ + H_2O^* \rightleftharpoons UO_2(H_2O^*)_5^+ + H_2O$$

However, the reaction has been studied using quantum chemical methods (Vallet *et al.* 2004a). In this system no stable intermediate $UO_2(H_2O)_6^+$ was found, hence the reaction cannot be associative. It was only possible to identify the reaction pathway for the dissociative mechanism with the electronic activation energy $\Delta E^{\neq} = 36.4$ kJ mol^{-1}. As judged by the activation energy one would expect the rate of water exchange to be slower in the uranyl(v) aquo-ion than that for the A/I mechanisms of the uranyl(vi) ion. However, the rate of reaction is determined by the Gibbs energy of activation, $\Delta G^{\neq} = \Delta H^{\neq}(\approx \Delta E^{\neq}) - T\,\Delta S^{\neq}$, where the activation entropy is larger for the D than for the A/I reactions (Wilkins, 1991, p. 202). Hence it is a reasonable assumption that the rate of water exchange in $UO_2(H_2O)_5^+$ is not too different from that in $UO_2(H_2O)_5^{2+}$.

The rate of water exchange and the activation energy for the reaction

$$U(H_2O)_n^{4+} + H_2O^* \rightleftharpoons U(H_2O^*)_n^{4+} + H_2O$$

has been determined experimentally (Farkas *et al.*, 2000b). The coordination number *n* is probably (9 ± 1), the rate constant 5.4×10^6 s^{-1} at 298 K and the activation enthalpy 34 kJ mol^{-1}. From the experimental data alone, it is not possible to determine the reaction mechanism. However, a quantum chemical study by Yang *et al.* (2003) of the water exchange in the corresponding thorium system indicates that the water exchange between $Th(H_2O)_9^{4+}$ and the water

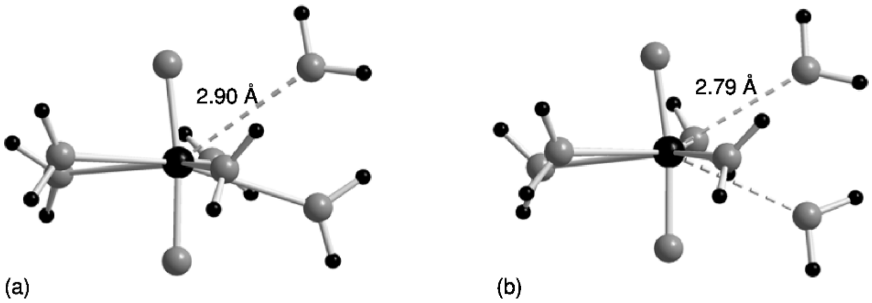

Fig. 5.67 (*a*) *Transition state in the A mechanism for the water exchange in the uranyl*(vi) *aqua ion. The geometry of the intermediate is very close to that of the I transition state*; *the bond distance in the entering and leaving water molecules are both* 2.65 Å. (*b*) *Transition state in the I mechanism. The U–H_2O distance for the two ligands above and below the equatorial plane in the I transition state is* 2.79 Å.

solvent takes place through an associative mechanism; from this we suggest that the mechanism is the same also for $U(H_2O)_9^{4+}$.

There are no experimental data for ligand exchange reactions in U(iii) complexes, but Helm and Mehrbach (1999) have made extensive studies of the water exchange reactions of the trivalent lanthanides that are chemically very similar to the trivalent actinides. Based on these data, one expects the substitution mechanisms on U(iii) to be similar to the nine-coordinated early lanthanides and to follow a dissociative mechanism.

(c) Water exchange in uranyl(vi) and uranium(iv) complexes

It is often assumed that the rate of water exchange at metal complexes is larger than that of the corresponding aqua ions. This does not seem to be the case for uranyl(vi) complexes as shown by the rate constant of water exchange in $UO_2(oxalate)F(H_2O)_2^-$ and $UO_2(oxalate)F_2(H_2O)^{2-}$, that are approximately 2×10^3 s^{-1} (Table 5.39); this is much smaller than that of $UO_2(H_2O)_5^{2+}$ ($k_{ex} = 1.3 \times 10^6$ s^{-1}; Szabó *et al.*, 1997). The rate constant of water exchange in $UF(H_2O)_8^{3+}$ is not significantly different from that in $U(H_2O)_9^{4+}$ (Farkas *et al.*, 2000b).

(d) Rates and mechanisms of complex formation reactions with inorganic and organic ligands

The rates and mechanisms of complex formation reactions have been studied both in equilibrium systems using NMR methods and in non-equilibrium systems using mainly stopped-flow and relaxation methods. In the former case the reactions are typically

$$ML_n + L^* \rightleftharpoons ML_n^* + L;$$

The rate constants in the forward and reverse directions are denoted k_1 and k_{-1}, respectively; as the system is in equilibrium the *rates* in the forward and reverse directions are the same. This is not the case in the non-equilibrium reactions where one often can arrange the experimental conditions so that the reverse reaction can be neglected; that is the reactions studied are of the type

$$\mathrm{ML}_n + \mathrm{L} \rightarrow \mathrm{ML}_{n+1}$$

Some examples of experimental data, rate constants, and activation parameters are given in Table 5.39. The rate equations and reaction mechanisms have been deduced by investigating how the reaction rate depends on the concentration of reactants, products, and catalysts like H^+. The mechanistic deductions are complicated for multidentate ligands that in general are moderately strong bases; the rate of reaction is therefore often strongly dependent on the pH. Hines *et al.* (1993), Ekstrom and Johnson (1974), and Pippin and Sullivan (1989) give examples of such systems using the ligands diphosphonic acids and 4-(2-pyridylazo) resorcinol. However, the mechanisms of these reactions are far from clear. The rates of exchange for the ligands in Table 5.39 have been studied in more detail and some general comments about rate constants and mechanisms can therefore be made.

The rate of dissociation of coordinatively saturated complexes varies strongly with the strength of the complexes, e.g. from $2.7 \times 10^3\ \mathrm{s}^{-1}$ for the acetate exchange in $UO_2(\text{acetate})_3^-$ to $0.38\ \mathrm{s}^{-1}$ for the rate of dissociation of UO_2(dipicolinate); the latter ligand forms a very strong three-dentate chelate complex. The rate of formation and dissociation of UO_2(dipicolinate) and $UO_2(CO_3)F_3^{3-}$ are proton-catalyzed; the same is certainly the case for UO_2(oxydiacetate), but here there is only experimental data at one pH.

For multidentate ligands the mode of coordination is not always known and it is also unlikely that the formation or dissociation of such complexes takes place in one step. Hence, the experimental rate equation does not provide information on the rate-determining step. Some information may be obtained using the Eigen–Wilkins mechanism as exemplified by the rate constant for the formation of UO_2(dipicolinate) and UO_2SO_4. Both rate constants have nearly the same value (Table 5.39) indicating that the reaction is not strongly dependent on the entering ligand; this is a typical feature of dissociative reactions where the rate of water dissociation from the first coordination sphere is rate-determining. However, in the Eigen–Wilkins mechanism the experimental rate constant is a product of the rate of water exchange and the equilibrium constant for the formation of an outer-sphere complex with the entering ligand. A crude estimate of K_{os} for sulfate and dipicolinate is 5–50 M^{-1}, which would correspond to a rate constant for the water dissociation equal to $(0.7–0.07) \times 10^3\ \mathrm{s}^{-1}$. This is very different from the experimental value for the water exchange, indicating that the mechanism is more complex, suggesting that the rate of chelate ring closure/ring opening might have a significant effect on the rate of formation/dissociation of the complexes. Hurwitz and Kustin (1967) have studied the rate and mechanism of reactions between UO_2^{2+} and SO_4^{2-}, SCN^-, CH_3COO^-, and $ClCH_2COO^-$ using the temperature jump method. The rate of complex formation with sulphate is 180 $\mathrm{M}^{-1}\ \mathrm{s}^{-1}$ at 20°C, very different from the value obtained by Moll *et al.* (2000b) using NMR. This is not an ionic strength effect that would result in a larger rate constant at lower ionic strength (Wilkins, 1991, p. 110). The bimolecular rate constants for the formation of the 1:1 complex between UO_2^{2+} and actate and monochloracetate are 1050 and 110 $\mathrm{M}^{-1}\ \mathrm{s}^{-1}$. Hurwitz and Kustin (1967) note that the most significant feature of their observations is the relative slowness of the substitution reactions and their strong ligand dependence. This indicates that the substitution reactions are associative.

Jung *et al.* (1988) have determined the rate and mechanism of the formation and decomposition of the binuclear hydroxide complex $[(UO_2)_2(OH)_2]^{2+}$. The rate is sufficiently slow so that NMR line broadening of $U^{17}O_2^{2+}$ can be used. The rate equation is

$$\mathrm{Rate} = k_2[UO_2^{2+}][UO_2OH^+] - k_{-2}K_a[H^+][(UO_2)_2(OH)_2^{2+}]/2$$

where K_a is the equilibrium constant for the reaction $(UO_2)_2(OH)_2^{2+} + H^+ \rightleftharpoons (UO_2)_2(OH)^{3+} + H_2O$. The suggested mechanism consists of two steps:

$$UO_2^{2+}UO_2OH^+ \rightleftharpoons (UO_2^{2+} \ldots UO_2(OH^+)) \rightarrow [UO_2 - (OH) - UO_2]^{3+}$$

that are followed by the fast reaction

$$(UO_2)_2(OH)^{3+} + H_2O \rightleftharpoons (UO_2)_2(OH)_2^{2+} + H^+.$$

The first step is the formation of an outer-sphere ion pair and the second is rate determining. The estimated rate constant for this step is $7.6 \times 10^5\ \mathrm{s}^{-1}$, close to the rate of water exchange in the aqua ion. Frei and Wendt (1970) have studied the rate of dissociation of the binuclear complex using the stopped-flow method and also they suggested a mechanism where a single OH-bridged intermediate is formed.

Ligand exchange between a limiting complex (the complex with the largest number of coordinated ligands) and free ligand is most conveniently studied by using NMR methods. A typical example is the rate of ligand exchange for the reaction

$$UO_2F_5^{3-} + {}^*F^- \rightleftharpoons UO_2{}^*F_5^{3-} + F^-$$

As one reactant is a coordinatively saturated complex it is unlikely that the ligand exchange takes place according to an associative mechanism. It also turns out that the rate of ligand exchange for the above and many other reactions involving limiting complexes is independent on the concentration of free ligand, confirming that the exchange mechanism is dissociative (Vallet *et al.*, 2002). This result is supported by quantum chemical calculations, which demonstrate that there is no stable intermediate $UO_2F_6^{4-}$ (Ikeda *et al.*, 1984; Szabó *et al.*, 1997; Vallet *et al.*, 2002).

(e) Mechanisms of intramolecular reactions

Important examples within this group are chelate ring opening/ring closure reactions, exemplified by the complex UO_2(picolinate)F_3^{2-}, (Fig. 5.68) (Szabó *et al.*, 1997; Vallet *et al.*, 2004b) and the experimental data in Table 5.39. In this complex there are three non-equivalent fluoride ligands, F_A, F_B and F_C, as shown in the ^{19}F NMR spectrum. The central peak, F_C, is narrow, indicating a slow exchange on the NMR time-scale while the other two peaks are broad, corresponding to a rate constant of 300 s^{-1} for the exchange between the F_A and F_B sites. This exchange is a result of an intramolecular process as the intermolecular exchange between coordinated and free fluoride is much slower, k_{obs} = 13 s^{-1} for F_A and F_B and 24 s^{-1} for F_C. The intramolecular exchange between F_A and F_B is the result of a a chelate ring opening/closure reaction that results in a rotation of the picolinate ligand and an exchange of the F_A and F_B sites The rate of exchange for the intermolecular exchange of picolinate is much slower, 4.7 s^{-1}.

The exchange between the different isomers of UO_2(picolinate)$_2F^-$ (Fig. 5.69) probably also takes place through a ring opening/ring closure reaction; a similar reaction mechanism has also been proposed for the kinetics of intra- and

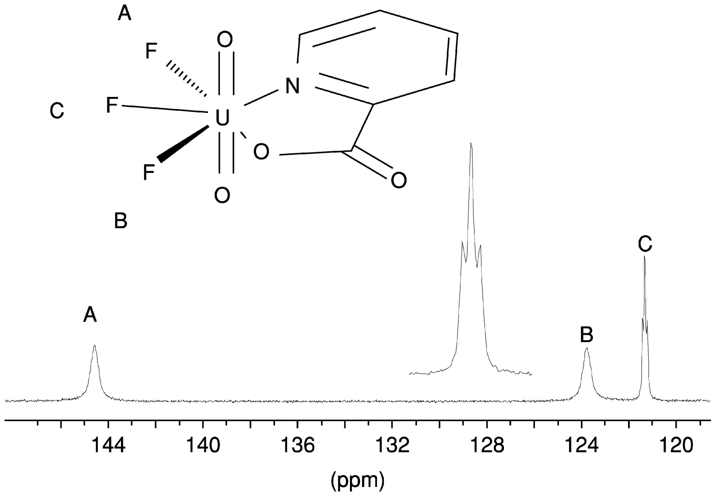

Fig. 5.68 *The ^{19}F NMR spectrum of UO_2(picolinate)F_3^{2-}at –5°C showing peaks for the three different fluorides (from Szabó* et al. *(1997), reproduced by the permission of American Chemical Society). There is no visible spin–spin coupling in the exchanged broadened peaks for fluorides A and B. Spin–spin coupling, a collapsed doublet of doublets, is evident in the narrow peak C, cf. the insert.*

(1997), *reproduced by the permission of American Chemical Society*). *The exchange presumably takes place through chelate ring opening/ring closure reactions.*

intermolecular exchange reactions of nonamethyl-imidodiphosphoramide (NIPA) in $UO_2(NIPA)_3^{2+}$ (Bokolo *et al.*, 1981).

Intramolecular reactions of the type encountered in $UO_2(picolinate)_2F^-$ do not necessarily proceed through chelate ring opening/ring closure as exemplified by $UO_2(acac)_2L$, in Fig. 5.70, where acac is a β-diketonate like acetylacetonate or dibenzoylmethanate and L an uncharged ligand such as dimethylsulfoxide (DMSO) (Ikeda *et al.*, 1984). The two methyl groups in the acetylacetone ^{13}C NMR spectrum are equivalent at room temperature due to fast exchange, but not at low temperature. The rate of intermolecular exchange between coordinated and free acac is slow and the fast exchange between the two methyl groups is therefore not the result of chelate ring opening/ring closure but of the fast dissociation/reentry of the ligand L that also results in exchange between the methyl groups (Fig. 5.70); the chelate ring opening is a very slow reaction.

Kramer and Maas (1981) have studied the fluxionality in U(VI) complexes of trifluoroacetylacetonate and various uncharged bases and suggest that the fluxionality of the complexes is a result of an intramolecular base migration; however, it is difficult to envisage that such a reaction is geometrically feasible.

(f) Rate and mechanism of ligand exchange in non-aqueous systems

The proposed mechanisms and activation parameters for ligand exchange in uranyl(VI) complexes between a number of uncharged ligands in non-aqueous systems are given in Table 5.40. The experimental rate constant k_{obs} for many of the reactions is given by

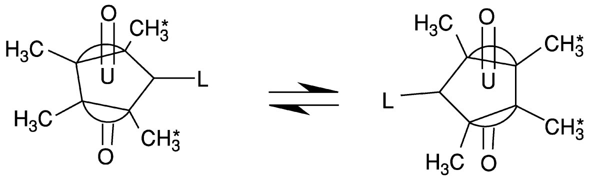

Fig. 5.70 *Ligand exchange in acetylacetonato complex $UO_2(acac)_2L$. The methyl groups in the coordinated acetylacetonate are non-equivalent as a result of their different chemical surroundings. The two sites are in fast exchange at room temperature as a result of the fast dissociation/re-entry of the ligand L.*

$$k_{\mathrm{obs}} = k_1 + k_2[\mathrm{L}],$$

where [L] is the free ligand concentration. In most systems k_2 is equal to zero, indicating a dissociative mechanism as seen in Table 5.40. When $k_2 \neq 0$ the rate of exchange depends on the ligand concentration, indicating an associative pathway. The difference in exchange mechanism for water (associative or associative interchange mechanism) and the dissociative pathway for the ligands in Table 5.40 is probably due to the larger steric constraints for the latter ligands. The occurrence of two parallel pathways, e.g. for DMSO indicates that the energy difference between complexes with four-, five-, and six-coordinated DMSO ligands is small. It is worth noting that there is no connection between the suggested mechanisms and the activation entropy for these reactions that all involve an uncharged ligand.

(g) Rate and mechanism of 'yl'-oxygen exchange in uranyl(VI) and uranyl(V) complexes: isotope exchange reactions

The rate of exchange between the 'yl'-oxygen atoms in UO_2^{2+}(aq) and the water solvent is very slow, the half-life is 5000 to 10000 h as demonstrated by Gordon and Taube (1961a) using ^{18}O-enriched uranyl(VI). They noticed that the rate of exchange depends on the hydrogen ion concentration and that the reaction was photo-catalyzed. The fact that the exchange is very fast in the photo-excited state of the uranyl(VI) aqua ion (Bell and Buxton, 1974) has been used to prepare uranyl(VI) complexes where the 'yl'-oxygens are isotope-enriched in ^{17}O or ^{18}O (Howes *et al.*, 1988). The rate of exchange of the 'yl'-oxygens and the water solvent is strongly catalyzed by UO_2^+(aq) (Gordon and Taube, 1961b). These two observations indicate that the exchange is related to the weakening of the U–O$_{\mathrm{yl}}$ bond. In the photo-excited state, this is the result of transfer of a bonding electron to an empty f-orbital, and in UO_2^+(aq) from the f-electron that is localized in a nonbonding f-orbital (Vallet *et al.*, 2004a). There are few precise and reproducible experimental observations and the mechanism for the exchange reaction has therefore not yet been clarified. Gordon and Taube (1961b) suggested that the rate law for the UO_2^+-catalyzed exchange

Table 5.40 *Mechanisms and activation parameters for the exchange of monodentate uncharged ligands, L, in the uranyl(*VI*) complexes $UO_2L_5^{2+}$ and $UO_2L_4^{2+}$. The solvent is deuterated acetone or dichloromethane. The ligands are: dimethylsulfoxide (DMSO),* N,N,*-dimethylacetamide (DMA), trimethylphosphate (TMP), triethylphosphate (TEP),* N-*methylacetamide (NMA), diethylphosphate (DEP), tetramethylurea (TMU), and hexamethylphosphoramide (HMPA).*

$U^*O_2^{2+} + H_2O \rightleftharpoons UO_2^{2+} + H_2{}^*O$ is first order in $[UO_2^+]$ and suggest the mechanism

$$UO_2^+ + H_2{}^*O \rightleftharpoons U^*O_2^+ + H_2O$$

$$U^*O_2^+ + UO_2^{2+} \rightleftharpoons U^*O_2^{2+} + UO_2^+$$

where the first reaction is assumed to be fast, but the details of the oxygen exchange are not known and quantum chemical studies, similar to those of Schreckenbach *et al.* (1998) and Clark *et al.* (1999) on UO_2^{2+}, have not been made to our knowledge. Howes *et al.* (1988) have studied the second reaction and use the experimental data, in combination with the Marcus' cross-relations, to estimate the rate constant for the outer-sphere self-exchange to be in the range 1–15 M^{-1} s^{-1}, a value that is in good agreement with quantum chemical estimates by Privalov *et al.* (2004).

There are a number of other experimental studies of exchange between uranyl (VI) complexes and water, using ^{17}O-enriched uranyl(VI). This exchange is pH-dependent and much faster than in the $UO_2^{2+}(aq)$. The half-life is less than 1 h in the pH range where polynuclear complexes containing hydroxide/oxide bridges are present (Moll *et al.*, 2000b); the rate of exchange is much slower in $UO_2(OH)_4^{2-}$ and $UO_2(OH)_5^{3-}$ and very slow in limiting complexes that do not contain water or hydroxide in the first coordination sphere. Schreckenbach *et al.* (1998) and Clark *et al.* (1999) have discussed the mechanism, however the estimated activation energy seems large (160 kJ mol^{-1}).

(h) Isotopic exchange reactions involving uranium

Isotopic exchange using ^{233}U as a probe has been used to study the rate and mechanism of exchange reactions between UO_2^{2+}, UO_2^{+}, and U^{4+}. These studies have been made in acid solutions where the degree of hydrolysis is known. The exchange can take place either through bond breaking/bond formation or through electron transfer. The following exchange reaction is a typical example (Rona, 1950; Masters and Schwartz, 1961):

$$U^{4+}(aq) + {}^{*}UO_2^{2+}(aq) + 2H_2O \underset{k_r}{\overset{k_f}{\rightleftharpoons}} 2{}^{*}UO_2^{+}(aq) + 4H^{+}$$

where *U denotes uranium enriched in ^{233}U. The reaction follows two parallel pathways where the rate of exchange for the forward reaction at [U(IV)] < 0.01 M is equal to

$$\text{Rate} = k_f[U^{4+}][UO_2^{2+}][H^+]^{-3} \quad \text{with } k_f = 2.1 \times 10^{-7}\ \text{M}^{-1}\ \text{s}^{-1} \text{ at } 25°\text{C}$$

Imai (1957) studied the rate for the reverse reaction and found

$$\text{Rate} = k_r[UO_2^{+}]^2[H^+] \quad \text{with } k_r = 436\ \text{M}^{-2}\ \text{s}^{-1} \text{ at } 25°\text{C}$$

The ratio $k_r/k_f = 2 \times 10^9$ M^4 is in good agreement with the experimental equilibrium constant 1×10^9 M^4, indicating that both reactions have the same transition state. A slightly lower value of $k_r \approx 130$, was determined by Kern and Orleman (1949). The rate of exchange of the forward reaction is slow because it goes thermodynamically 'uphill', a result of the extensive bond breaking/bond formation during the exchange. The reverse reaction is fast because the reaction is now thermodynamically favored.

The intimate mechanism for most isotope exchange reactions is not known; for the U(IV)–U(V)–U(VI) reaction there is only information on the stoichiometry of the activated complex, $[HOUOUO_2^{3+}]^{\neq}$ and the activation energy 157 kJ mol^{-1}. At U(IV) concentrations higher than 0.01 M, there is a significant contribution from a second reaction pathway and the rate of exchange is now

$$\text{Rate} = k[U^{4+}]^2[UO_2^{2+}][H^+]^{-2}$$

but the mechanistic implications are not clear.

It is often difficult to decide if isotope exchange takes place through bond breaking/bond formation, or as a result of electron transfer; the isotope exchange between uranyl(VI) and uranyl(V) and other actinyl ions are typical examples. Kato *et al.* (1970) studied the exchange between UO_2^{2+} and U^{4+} by measuring the transfer of ^{18}O-enriched 'yl' oxygen to water. The rate constant was 6.5×10^{-4} M^{-1} s^{-1}, is very different from that of Masters and Schwartz (1961) that used different experimental conditions. Kato *et al.* suggested that the activated complex has the composition $[U(IV)U(VI)]^{\neq}$ and that the rate of oxygen exchange and electron exchange are of the same order of magnitude.

A number of the redox reactions to be discussed in the following section have been investigated experimentally using isotope exchange technique.

(i) Rate and mechanism of redox reactions

These reactions are in general studied using isotope exchange as exemplified by

$$U^*O_2^{2+}(aq) + UO_2^+(aq) \rightleftharpoons UO_2^{2+}(aq) + U^*O_2^+(aq)$$

The rate of exchange has been studied using ^{18}O-enriched UO_2^{2+} by following the isotope distribution using mass spectroscopy after separation of U(VI) and U(V) (Gordon and Taube, 1961b; Masters and Schwartz, 1961). The experimental rate of exchange is equal to

$$\text{Rate} = k_{obs}[UO_2^{2+}][UO_2^+]$$

with $k_{obs} \approx 50$ M^{-1} s^{-1} (Gordon and Taube, 1961b), close to the more accurate determination of the corresponding exchange reaction between Np(VI) and Np(V), $k_{obs} \approx 110$ M^{-1} s^{-1}, determined by Cohen *et al.* (1954). Howes *et al.* (1988) report rate constants in the range 1–15 M^{-1} s^{-1}. Privalov *et al.* (2004) have discussed the mechanism for the U(V)–U(VI) electron exchange between the aqua-ions, the fluoride, and the carbonate complexes using quantum chemical methods. Both outer-sphere and inner-sphere mechanisms were studied; the former for the aqua ions using the Marcus model and the latter using an inner-sphere model for binuclear complexes containing hydroxide, fluoride, and carbonate bridges. The calculated rate constant for the homogeneous electron exchange (outer-sphere) between $UO_2^{2+}(aq)$ and $UO_2^+(aq)$ is 26 M^{-1} s^{-1} in fair agreement with experimental data. The rate of electron transfer for the inner-sphere reactions is much faster, but here there are no experimental data that can be used for comparison. This study provides a model for the intimate reaction mechanisms as exemplified by the following structure of the precursor and transition state structures (Fig. 5.71).

The kinetics of redox reactions is also discussed in Chapter 23.

Rate constants and reaction mechanisms for a number of redox reactions involving uranium have been reported by Newton (1975) and in the second edition of this book (Katz *et al.*, 1986). It is not possible to discuss all this

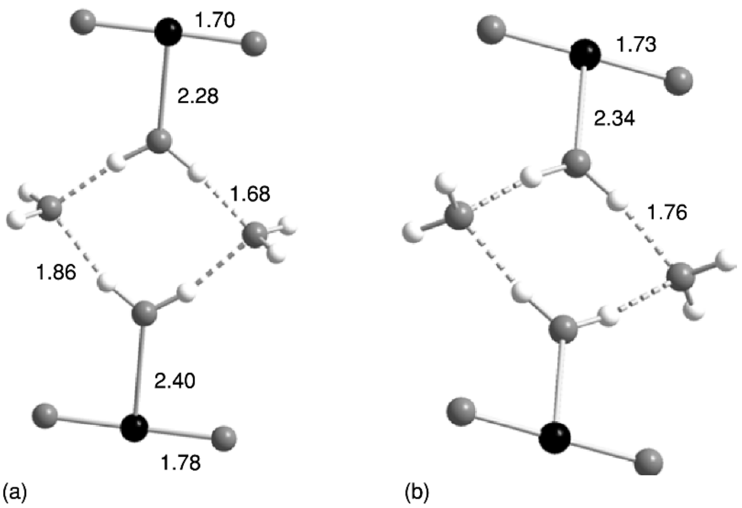

Fig. 5.71 *Quantum chemical model of the precursor* $[UO_2^{2+} \ldots UO_2^{+}]$ *in the outer-sphere electron transfer reaction* $U^*O_2^{2+}(aq) + UO_2^{+}(aq) \rightleftharpoons UO_2^{2+}(aq) + U^*O_2^{+}(aq)$ *from Privalov* et al. (2004). *The model is focused on the bridge between the two uranyl ions and their complete coordination spheres are therefore modeled using a continuum model.* (*a*) *shows the precursor with uranyl(*V*) and uranyl(*VI*) ions and* (*b*) *the transition state where the two uranyl ions are equivalent.*

information and we have accordingly selected a few examples that illustrate the interpretation of the experimental rate laws. A prerequisite for the mechanistic discussion is information on the equilibrium system, i.e. the complexes present in the test solutions under different experimental conditions. When determining the experimental rate law, care must be taken to identify possible parallel reaction pathways and possible catalysts. We will discuss the oxidation of U(IV) with Pu(VI) as this reaction is not only of scientific interest, but also important in nuclear reprocessing (Newton, 1958). In acid solutions of moderate concentration of the reactants, there is a complete reduction of Pu(VI) to Pu(III). When the reactant concentrations are about 10^{-4} M 96% of the U(IV) reacts according to

$$2\mathrm{Pu(VI)} + \mathrm{U(IV)} \rightleftharpoons 2\mathrm{Pu(V)} + \mathrm{U(VI)}$$

and the remaining 4% react according to

$$2/3\mathrm{Pu(VI)} + \mathrm{U(IV)} \rightleftharpoons 2/3\mathrm{Pu(III)} + \mathrm{U(VI)}$$

The latter two equations only represent the change in oxidation states of the actinides but do not account for the overall stoichiometry. At constant hydrogen ion concentration, the experimental rate law is

$$-\frac{\mathrm{d}[\mathrm{Pu}(\textsc{vi})]}{\mathrm{d}t} = 2k''[\mathrm{Pu}(\textsc{vi})][\mathrm{U}(\textsc{iv})]$$

This rate equation requires that the activated complex has the composition $[\mathrm{Pu(VI)}\cdots\mathrm{U(IV)}]^{\neq}$; as the hydrogen ion concentration is constant, there is no information of the hydrogen ion concentration dependence of the reaction rate. Based on this limited information, a possible reaction mechanism that involves the following two elementary reactions has been suggested (charges have been omitted):

$$\mathrm{Pu}(\textsc{vi}) + \mathrm{U}(\textsc{iv}) \rightleftharpoons \mathrm{Pu}(\textsc{v}) + \mathrm{U}(\textsc{v})$$

$$\mathrm{Pu}(\textsc{vi}) + \mathrm{U}(\textsc{v}) \rightleftharpoons \mathrm{Pu}(\textsc{v}) + \mathrm{U}(\textsc{vi})$$

The first reaction is rate-determining as it involves a major rearrangement between the coordination spheres of reactants and products, while the second is fast because these rearrangements are minor.

Additional mechanistic information is obtained by investigating how the rate of reaction depends in the hydrogen ion concentration. One finds that the rate is

$$-\frac{\mathrm{d}[\mathrm{Pu}(\textsc{vi})]}{\mathrm{d}t} = 2k''\left(1 + \frac{K}{[\mathrm{H}^+]}\right)[\mathrm{PuO}_2^{2+}]\,[\mathrm{U}^{4+}]$$

This rate law suggests that there are two parallel pathways according to the following elementary reactions:

$\mathrm{U}^{4+} + \mathrm{H_2O} = \mathrm{UOH}^{3+} + \mathrm{H}^+$ (a fast equilibrium prior to the rate-determining step);

$\mathrm{UOH}^{3+} + \mathrm{PuO}_2^{2+} \rightleftharpoons \mathrm{HOUOPuO}^{5+}$ (rate-determining step in a reversible reaction);

$\mathrm{HOUOPuO}^{5+} = \mathrm{OUOPuO}^{4+} + \mathrm{H}^+$ (a fast equilibrium reaction);

$\mathrm{OUOPuO}^{4+} + \mathrm{H_2O} \rightleftharpoons \mathrm{UO}_2^+ + \mathrm{PuO}_2^+ + 2\mathrm{H}^+$ (a slow equilibrium reaction).

The elementary reactions above provide information on the stoichiometric mechanism, but not the details at the microscopic level, as that exemplified in Fig. 5.71 for the electron transfer reaction

$$\mathrm{U^*O}_2^{2+}(\mathrm{aq}) + \mathrm{UO}_2^{+}(\mathrm{aq}) \rightleftharpoons \mathrm{UO}_2^{2+}(\mathrm{aq}) + \mathrm{U^*O}_2^{+}(\mathrm{aq}).$$

5.10.4 Fluorescence properties and photochemistry of uranyl(VI) complexes

Only light that is absorbed by a substance is effective in producing a photochemical change; Grotthuss and Draper stated this principle of photochemical activation in 1818, long before the quantum theory. According to quantum theory, the primary step of a photochemical reaction is the activation of *one* molecule by *one* absorbed quantum of radiation. The absorption of a photon leads to a transition from a singlet ground state to a singlet excited state; this is followed by a number of very fast processes with lifetimes in the picosecond

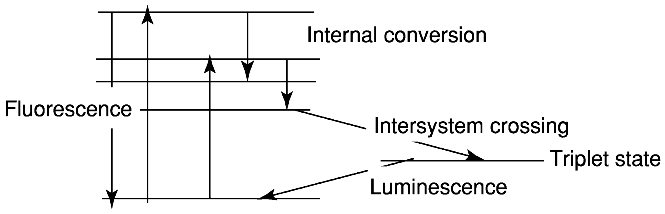

Fig. 5.72 *Molecular energy levels where the arrows denote the corresponding process for energy loss of the excited states. The ground state is a singlet, the excitation takes place without change of spin. The excited states can lose energy by fluorescence back to the ground state, via internal conversion from higher to lower excited states and by intersystem crossing to the triplet state. The typical fluorescence lifetime in the excited state is* 10^{-8} *to* 10^{-9} s *and for internal conversion* 10^{-12} s. *The energy loss from the triplet state to the ground state takes place either by luminescence/phosphorescence or thermally. In addition energy dissipation can take place through non-radiative decay and collisional quenching.*

range that take place before any photochemical reaction can occur. *Fluorescence* takes place from an excited singlet to the ground state, *internal conversion* between the excited singlet states, and *intersystem crossing* from the lowest excited singlet state to the triplet state (Fig. 5.72). The lifetime of the triplet state is long (micro to milliseconds) in comparison with that of the singlet states; the radiative emission from triplet to singlet is called phosphorescence. The long lifetime of the triplet also makes thermal energy dissipation possible.

There are other energy dissipation pathways than fluorescence from the excited states such as non-radiative transfer of the excitation energy to vibrational excitation in the coordinated ligands and the solvent and in collisional pathways, so called dynamic quenching; a more detailed discussion is given by Szabó *et al.* (2006). The intensity of fluorescence or phosphorescence depends on the competition between these physical and chemical processes. The quantum yield, Q_Y, is defined as the ratio between the number of photons emitted and absorbed and this quantity is accordingly strongly dependent on the different quenching mechanisms

$$Q_Y = \frac{1/\tau_n}{1/\tau_n + k_{nr}} = \frac{\tau}{\tau_n}$$

where τ_n is the lifetime in the absence of non-radiative processes and k_{nr} the rate constant for non-radiative decay; τ is the lifetime in the presence of non-radiative processes. In systems with dynamic quenching it is $1/\tau = 1/(1/\tau_n + k_{nr} + k_q)$, where k_q is the rate constant for collision quenching.

In addition to these quenching processes, the fluorescence intensity may also depend on static quenching that is the result of the formation of a non-fluorescent complex with a ligand, L, in the ground state. In order to understand and use information of fluorescence intensity and fluorescence lifetimes, it is essential to be able to distinguish and quantify all these mechanisms. Static and dynamic quenching can be distinguished by lifetime analysis (Toraishi *et al.*, 2004).

In steady-state excitation the concentration of excited molecules and therefore the fluorescence intensity is constant. Hence, we have the following relations in the absence and presence of quenching:

$$\frac{dI^*}{dt} = f - (1/\tau_0)[I^*] = 0;$$

and

$$\frac{dI^*}{dt} = f - \left(1/\tau_0 + k_q[L][I^*]\right) = 0$$

where f is the light flux, I^* is the concentration of the fluorescent species with a lifetime τ_0 in the absence of the quencher L. k_q is the rate constant for fluorescence decay in the presence of L. Hence

$$\left(\frac{I}{I_0}\right)^{-1} = \frac{1/\tau_0 + k_q[\mathrm{L}]}{1/\tau_0} = 1 + k_q\tau_0[\mathrm{L}]$$

where I and I_0 represent the measured fluorescence intensity in the presence and absence of L; this is the Stern–Volmer equation. The fraction of excited fluorophores relative to the total is equal to

$$\left(\frac{I}{I_0}\right) = \left(\frac{\tau}{\tau_0}\right)$$

which for the case of only static quenching in the ground state reduces to $(I/I_0) = 1$ because then $\tau = \tau_0$.

In uranyl(VI) systems where the ligand is a strong quencher, the rate constant k_q is very large; it is then not possible to detect the fluorescence spectrum for the complexes (e.g. Moll *et al.*, 2003).

The photochemistry of uranium compounds is a ‘classical’ field of research that dates back to the Becquerels more than 100 years ago. The experimental quantities are the excitation and emission spectra and the lifetime(s) of the excited state(s) as a function of chemical parameters. The chemistry of photo-excited UO_2^{2+} has been extensively studied, both as a tool for synthesis, as a method to determine equilibrium constants in ground and excited states, and for elucidation of luminescence quenching mechanisms. Recent reviews by Baird and Kemp (1997), Fazekas *et al.* (1998), and Yusov and Shilov (2000) provide an introduction to the literature.

The photo-oxidation of oxalic acid was used in the first chemical actinometers to measure photon flux based on the reactions

$$\begin{aligned}&UO_2^{2+} + h\nu \rightarrow (UO_2^{2+})^*;\\&(UO_2^{2+})^* + (COOH)_2 \rightarrow UO_2^{2+} + CO_2 + CO + H_2O\end{aligned}$$

The actinometer must be calibrated to determine the quantum efficiency at the wavelength used.

The excited states responsible for luminescence emission have a charge-transfer character as a result of excitations from the σ_u or σ_g bonding U–O orbitals to an empty f-orbital via internal conversion and intersystem crossing as outlined in Fig. 5.72. The resulting triplet state is $^3\Delta_g$, or to be more precise the $\Omega = 1_g$ component of the relativistic $^3\Delta_g$ state (Zhang and Pitzer, 1999; Matsika *et al.*, 2001) and the transition to the ground state is accordingly spin forbidden, which accounts for the long lifetime. The very long lifetime in comparison with those from electronically excited states of organic molecules is the basis for the photo-reactivity of $(UO_2^{2+})^*$. The photo-excited state is a very strong oxidant with an estimated oxidation potential of 2.6 V. The probable deactivation pathways are (Fazekas *et al.*, 1998):

- intra-molecular radiationless deactivation via O-H stretch modes of coordinated water;
- intra-molecular energy transfer to vibrational modes of the water solvent as in rare-earth metal ions;
- electron transfer and radical formation

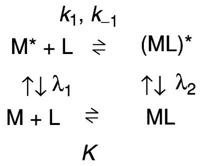
  $$(UO_2^{2+})^* + H_2O \rightarrow UO_2^+ + (H_2O^+)^*;$$

  or hydrogen abstraction

  $$(UO_2^{2+})^* + H_2O \rightarrow UO_2H^+ + OH^*$$

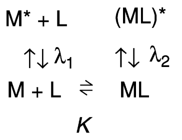
The experimental basis for photochemical studies is provided by fluorescence spectroscopy and measurements of the decay of the fluorescence as a function of chemical parameters. The terminology is often misleading, the majority of the experimental 'fluorescence' spectra of uranyl(VI) systems refer to phosphorescence, often denoted luminescence. In the following we will use the luminescence terminology. Despite all experimental efforts there is no consensus about the primary deactivation processes. The luminescence properties of the uranyl(VI) ion in water solution can be used as an example. When the pH is increased in the UO_2^{2+}–water system, the peaks of the emission spectrum are displaced towards longer wavelength. At the same time, the luminescence lifetime is no longer mono-exponential; this is presumably a result of the formation of hydroxide complexes (Fazekas *et al.*, 1998). Moriyasu *et al.* (1977) made similar observations on other uranyl(VI) systems where complexes with fluoride and phosphate were formed, in particular they observed a strong enhancement of both the luminescence intensity and its lifetime that is the basis for an analytical method to determine uranium in low concentration. The increase of the lifetime of the triplet state is assumed to be a result of shielding of the uranyl ion from water that is an efficient quencher. Some authors explain the non-exponential luminescence decay by exciplex formation (Deschaux and Marcantanatos, 1979), other by a reversible crossing between two different excited uranyl states (Formosinho and Da Graca Miguel, 1984; Formosinho *et al.*, 1984). Billard and Lützenkirchen (2003) have discussed the problems encountered when analyzing experimental luminescence data in terms of elementary reactions as discussed below.

Laser-induced fluorescence spectroscopy is extensively used as a tool for the analytical determination of trace amounts of uranium as described in Chapter 30. The technique is also used to determine equilibrium constants and the speciation of uranium(VI) in aqueous solution both in laboratory and environmental systems. This raises the question if the measured equilibrium constant, K_{app}, refers to the ground or the excited state, a problem that has been discussed by Billard and Lützenkirchen (2003). Their starting point is the following mechanistic scheme (Scheme 5.2): where K is the equilibrium constant in the ground state, k_1 and k_{-1} the rate constants for the formation and dissociation of ML*, and λ_1 and λ_2 the rate constants for decay of M* and ML*.



Scheme 5.2 *Mechanistic scheme for the complex formation between M and L in ground and excited state. The notation is explained in the text.*

In the experimental studies, time-resolved spectra are measured at different total concentrations of M and L, where the former is the fluorescence probe and the latter is assumed to be non-absorbing at the excitation wavelength. Scheme 5.2 has been used to deduce rate constants k_1 and k_{-1} and information on ground state and excited state chemistry from the amplitude of the emission spectra and ground state concentrations. In the case where there is no interaction between M* and L, or when the rate constants k_1 and $k_{-1} \ll \lambda_1$ and λ_2, Scheme 5.2 is reduced to Scheme 5.3 as follows:



Scheme 5.3 *Mechanistic scheme for reactions where the complex formation in the excited state can be neglected.*

where the measured lifetimes now represent M* and ML*. Billard and Lützenkirchen (2003) discuss the conditions under which K_{app} is a satisfactory approximation for the equilibrium constant K in the ground state. In their Model A, k_1 and $k_{-1} \ll \lambda_1$ and λ_2 and $K_{\mathrm{app}} = K$ is then a good approximation. When k_1 and $k_{-1} \gg \lambda_1$, the chemistry in the excited state is dominating and the apparent equilibrium constant, K_{app} is then equal to

$$K_{\mathrm{app}} = K^* \frac{\alpha\tau_1}{\beta\tau_2}$$

where α and β are the molar absorption coefficients and τ_1 and τ_2 the lifetimes of M* and ML* (Model C). In systems where k_1 and $k_{-1} \approx \lambda_1$ and λ_2, one has to use numerical simulations to deduce the rate constants from the experimental data (Model B). K^* is the equilibrium constant for the formation of ML*.

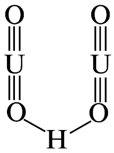
Billard and Lützenkirchen (2003) discuss a number of time-resolved laser fluorescence studies of uranyl complexes using the model outlined above. For example, in the uranyl–hydroxide system can be described by either Model A or B. Lopez and Birch (1997) observed two decay times that were independent of pH in the range 2.5–4.5, indicating that $K_{\mathrm{app}} = K$.

(a) Quenching mechanisms of the uranyl ion

Quenching is in general described by the Stern–Volmer mechanism as described previously; it can proceed through a number of different reactions as outlined by Baird and Kemp (1997). Quenching by halide ions most likely takes place by electron transfer as indicated by the fact that the quenching efficiency depends on the oxidation potential, and decreases in the order $I^- > Br^- > Cl^- > F^-$; metal ions in low oxidation states like Ag^+, Fe^{2+}, and Mn^{2+} are also efficient quenchers that also act through an electron transfer mechanism.

Many organic compounds are very efficient quenchers and the mechanism involves either a process where the quencher forms a short-lived exciplex with the excited uranyl, or an electron transfer. In the latter case, the relative quenching rate depends on the ionization potential of the quencher (as for the halide ions). Burrows and Kemp (1974) have reviewed quenching reactions with different alcohols where hydrogen abstraction may be an important quenching mechanism as indicated by large primary hydrogen isotope effects.

The lifetime of the excited uranyl ion, $(UO_2^{2+})^*$ depends strongly on the total concentration of uranium (self-quenching), an observation that has been described by Deschaux and Marcantonatos (1979) and others as due to the formation of the binuclear exciplex



(b) Photochemistry of the uranyl(VI) ion

Rabinowitch and Belford (1964), Balzani and Carassiti (1970), and Güsten (1983) have reviewed the photochemistry of uranyl(VI) with organic substrates. The reactions involve oxidation of the substrate and reduction to uranyl(V); in the absence of oxygen, a subsequent fast reaction leads to formation of uranyl (VI) and uranium(IV). In the presence of oxygen, uranyl(V) is rapidly oxidized to uranyl(VI) and accordingly the uranyl(VI) ion acts as a photo-catalyst, e.g. for the oxidation of alkanes, alkenes, alcohols, and aldehydes. The uranyl ion has also been used as a photo-catalyst for DNA footprinting as described in Section 5.11. All these reactions seem to take place by hydrogen abstraction from a C–H bond, followed by uranium-mediated product formation (Wang *et al.*, 1995). The mechanism can schematically be described by the following reactions, where SH_2 is the organic substrate, and S_{ox} the final oxidation product, an aldehyde or carboxylic acid.

$$SH_2 + (UO_2^{2+})^* \rightarrow SH^+ + UO_2^+ + H^+;$$
$$2SH^+ \rightarrow SH_2 + S_{ox};$$
$$2UO_2^+ \rightarrow UO_2^{2+} + U(\text{IV}).$$

5.11 ORGANOMETALLIC AND BIOCHEMISTRY OF URANIUM

There is an extensive organometallic chemistry for uranium(III) and uranium (IV); in fact, most of the organometallic chemistry as described in Chapters 25 and 26 deals with uranium and a detailed description of the synthesis and properties of organometallic uranium compounds can be found there. For historical reasons, we will here mention a few examples; the field was started by Wilkinson with the preparation of $(\eta^5\text{-cyclopentadienyl})_3UCl$ (Reynolds and Wilkinson, 1956), followed by reports from Fischer and Hristidu (1962) of additional cyclopentadienyl compounds, e.g. tetrakis(η^5-cyclopentadienyl)uranium(IV) (Fischer and Hristidu, 1962). The 'sandwich' compound uranocene, bis(π-cyclooctatetraene) uranium(IV), $U(C_5H_5)_2$ was prepared by Streitweiser and Müller-Westerhoff (1968). These compounds are π-complexes where uranium is coordinated by the cyclic ligands through their delocalized π-orbitals. Other complexes with the cyclopentadienyl ion $C_5H_5^-$ are $U(\eta^5\text{-}C_5H_5)_3$, $U(\eta^5\text{-}C_5H_5)_4X$, where X is an alkyl group, an alkoxy group, or BH_4. For description of these and other metal organic compounds the reader is referred to Chapter 25.

The biochemistry of uranium is totally dominated by investigations of the coordination of the uranyl(VI) ion to proteins, DNA/RNA and polysaccharide coatings in cell walls. In the proteins, the bonding takes place at the carboxylate and amino groups, in DNA/RNA at the phosphate groups, and in the polysaccharides at deprotonated OH groups. The strong binding of uranium has been used to make heavy-atom derivatives in protein crystallography (Tame, 2000) and as staining reagent in electron microscopy (Gray, 1994, 2001).

Photochemical oxidation of polydeoxynucleotides by UO_2^{2+} has been used for footprinting of DNA (Nielsen *et al.*, 1988). This is a technique used to identify the DNA region where a particular protein is bonded. It involves labeling of one end of a DNA chain with ^{32}P; addition of UO_2^{2+} that binds to the phosphate groups and then irradiation with near-UV light to obtain photo-excited uranyl(VI) that abstracts a hydrogen from a nearby C–H group, resulting in cleavage of the DNA backbone diester chain both in single- and double-stranded DNA. The cleavage is random and not sensitive to the base sequence; it results in ^{32}P fragments of different lengths that can be identified through gel electrophoresis. When a protein is bonded to certain base sequences of DNA, these regions are not accessible to UO_2^{2+} and are therefore protected from cleavage; this results in a different fragmentation pattern and the base sequence where protein bonding takes place can therefore be identified. For details, see Stryer (1988). An important advantage of this method, as compared to the use of DNA-se enzymes as 'scissor', is the small size of the uranyl(VI) ion compared to the enzymes.

The uranyl ion has been used as a very efficient regioselective and stereoselective catalyst for the synthesis of oligonucleotides in solution (Sawai *et al.*, 1989, 1990, 1992, 1996; Shimazu *et al.*, 1993).

Uranium in the form of uranyl(VI) compounds is taken up by living organisms. In mammals the uranium is bonded to proteins, e.g. transferrin, with a residence time of several hours during which it is gradually transported and incorporated into bone tissue. The residence time is long and removal requires an extensive treatment with different sequestering agents (Scapolan, 1998). A detailed discussion of the behavior of uranium and other actinides is given in Chapter 31.

5.12 ANALYTICAL CHEMISTRY

There is wide array of options available for the determination of uranium including both classical wet chemical and instrument-based spectrometric techniques. The purpose of this section is to provide an overview of the analytical techniques and methods applicable to the determination of uranium in a variety of matrices with an emphasis on those techniques and methods useful for samples with uranium concentrations larger than 1 μg per gram of sample. An extensive review of the techniques and methods that are used for the determination of uranium at trace and ultra-trace (less than 1 μg per gram of sample) concentrations in geological, environmental, and biological matrices is given in Chapter 30.

5.12.1 Chemical techniques

(a) Sample preparation

Most bulk analytical techniques require that a stable, aqueous solution be prepared prior to analysis and element determination. The dissolution of uranium containing compounds and materials is typically performed either by fluxed fusion decomposition or acid dissolution. Fluxed fusion decomposition is the first step in many standard classical wet chemical procedures used for the determination of uranium at major and minor concentrations in uranium containing ores. Ingamells and Pitard (1986) describe a chemical method for the determination of uranium in silicate minerals. In this method a several-gram quantity of silicate material is decomposed via fusion with Na_2O_2 in a platinum crucible. The fusion mass is dissolved in dilute HNO_3 and uranium is precipitated with a mixture of Na_2CO_3 and K_2CO_3 (Sandell, 1959). This precipitate is evaporated and redissolved in dilute HNO_3 before further purification or direct determination of uranium. Other fluxes that can be used for the fusion of uranium containing materials include hydroxides, carbonates, bisulfates, hydrosulfates, pyrosulfates, tetraborates, and metaborates (Dean, 1995).

Nearly all uranium compounds and uranium containing alloys can be dissolved in HNO_3. As briefly discussed in Section 5.6.4, uranium metal dissolves very rapidly in HCl, but a voluminous black residue is left unless a small amount of fluosilicate ion is present. uranium containing minerals, such as autunite, carnallite, gummite, phosphuranylite, torbernite, tyuyammite, uraninite, and uranophane will dissolve via open vessel digestion with HNO_3, HCl, and H_2SO_4 (Meites, 1963). Acid leaching with HNO_3, HCl, or H_2SO_4 has been used for industrial scale recovery of uranium from its ores. The various leaching processes for uranium ores are discussed in more detail in Section 5.4.3. A mixture of HF and HNO_3 can be employed when dissolution of silicates is required. When this mixture is used, complete recovery of uranium requires conversion of UF_4 to a soluble form by fuming with $HClO_4$ or H_2SO_4 or by complexation of F^- with H_3BO_3.

Separation and preconcentration of uranium can be achieved by most of the common chemical and physical separation methods: precipitation, coprecipitation, volatilization, electrolysis, liquid–liquid extraction, and ion-exchange chromatography. The simplest methods for the separation of uranium from solution are by precipitation or coprecipitation. Precipitation of uranium can be accomplished using inorganic and organic precipitants (Gindler, 1962). The formation of many precipitates in uranium containing solutions that also contain other anions and cations typically yields a group separation of uranium along with other elements. Uranium will coprecipitate from a carbonate-free solution with Fe(III) and Al(III) hydroxides. Carbonate is removed by heating the solution. Coprecipitation is accomplished by adding a macroscopic amount of Fe(III) or Al(III) to an acidified solution and adjusting the solution pH to basic with the addition of NH_4OH. Separation of uranium can also be accomplished by coprecipitation with $Ca(OH)_2$, $(NH_4)_2CO_3$, and $(NH_4)_2S$ (Rodden and Warf, 1950). Precipitation of uranium from acidic solutions can be performed fairly selectively as a peroxide or oxalate.

Electrochemical separation of uranium can be accomplished via Hg-cathode electrolysis and electrolytic deposition on a variety of solid metal electrodes (Casto, 1950) as well as electrodialysis and pyrometallurgical processes (Gindler, 1962). Electrodeposition from an electrolyte matrix adjusted to pH 3.5 onto a metal planchet is the most common method for the preparation of a thin sample for high-resolution alpha-spectrometric determination (Kressin, 1977 and references therein). Further discussion on sample preparation by electrodeposition for alpha spectrometry is given in Chapter 30, section 3.1.

Liquid–liquid extraction of uranium can be accomplished using organic acids, ketones, ethers, esters, alcohols, and phosphoric acid derivatives (Lally, 1992). In many cases, extraction of uranium can be greatly enhanced with the addition of nitrate salts to the solution (Gindler, 1962). Uranium(IV) can be extracted with ethyl acetate after treatment of an acidified solution with $Al(NO_3)_3 \cdot 9H_2O$ (Guest and Zimmerman, 1955). Uranium(VI) can be extracted with 25% TBP in toluene (Mair and Savage, 1986). Methyl isobutyl ketone has been used in large-scale uranium-separation processes. Recently, several uranium-specific exchange resins have been developed for the separation of uranium from acidic matrices. While these resins function by passing uranium-containing solution down an exchange column containing the material, the separation is based on liquid–liquid extraction. One of these extraction chromatographic resins, TRU Spec resin, consists of octyl(phenyl)-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide in tri(*n*-butyl)phosphate supported by an inert polymeric substrate, Amberlite XAD-7 (Horwitz *et al.*, 1993). The second extraction chromatographic resin, U/TEVA Spec resin consists of diamylphosphonate sorbed on Amberlite XAD-7. This resin possesses tetravalent ion specificity.

Cation exchange is not a commonly used method for the separation of uranium due to the lack of selectivity of the UO_2^{2+} cation over other divalent metal ions. UO_2^{2+} forms strong anionic sulfate and weaker chloride complexes that can be the basis for uranium separation from other metals in solution via anion exchange. Uranium separations can be performed by use of basic anion-exchange resins such as Dowex-1, Dowex-2, Amberlite IRA-400, Amberlite IRA-410, and Bio-Rad AG1X8 from solutions of HCl, HF, HNO_3, H_2SO_4, $(NH_4)_2CO_3$, and H_3PO_4 (Gindler, 1962).

(b) Sample analysis

Total analysis techniques (also known as classical techniques) are the most accurate of all the available methods for uranium determination. Because these techniques provide definitive results, they are typically used as the basis for establishing primary uranium standards and are used extensively in the areas of material control, accountability, and safeguards. Volumetric and gravimetric techniques have both been applied for high accuracy determination of macroscopic quantities of uranium.

Volumetric techniques provide the highest precision and accuracy for uranium determination. Volumetric determination of uranium can be performed via complexation titration with ethylenediaminetetraacetic acid (EDTA). However, the most widely used method is a redox titration where U(VI) is first reduced (e.g. in a Jones reductor) and then back-titrated via oxidation with $KMnO_4$ or Ce(IV) using 1,10-phenanthroline as an indicator (Dean, 1995). The method of Davies and Gray (1964) utilizes excess Fe(II) to reduce U(VI) to U(IV) in a concentrated

H_3PO_4 solution containing H_2NSO_3H. The Fe(II) is selectively oxidized with the addition of HNO_3 in the presence of a Mo(IV) catalyst. After addition of H_2SO_4, U(IV) is titrated with standard Cr(VI) with Ba-diphenylaminesulfonate as an indicator. A modified version of this method has been developed in which the end point is determined potentiometrically (American Society for Testing and Materials, 1994, ASTM C1267–94). This method is exceptionally accurate (relative bias –0.042% and within laboratory variation 0.042%), but requires milligrams of uranium in the sample aliquot.

The necessity for the preparation of redox standard solutions can be circumvented by electrochemical titrations. Coulometric titration of uranium can be performed in both constant-current and controlled-potential titration. Procedures for oxidative coulometric titration of U(IV) and reductive coulometric titration of U(VI) in constant-current mode have been developed. Oxidative coulometric titration of U(IV) is performed via the electrogeneration of Ce(IV) subsequent to preparation of U(IV) by reduction with cadmium amalgam (Furman *et al.*, 1953). Reductive coulometric titration of U(VI) is performed with electrogenerated Ti(III) at a platinum cathode with amperometric endpoint detection (Kennedy and Lingane, 1958). Errors are as low as ±0.3%. An improved version of this method has been developed that is capable of a precision of 0.008% (Marinenko *et al.*, 1983). Methods for oxidative controlled-potential titration of U(IV) and reductive controlled-potential titration of U(VI) have been developed. Oxidative controlled-potential titration of U(IV) can be performed in 1 M $HClO_4$ at a platinum electrode (Boyd and Menis, 1961). The most established controlled-potential coulometric titration of uranium utilizes a mercury pool for reduction of U(VI) (McEwen and DeVries, 1959). Experimental conditions have been established which enable uranium to be determined via controlled-potential coulometric titration at a platinum electrode (Davies *et al.*, 1970). Use of the platinum electrode has several advantages including the possibility of simultaneous consecutive determinations of Fe(III) and U(VI), or Pu(IV) and U(VI) in the same cell.

Gravimetric determination of the uranium content of uranium ores can be performed via the sulfide–carbonate–hydroxide method. In this method, the solid U-containing ore sample is dissolved with HNO_3 and H_2SO_4. Arsenic is first removed via addition of HBr. A treatment of the acidic solution with H_2S precipitates a large number of cations as sulfides; Co and Ni are precipitated with H_2S at low acidity; Al, Cr, and Fe are removed with subsequent addition of NH_4OH and $(NH_4)_2CO_3$;. The solution is then reacidified with HCl and U is precipitated with NH_4OH. The precipitate is filtered, washed, ignited, and determined gravimetrically as U_3O_8. Alternatively, the sample can be decomposed via fluxed fusion followed by dissolution in HCl and precipitation of U(IV) on the addition of 6% cupferron solution. The precipitate is filtered, washed, ignited, and determined gravimetrically as U_3O_8. This separation effectively removes Al, Cr, Mn, Zn, and PO_4^{3-} but the presence of Fe, Ti, V(V), and Zr would interfere with the uranium determination

(Dean, 1995). In general, the use of gravimetric methods is limited due to lack of specificity.

5.12.2 Nuclear techniques

The natural radioactivity inherent to uranium isotopes provides the means for their direct analysis by radiometric analytical techniques. While several radiometric techniques are amenable to the determination of uranium at concentrations higher than 1 μg per gram of sample, the most frequently used are high-resolution alpha and gamma spectrometries. Complete isotopic analysis of the naturally occurring isotopes ^{238}U, ^{235}U, and ^{234}U can be performed via high-resolution alpha spectrometry. Alpha-spectrometric determination requires complete sample dissolution, chemical separation of uranium, followed by preparation of a thin source, typically via electrodeposition or precipitation (Kressin, 1977 and references therein). Either ^{232}U or ^{236}U can be used as isotopic recovery spikes. Backgrounds and efficiencies of typical alpha spectrometers equipped with a 450-mm^2 ion-implanted Si detector would require a total of 0.4 μg of natural uranium to achieve 10% counting statistics for a 24-h sample count. Examples of several applications of alpha spectrometry for the determination of uranium and the measurement of U-series disequilibria are given in Ivanovich and Murray (1992).

High-resolution high-purity germanium (HPGe) detectors are capable of high-specificity measurement of individual radionuclide γ-rays and virtually eliminates the need for chemical treatment of samples. Due to its long half-life, the quantification of ^{238}U is usually based on the measurement of the 92.5 keV or the 63.3 keV γ-ray doublets produced by the short-lived daughter ^{234}Th provided secular equilibrium has been achieved (Harbottle and Evans, 1997). Determination of ^{238}U can also be performed by measurement of the 1001 keV γ-ray from the decay of ^{234m}Pa ($t_{1/2} = 1.175$ minutes). The low branching ratio for this γ-ray precludes its use for samples with uranium concentrations smaller than 10 μg per gram of sample. In the case of ^{235}U, direct quantification can be performed using its 185.7-keV γ-ray. A correction for interference from the 186.1 keV γ-ray, ^{226}Ra ($t_{1/2} = 1600$ years), is required for samples in secular equilibrium.

Radiometric determination of uranium can also be performed utilizing scintillation detection after chemical separation of uranium from interfering radionuclides. A standard test method for the determination of uranium in water by high-resolution alpha liquid-scintillation spectrometry utilizes a selective extractive scintillator solution containing dialkyl phosphoric acid (ASTM D6239–98, 1998).

Activation analysis of uranium is typically performed subsequent to irradiation with thermal neutrons. Uranium is essentially unique among naturally occurring elements in that neutron activation analysis (NAA) can be performed by detection of delayed neutrons (Parry, 1991). This method is highly specific for uranium and has been used for many years in the exploration of uranium ores. NAA with delayed-neutron detection can be automated for online and unattended determination of uranium content in solid and liquid samples.

The coupling of NAA with high-resolution gamma spectrometric detection (instrumental neutron activation analysis, or INAA) yields a highly specific and sensitive method for the determination of uranium. At high concentrations, uranium can be determined by INAA via measurement of the 74 keV γ-ray photo peak from the decay of ^{239}U ($t_{1/2} = 23.5$ minutes). Minor and trace quantities of uranium are typically determined by INAA via the ^{238}U(n,γ)^{239}U(β^-, 23.5 minutes)^{239}Np reaction with measurement of the 105 keV γ-ray photo peak from the decay of ^{239}Np (Parry, 1991). Enhanced sensitivity can be achieved by performing post-irradiation chemical separations (radiochemical neutron activation analysis, or RNAA) (Anders *et al.*, 1988). Both INAA and RNAA are applicable to the determination of trace and ultra trace concentrations of uranium and are further discussed in Chapter 30, section 3.3.

5.12.3 Spectrometric techniques

Uranium is amenable to determination by several fundamentally different spectrometric techniques including spectrophotometry, atomic absorption spectrometry (AAS), atomic emission spectrometry (AES), fluorometry, phosphorimetry, X-ray fluorescence (XRF), and mass spectrometry.

Spectrophotometric determination of uranium can be performed subsequent to sample dissolution, separation of uranium, complexation with an appropriate chromophore, and colorometric determination by comparison with prepared standards. For example, uranium can be determined colorimetrically in the aqueous phase after complexation with 4-(2-pyridylazo)recorcinol (PAR) (Pollard *et al.*, 1959) or as an organic-miscible complex with 4-(2- pyridylazo) napthol (PAN) (Pollock, 1977).

Selectivity of uranium spectrometric determination can be improved using techniques based on atomic absorption and emission. The determination of uranium via AAS techniques can be performed using flame sources (FAAS) or graphite furnace sources (GFAAS). FAAS determination of uranium is performed via the 358.5 nm absorption line using a nitrous oxide/acetylene flame. The detection limit for AAS is 40 μg mL^{-1} for uranium in solution (Dean, 1995). GFAAS can achieve detection limits of 30 ng mL^{-1} in much smaller sample volumes (20 μL). Both AAS and GFAAS are single-element methods that can achieve accuracies greater than $\pm 1\%$ if uranium concentrations are significantly higher than the detection limits.

Sensitivity of atomic spectrometric techniques can be improved via excitation in a high-temperature inductively coupled plasma (ICP) source followed by atomic emission spectrometric (AES) determination. The emission spectrum of U consists of thousands of resolvable lines. ICPAES determination of uranium based on the 385.96 nm emission line can achieve detection limits of 20 ng mL^{-1} with accuracies of ±1% if concentrations are significantly higher than the detection limits (Dean, 1995). While all atomic spectrometric techniques generally determine total uranium concentration without isotopic selectivity, a high-resolution ICPAES has been developed for the determination of uranium isotopic ratios (Edelson, 1992).

Uranium is unique among most elements in that it can be determined directly via fluorometry without the addition of a fluorescent chelating agent. The fluorometric technique can determine uranium concentrations as low as 5 ng mL^{-1} (ASTM D2907–91, 1991a). Superior detection limits can be achieved by utilizing the ability of uranyl ions to phosphoresce when excited to a triplet state. The uranyl ion can be directly determined phosphorometrically in a H_3PO_4 or H_2SO_4 solution. The pulsed-laser phosphorometric technique can determine uranium concentrations as low as 50 pg mL^{-1} (ASTM D5174–91, 1991b). Further discussion of the fluorometric and phosphorometric techniques is given in Chapter 30 (Sections 30.4.1 and 30.4.2, respectively).

X-ray fluorescence (XRF) can provide qualitative identification and quantitative determination of uranium in a variety of matrices. A procedure for the determination of uranium in soils can be found in ASTM C1255-93 (1993). This procedure can be used to determine as little as 20 μg per gram of uranium.

Mass spectrometry is the most sensitive method for the determination of uranium. In contrast to most of the atomic spectrometric techniques outlined previously, mass spectrometry also provides the means for the determination of uranium isotopic composition. As such, mass spectrometry is an essential tool for the determination of uranium in nuclear fuel cycle applications, material control and accountability, environmental chemistry, geochemistry, and cosmo-chemistry. While a variety of mass spectrometric methodologies have been applied to the determination of uranium (Section 30.5; Wolf, 1999 and references therein), the most commonly used mass spectrometric methods for the determination of uranium are electron-impact gas source mass spectrometry, thermal ionization mass spectrometry (TIMS), and inductively coupled plasma mass spectrometry (ICPMS).

Electron-impact gas source mass spectrometry is used specifically for uranium isotopic analysis to monitor U-enrichment processes. Typically, UF_6 is analyzed in ultracentrifuge and thermal diffusion processes and uranium vapor is analyzed in laser enrichment processes (Platzner, 1997). Measurement by gas source mass spectrometry requires approximately 100 mg of sample. Such instruments are used in production line applications and can achieve a precision of ±0.40% for UF_6 with >1% ^{235}U enrichment (Nagatoro *et al.*, 1980). Highly portable quadrupole mass analyzers have been designed for UF_6 isotopic analysis in nuclear safeguard applications (Depaus *et al.*, 1987). A standard method for the isotopic analysis of UF_6 with an electron-impact gas source mass spectrometer utilizing a single standard has been developed for nuclear fuel cycle applications (ASTM C1344-97, 1997).

TIMS is one of the most precise and accurate methods for single element isotope ratio determination and is used when small masses of uranium are analyzed. Instruments configured with multiple Faraday detectors can routinely determine major uranium isotope ratios to a precision better than 0.05% (Walder, 1997) and require less than 1 μg of U. TIMS is a commonly used method in nuclear fuel cycle applications including the isotopic analysis of hydrolyzed UF_6 and uranyl nitrate solutions (ASTM C1413–99, 1999) and for the determination of atom percent fission in irradiated nuclear fuels (ASTM E244-80, 1980). Determination of uranium concentrations is performed via isotope dilution (ID) analysis typically using ^{233}U as an isotopic spike. The high sensitivity of TIMS makes this method suitable for the determination of uranium concentrations and isotopic composition at trace and ultra-trace concentrations such as in geological and cosmo-chemical materials. Procedures and applications of TIMS to uranium measurements in geological samples are summarized in Chen *et al.* (1992) and references therein. The TIMS methodology is capable of determining $^{234}U/^{238}U$ ratios with a precision of 0.5% (2σ) for a sample size of 5×10^9 ^{234}U atoms. The primary disadvantage of TIMS is that extensive sample preparation is required and only one element can be determined in a given prepared sample. Further discussion of the application of TIMS to trace and ultratrace analysis is given in Chapter 30, section 5.1.

A review of the trends of the techniques used for elemental determination indicates that ICPMS is one of the most commonly used methods today (Lipschutz *et al.*, 2001). ICPMS has found applications for the determination of uranium in waters, soils, sludges, wastes, nuclear materials, biological, geological, and cosmo-chemical materials (Chapter 30, section 5.4 and references therein). The strength of ICPMS resides in its high sensitivity, multielement, high sample throughput capabilities. Quantification is typically performed based on external calibration using the most abundant uranium isotope ^{238}U. Solutions can be analyzed with minimal or no sample pre-treatment. Considering the sensitivities of modern state-of-the-art instruments, a minimum detection limit (MDL) of less than 100 fg in a 1 mL sample is readily attainable for uranium determination by ICPMS (Brenner *et al.*, 1998). The combination of an ICP source with a high-precision, double-focusing, mass spectrometer in a single detector configuration (HR-ICPMS) results in an instrument capable of determining less than 1 fg uranium in 1mL solution (Wolf, 1999). This corresponds to a detection limit of approximately 3×10^6 atoms of uranium. Moens and Jakubowski (1998) have published a review of HR-ICPMS instrumentation and applications. Configuration of HR-ICPMS with multiple detectors (MC-ICPMS) yields a method possessing all the attributes of HR-ICPMS with enhanced precision. The routine use of MC-ICPMS in nuclear fuel cycle applications has the potential to dramatically decrease the cost of sample analysis by means of increased sample throughput while maintaining the high precision required for fuel fabrication. A five-fold improvement in sample throughput has been demonstrated for the analysis of hydrolyzed UF_6 with accuracy and precision comparable to TIMS (Walder and Hodgeson, 1994). High sensitivity makes MC-ICPMS particularly attractive for uranium isotope determination in geo-chronological applications. A review of MC-ICPMS instrumentation and applications to uranium isotopic analysis in geological samples has been reported (Halliday *et al.*, 1998). This paper reviews results of replicate analysis of NIST SRM-906 measured by TIMS and MC-ICPMS. Precisions comparable to the best achievable TIMS precisions were achieved. The external reproducibility of MC-ICPMS was superior to TIMS. Further discussion of the application of MC-ICPMS techniques to trace and ultratrace uranium analysis is given in Chapter 30, section 5.4, of this book.

CHAPTER SIX

NEPTUNIUM

Zenko Yoshida, Stephen G. Johnson, Takaumi Kimura, and John R. Krsul

6.1 HISTORICAL

The first report on the discovery of neptunium was in 1940 by McMillan and Abelson (1940), although McMillan did the preliminary work in 1939 and published his findings (McMillan, 1939). He did not claim that a new element had been discovered until confirmatory measurements had been undertaken in the following year. The production of neptunium was accomplished by placing a layer of uranium trioxide on paper with several aluminum or paper foils and then exposing this to neutrons from a cyclotron. Examination of the uranium paper sample containing the non-recoiling fraction displayed that two new radioactive components had been created. One component displayed a 23 min half-life, later identified as U-239, while the second exhibited a 2.3 day half-life. Both components decayed via β particle emission. Preliminary chemical analysis was performed to determine the behavior of the 2.3 day component and resulted in the contradictory assignment of this component as that exhibiting an atomic number of 93, but not being transuranic in nature (Segrè, 1939). Segrè noted in his paper that his conclusions were contradictory. However, the following quotation is from his paper, "The necessary conclusion seems to be that the 23 minute uranium decays into a very long-lived 93 and that transuranic elements have not yet been observed." The primary stumbling block to the proper assignment of the material as transuranic in nature was the lack of observation of any alpha decay activity that would emanate from the daughter product of the beta decay of this new material with an atomic number 93. It was this work by Segrè (1939) that led McMillan and Abelson to revisit the chemical analysis and determine its properties in greater depth.

To initiate their work they first had to generate more material. In doing this they were able to confirm the 'linked' nature of the 23 min and 2.3 day half-life materials observed. The ratio of these two materials was observed to remain constant. This also confirmed the earlier suggestion by Hahn *et al.* (Quill, 1938) that the following reaction was possible when uranium underwent neutron bombardment:

$$\mathrm{U} + \text{neutron} \rightarrow \mathrm{U}(23\,\text{minute}) \rightarrow \text{Eka-Re} \tag{6.1a}$$

$$^{238}\mathrm{U}(\mathrm{n},\gamma)^{239}\mathrm{U}(\beta^-, 23\ \text{min}) \rightarrow {}^{239}\mathrm{Np}(\beta^-, 2.3\ \ \text{day}) \rightarrow {}^{239}\mathrm{Pu} \tag{6.1b}$$

Differences between the rare earths and this element were observed immediately by McMillan and Abelson (1940) because it did not form a precipitate when exposed to HF in the presence of bromate, an oxidizing agent, in a strong acid. It did form a precipitate with HF in the presence of SO_2, a reducing agent. This bifurcated behavior in the presence of HF was thought to explain the incorrect assignment of this element as a rare earth by Segrè (1939) since the oxidizing potential of the solution had not been well controlled in earlier experiments (Segrè, 1939). Further evidence strongly suggested that the material was indeed an actinide, such as, precipitation in the reduced state with a thorium carrier by iodate and in the oxidized state with a uranium carrier by acetate. Also the precipitation with thorium carrier in the presence of H_2O_2 and precipitation in a carbonate-free basic solution indicated actinide-like behavior. Careful confirmatory measurements, which involved uranium that had undergone neutron bombardment and subsequent purification via fluoride precipitation in the presence of SO_2, showed the in-growth of the new element with a 2.3 day half-life. The new material was observed to exhibit a beta particle of energy approximately 470 keV. Further speculation by McMillan and Abelson regarding the daughter product, which would have atomic number 94 and a mass number of 239, was also recorded but will be discussed in Chapter 7 of this work. The element discovered by McMillan and Abelson was named after the planet Neptune, which is the first planet beyond Uranus in our solar system. This system was likewise followed for naming plutonium as its orbit was beyond Neptune.

6.2 NUCLEAR PROPERTIES

Twenty-two isotopes of neptunium are now known (Table 6.1). The isotope ^{237}Np has a sufficiently long half-life ($t_{1/2} = 2.144 \times 10^6$ years) that can be handled at weighable quantities. It is the most significant neptunium

Table 6.1 *Nuclear properties of neptunium isotopes.*

Mass number	*Half-life*	*Mode of decay*	*Main radiations* (MeV)	*Method of production*
226	31 ms	EC, α	α 8.044	^{209}Bi(^{22}Ne,5n)
227	0.51 s	EC, α	α 7.677	^{209}Bi(^{22}Ne,4n)
228	61.4 s	EC, α		^{209}Bi(^{22}Ne,3n)

[a] Not known whether ground-state nuclide or isomer.

isotope for chemists. ^{237}Np is synthesized by neutron irradiation of uranium according to the reactions (6.2) to (6.4). In conventional nuclear reactors ^{237}Np is generated as a by-product mainly through reactions (6.2) and (6.3). The latter reaction predominates in reactors with fuels of enriched ^{235}U.

$$^{238}\mathrm{U}(n,2n)\,^{237}\mathrm{U}\xrightarrow[6.75\,\mathrm{d}]{\beta^-}\,^{237}\mathrm{Np} \tag{6.2}$$

$$^{235}\mathrm{U}(n,\gamma)\,^{236}\mathrm{U}(n,\gamma)^{237}\mathrm{U}\xrightarrow{\beta^-}\,^{237}\mathrm{Np} \tag{6.3}$$

$$^{238}\mathrm{U}(n,\gamma)\,^{239}\mathrm{U}\xrightarrow{\beta^-}\,^{239}\mathrm{Np}\xrightarrow{\beta^-}\,^{239}\mathrm{Pu}(n,\gamma)^{240}\mathrm{Pu}\xrightarrow{\beta^-}\,^{240}\mathrm{Am}(n,\gamma)^{241}\mathrm{Am}\xrightarrow{\alpha}\,^{237}\mathrm{Np} \tag{6.4}$$

The isotopes ^{238}Np and ^{239}Np have relatively short half-lives and are useful as radioactive tracers for analytical applications or for fundamental chemistry research. They are synthesized by neutron irradiation of ^{237}Np and ^{238}U, respectively, through the following reactions:

$$^{237}\mathrm{Np}(n,\gamma)^{238}\mathrm{Np} \tag{6.5}$$

$$^{238}\mathrm{U}(n,\gamma)^{239}\mathrm{U}\xrightarrow{\beta^-}\,^{239}\mathrm{Np} \tag{6.6}$$

The isotopes ^{235}Np and ^{236}Np are synthesized by cyclotron irradiation of ^{235}U according the following reactions:

$$^{235}\mathrm{U}(d,n)^{236}\mathrm{Np} \tag{6.7}$$

$$^{235}\mathrm{U}(p,n)^{235}\mathrm{Np} \tag{6.8}$$

The isotopes heavier than ^{237}Np are unstable with respect to β^- decay. Isotopes lighter than ^{237}Np decay by electron capture and also are unstable with respect to alpha decay.

6.3 PRODUCTION OF PRINCIPAL NEPTUNIUM ISOTOPES

The principal isotopes of neptunium are generated by irradiation of uranium with neutrons. Of the 22 isotopes listed in Table 6.1, only ^{235}Np, ^{236}Np and ^{237}Np have half-lives long enough to permit accumulation. Neptunium-237 is generated by reactions (6.2), (6.3) and (6.4). However, by irradiating uranium, only ^{237}Np is capable of accumulating. Neptunium-239 is produced from irradiation of ^{238}U and the decay of the resulting ^{239}U, however, the half-life of ^{239}Np, 2.3565 days, is too short for accumulation. Irradiation of uranium by neutrons is unsuitable for the generation of ^{235}Np and ^{236}Np. Therefore only ^{237}Np is produced in any significant quantities. Currently, the production of plutonium is the source of ^{237}Np where the isotope is a by-product of the process. Significant quantities also reside in spent fuel, in high-level waste (HLW), and in solutions containing ^{237}Np stored at various reprocessing facilities. There are no known commercial uses for neptunium. The need for ^{238}Pu as a heat source for radioisotope thermoelectric generators (RTGs) and radioisotope heater units (RHUs) is the main reason to separate and purify ^{237}Np. RTGs are used to supply electricity to space vehicles used in the Galileo, Ulysses, and Cassini NASA missions (see Chapter 7). RHUs are used to provide heat for delicate instruments on space missions. Future needs to separate ^{237}Np and the other actinides from spent fuel and HLW may be required by the proposed transmutation of actinides residing in these materials. Removal of the transuranics, including especially ^{237}Np, has the advantage of eliminating concerns for the long-term storage of radioactive waste. A recent and rather novel use of ^{237}Np is to produce pure ^{236}Pu tracer to assess the amount of plutonium in the environment. Yamana *et al.* (2001) demonstrated that the irradiation of ^{237}Np with bremsstrahlung of an electron beam of 23 and 30 MeV produced ^{236}Pu with low ^{238}Pu impurity. Neptunium-237 could also be used in nuclear weapons; its critical mass is approximately 73 kg.

Plutonium-238 is generated by the reaction shown below:

$$^{237}\mathrm{Np}(\mathrm{n},\gamma)\ ^{238}\mathrm{Np} \xrightarrow{\beta^-} {}^{238}\mathrm{Pu} \qquad (6.9)$$

To obtain ^{238}Pu, ^{237}Np is separated from spent fuel by various modifications of the well-known plutonium and uranium recovery by extraction (Purex) process. After dissolution, neptunium is separated from the spent fuel by solvent extraction and ion exchange by careful adjustments of acid concentrations, oxidations states, and volume percent of tributyl phosphate (TBP). The separated neptunium is precipitated as neptunium oxalate, calcined to neptunium oxide, and fabricated into targets. Targets of the separated isotope are irradiated in a high neutron flux. After irradiation, the targets are cooled for a specific amount of time to allow for fission product decay and then dissolved. ^{238}Pu is then separated from ^{237}Np by taking advantage of the differences in the characteristic oxidation states of the resulting fission products, neptunium, and plutonium.

To date, the reprocessing of irradiated nuclear fuel has focused on the separation of plutonium and uranium from fission products and other actinides. Proposed transmutation and advanced nuclear fuel cycles will require the development of separations that include the actinides and are safe, efficient, and environmentally acceptable. The need for these new technologies will create significant opportunities for research and development activities in the field of actinide chemistry.

6.4 NEPTUNIUM IN NATURE

^{237}Np ($t_{1/2} = 2.144 \times 10^6$ years) has the longest half-life of neptunium isotopes. Because this half-life is considerably shorter than the age of the Earth, which is about 4.5×10^9 years, primordial ^{237}Np no longer exists on Earth.

Neptunium isotopes can be formed by nuclear reactions continuously taking place in the Earth's crust, resulting in a dynamic equilibrium between the rate of formation and the rate of decay. Neutron capture by ^{238}U produces ^{239}Np (see reaction (6.6)), and an (n,2n) reaction on ^{238}U forms ^{237}Np (see reaction (6.2)). The neutrons originate from the spontaneous fission of ^{238}U, the neutron-induced fission of ^{235}U, (α,n) reactions on elements of low atomic number, and/or fission or spallation reactions induced by cosmic rays. Small amounts of ^{239}Np are expected to occur in uranium minerals by continuous formation from ^{238}U, but its half-life of 2.36 days is too short to permit any significant equilibrium concentration to be reached (Garner *et al.*, 1948; Seaborg and Perlman, 1948; Levine and Seaborg, 1951). The isolation of microgram amounts of ^{239}Pu by Peppard *et al.* (1951) from Belgian Congo (now Democratic Republic of the Congo) uranium undoubtedly establishes the existence of ^{239}Np in nature. The isotope ^{237}Np itself has been identified in and isolated from a uranium ore concentrate from Belgian Congo and in other minerals (Peppard *et al.*, 1952). The maximum ratio of ^{237}Np to uranium in such minerals is about 10^{-12}.

The primary sources of neptunium in the biosphere, as with the other transuranium elements, are atmospheric nuclear explosions. On the basis of the analyzed results on global fallout, it was calculated that 2500 kg of ^{237}Np had been generated, which is comparable in mass with the quantity of plutonium (4200 kg of ^{239}Pu and 700 kg of ^{240}Pu) (Efurd *et al.*, 1984). There is little information about the man-made neptunium content of various natural materials, because of the low specific radioactivity of the long-lived ^{237}Np and the systematic difficulties in its determination (Novikov *et al.*, 1989). For global fallout, the ^{237}Np/^{239,240}Pu ratio lies within one order of magnitude $(1\text{–}10) \times 10^{-3}$. When 5×10^{-3} is taken as an average value of the ratio, the concentration of ^{239,240}Pu in seawater is 13×10^{-3} mBq L^{-1}, and the ^{237}Np concentration comprises 6.5×10^{-5} mBq L^{-1} (Holm *et al.*, 1987).

6.5 SEPARATION AND PURIFICATION

Reprocessing of spent nuclear fuels to recover reusable uranium and plutonium and the partitioning of high-level radioactive liquid wastes (HLW) constitute the main processes of the nuclear fuel cycle. ^{237}Np, α emitter with a 2.144×10^{6} years half-life, is one of the major nuclides to be separated from Purex process solutions and HLW. Several separation methods satisfying requirements for process-scale operation have been developed. At the same time, separation methods suitable for relatively small-scale operations are necessary to prepare pure neptunium as a source material in the synthesis of neptunium metal or its compounds, and to isolate or preconcentrate neptunium in analytical samples before determination.

Solvent extraction, ion-exchange chromatography, extraction chromatography, coprecipitation, and electrolytic deposition methods are used for the separation of neptunium ions. Most of the wet-chemical methods involve the control of neptunium ion oxidation states which varies between 3+ and 6+ or even 7+ and utilization of specific chemical behavior of the ion in each oxidation state. Well-established separation methods are reviewed by Burney and Harbour (1974). Choppin and Nash (1995) and Nash and Choppin (1997) recently evaluated separation methods. A report published by OECD/NEA (1997) reviewed separation chemistry of actinides in nuclear waste streams and materials.

6.5.1 Solvent extraction

Many extractants have been employed for the solvent extraction of neptunium ion (cf. reviews by Laskorin *et al.* (1985) and Rozen and Nikolotova (1988)). Multi-dentate β-diketone derivatives, organophosphorus compounds, and amine compounds are commonly used. Mathur *et al.* (2001) reviewed solvent extraction technology from the viewpoints of engineering the management of nuclear spent fuels and radioactive wastes.

Typical β-diketone, 2-thenoyltrifluoroacetone (HTTA, $pK_a = 6.23$), is most widely used for the extraction of neptunium ions. The separation scheme as shown in Fig. 6.1, which is for the analysis of ^{237}Np in sediments and soils by alpha-counting, inductively coupled plasma-mass spectrometry (ICP-MS), or neutron activation analysis, was proposed by Hursthouse *et al.* (1992) and is based on HTTA extraction and anion-exchange chromatography. In this procedure, Np(VI) and Np(V) in the sample solution are reduced to Np(IV), which is extracted from 1 M HNO_3 to 0.5 M HTTA (toluene) phase ($D_{\mathrm{Np(IV)}} \geq 10^3$). Here, D denotes the distribution ratio of a metal ion, which is a ratio of the concentration of the metal in the organic phase to that in the aqueous phase under the extraction equilibrium condition. Coexisting U(VI) and Pu(III) are not extracted ($D_{\mathrm{U(VI)}} \leq 5 \times 10^{-5}$ and $D_{\mathrm{Pu(III)}} \leq 10^{-5}$), which enables the separation of neptunium from plutonium and uranium. Np(IV) in the toluene phase is back-extracted into 8 M HNO_3 solution. Alternatively, Np(IV) in toluene is reduced to Np(V) and back-extracted to 1 M HNO_3 ($D_{\mathrm{Np(V)}} \leq 5 \times 10^{-4}$).

1-Phenyl-3-methyl-4-benzoyl-pyrazol-5-one (HPMBP, cf. Fig. 6.2) and its derivatives are useful extractants for actinide ions. The pK_a of HPMBP (4.11), which is smaller than the pK_a of HTTA, extracts Np(IV) from highly acidic solution, e.g. 1–4 M HNO_3. The ability of HPMBP to extract Np(IV) from such an acidic solution avoids an interference by hydrolysis of Np(IV). Np(VI) and Np(V) are not extracted under this condition.

The synergistic extraction with HPMBP and tri-*n*-octylphosphine oxide (TOPO) was employed to separate Np(V) from Am(III), Cm(III), U(VI), Pu(IV), and lanthanide(III) ions (Pribylova *et al.*, 1987). Zantuti *et al.* (1990) developed a

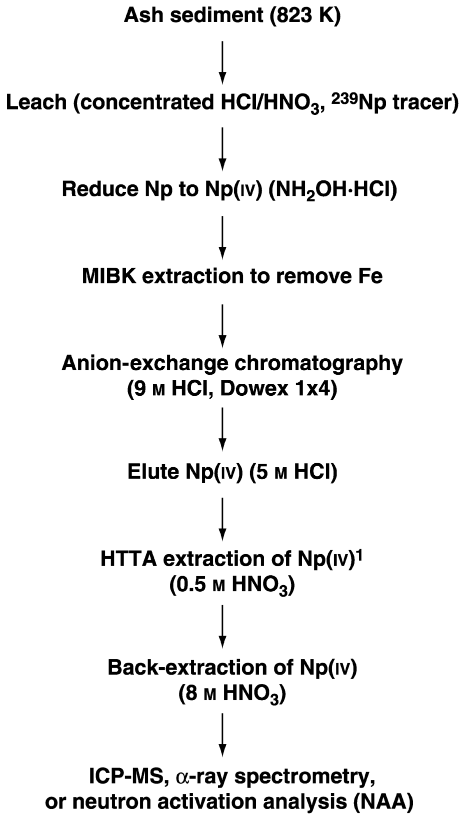

Fig. 6.1 *Procedure for the determination of* ^{237}*Np in sediment samples* (*Hursthouse* et al., 1992). [1]*HTTA extraction is repeated for α-ray spectrometry or NAA.*

method for the separation of a trace amount of neptunium from nitric acid solution containing a large quantity of uranium using the synergistic extraction with HPMBP and di-2-ethylhexylphosphoric acid. Tochiyama *et al.* (1989) showed that Np(V) was extracted efficiently with HPMBP in the presence of methyltrioctylammonium chloride. The 3-phenyl-4-bezoyl-5-isoxazolone was demonstrated to be powerful to extract Np(IV) and the procedure was developed for the separation of ^{237}Np from ^{236}Pu and ^{235}U in the irradiated sample of uranium target (Mohapatra and Manchanda, 1993).

Takeishi *et al.* (2001) studied the extraction behavior of actinide ions using bis (1-phenyl-3-methyl-4-acylpyrazol-5-one) derivatives H_2BPn, where n denotes the number of methylenes in a chain, having a structure as shown in Fig. 6.2. The log D vs $-\log[H^+]$ plots for the extraction of Np(IV) with various derivatives of HBPn ($n = 3, 4, 5, 6, 7, 8, 10, 22$) are shown in Fig. 6.3. The slopes of

(H_2BPn; $n = 3, 4, 5, 6, 7, 8, 10, 22$, etc)

Fig. 6.2 *Structure of pyrazolone derivatives.*

log *D* vs $-\log[H^+]$ plot as well as slopes of log *D* vs $\log[H_2BPn]$ plot suggest $Np(BPn)_2$ as the extracted species. The H_2BPn derivatives are a stronger extractant than HPMBP, which is one of the remarkable characteristics of quadridentate H_2BPn compared with bidentate HPMBP. H_2BP7 and H_2BP8 exhibit higher extractability than the other H_2BPn derivatives examined. Based on their data a procedure for the separation of actinide ions of various oxidation states using H_2BP7 or H_2BP8 was developed.

TBP is the most useful extractant for the separation of actinide ions at the process scale. The early works with TBP are summarized in the reviews by Geary (1955) and Schneider and Harmon (1961), which provide a wide scope of TBP extraction chemistry and engineering. Np(VI) and Np(IV) are extracted as $NpO_2(NO_3)_2(TBP)_2$ and $Np(NO_3)_4(TBP)_2$, respectively, and the extraction efficiency increases with increasing concentrations of TBP and HNO_3 (1–10 M). The distribution ratios of Np(IV) and Np(VI) are 3.0 and 12.0, respectively, between 4 M HNO_3 and 30% TBP(dodecane) at 298 K. The procedure for the separation of neptunium from uranium and plutonium consists in the adjustment of the oxidation state to Np(VI), co-extraction with U(VI) and Pu(IV) and back-extraction of Np(V) by the reduction of Np(VI) to Np(V).

The *n*-octyl(phenyl)-*N*,*N*-diisobutyl-carbamoyl methylphosphine oxide (CMPO) is an effective extractant for the separation of actinide ions from acidic solutions (Kolarik and Horwitz, 1988). The mixed organic solvent of (0.1–0.2) M CMPO + (1.2–1.4) M TBP in dodecane is usually employed. Distribution ratios for Np(IV), Pu(IV), and Pu(III) between nitric acid solution and 0.1 M

CMPO + 1.4 M TBP + dodecane are shown in Table 6.2 (Mincher, 1989). For the separation of neptunium and plutonium, the oxidation states are adjusted to Np(IV) and Pu(III) with 0.1 M Fe(II) sulfamate and Np(IV) is then extracted into the CMPO/TBP phase. Pu(III) is removed by stripping with 0.01 M HNO_3 in the presence of 3% hydroxylamine nitrate. Neptunium is removed from the organic phase by an aqueous solution containing complexing agents such as $(COOH)_2$, CO_3^{2-}, or ethylenediaminetetraacetic acid (EDTA). Mathur *et al.* (1996c) compared the extraction behavior of Np(IV), Np(VI), Pu(IV), and U(VI) from nitric acid solutions with CMPO, dibutyldecanamide (DBDA), dihexyldecanamide (DHDA), and bis-2-ethylhexylsulfoxide (BEHSO) in dodecane. The extraction ability is in the order of CMPO > BEHSO > DHDA > DBDA.

Bis(2-ethylhexyl)phosphoric acid (HDEHP), which shows distinguished capability for the extraction of trivalent actinides and lanthanides ions, is also utilized for the separation of neptunium from uranium, plutonium, and

Pu^{3+}	1.6	3.0	5.2	7.1	10	14

americium. After the oxidation state of the actinide ions are adjusted to Np(V), U(VI), Pu(IV), and Am(III) in 1 M HNO_3 by adding $NaNO_2$, all actinide ions except Np(V) are extracted with HDEHP. Np(V) is then oxidized to Np(VI) and extracted with HDEHP. Np(VI) is reduced to Np(V) and back-extracted with 0.1 M HNO_3.

The extraction behavior of Np(IV) and Pu(IV) was investigated using eight kinds of multi-dentate organophosphorus compounds such as dioxides of diphosphine and carbamoyl phosphoryl compounds (Rozen *et al.*, 1988). The extraction behavior of Np(V) was studied systematically with TBP, TOPO, and phosphine oxide derivatives (Rozen *et al.*, 1992). The results of K_{ex} suggested that the stability of the complex between Np(V) and the bidentate extractant was remarkably enhanced in the organic solution.

Solvent extraction with tri-*n*-octylamine (TnOA) has been extensively employed for the separation of ^{237}Np from environmental analytical samples. The separation scheme for ^{237}Np in soils and sediments, which was recommended by Yamamoto *et al.* (1994), is shown in Fig. 6.6 (see Section 6.10). Np(IV) in 10 M HCl is extracted with 10% TnOA (xylene) ($D_{Np(IV)} = 300$). Np(IV) is then back-extracted with a solution of 1 M HCl + 0.1 M HF.

Heptavalent neptunium ion as a form of $NpO_4(OH)_2^{3-}$ produced in 0.1–2 M LiOH (KOH) solution is extracted with various extractants such as TBP, TOPO, crown ether derivatives, HDEHP, etc. (Rozen *et al.*, 1990). The most effective extractant is dicyclohexyl-18-crown-6 ether (in TBP) or HDEHP. Karalova *et al.* (1992a,b) studied the solvent extraction of Np(VII) from alkaline solutions with HPMBP, bis(2-oxy-4-alkyl-benzoyl)amine, bis(2-hydroxy-5-octylbenzyl) amine, and 2-hydroxy-5-*tert*-butylphenyl disulfide. The highest extraction efficiency is obtained when Np(VII) exists as $NpO_4(OH)_2^{3-}$, suggesting that the extraction process involves removal of OH^- from $NpO_4(OH)_2^{3-}$ and H^+ from the OH groups of the extractant molecules. During the extraction process the reduction of Np(VII) to Np(VI) or the oxidation of the extractant is possible, which must be taken into account for the practical use of the Np(VII) extraction procedure.

(a) Neptunium control in advanced Purex process

Currently operated commercial reprocessing plants are based on the Purex process consisting of the solvent extraction of uranium and plutonium with TBP. In principle, all neptunium is rejected into the HLW as a form of inextractable Np(v). The oxidation state of neptunium ion in the process solution, however, varies significantly depending on the chemical environment. Np(v) is oxidized to Np(vi) in the presence of HNO_2 which coexists in nitric acid solution of high concentration; the Np(v) slowly disproportionates generating Np(vi) and Np(iv) in highly acidic solution. Thus, the neptunium behavior is not fully controlled in the Purex process and neptunium distributes in different fractions of the process. Fig. 6.4 shows possible oxidation states of neptunium ions in the main stream of the Purex process. Experimental results at the THORP miniature pilot plant indicated that only 30% of the total neptunium was found in the

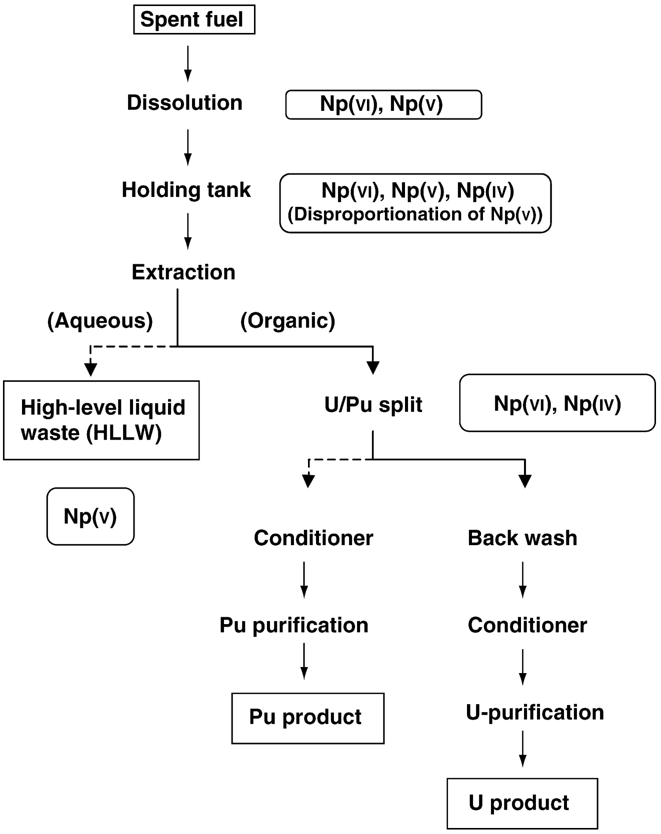

Fig. 6.4 *Flowsheet of the Purex process and the probable oxidation state of neptunium ion in the process solution.*

HLW (Taylor *et al.*, 1997). The remaining neptunium was extracted with uranium and plutonium in the solvent product.

Many attempts have been done to design an advanced Purex process. Taylor *et al.* (1997) summarized the chemical behavior of neptunium in the reprocessing plant. Recent R&D activities at BNFL (UK) attempt to control neptunium in the advanced Purex process. The advanced Purex process is required to satisfy criteria including cost and environmental impact. Reducing the size and complexity of the process and minimizing the secondary waste generation assist in fulfilling these requirements. Efficient control of neptunium within the flowsheet is an important goal assigned to the advanced Purex process. Several scenarios for the control of neptunium in the flowsheet are recommended, i.e. all neptunium is led to: (1) the HLW stream; (2) the Pu fraction; or (3) the U fraction followed by the isolation from uranium, or (4) the recovery in the Np fraction before the U/Pu split process. In all cases, the method to control neptunium behavior is based on precise control of the oxidation state of the ion. Such appropriate redox reagents must be chosen to fulfill all criteria including (1) kinetics of redox reaction, (2) decomposability after the use and (3) stability toward high acidity and radiation.

The back-extraction of Np(V) is an effective way to separate neptunium from Pu(IV) and U(VI) that remain in the organic phase. Many studies have been carried out to select suitable salt-free organic reagents to reduce Np(VI) to Np(V). Taylor *et al.* (1998a) confirmed the selectivity between the reduction of Np(VI) to Np(V) and Pu(IV) to Pu(III) by comparing reduction rates with a wide range of potential reductants such as carboxylic acids, aldehydes, ketones, guanidines, and hydrazine derivatives. The hydrazine derivatives, i.e. *tert*-butyl hydrazine and 1,1-dimethyl hydrazine, are most promising from both viewpoints of the selectivity in the reduction of Np(VI) toward that of Pu(IV) and the reduction kinetics. The results of demonstration solvent extraction tests show that the reduction of Pu(IV) is accelerated by the presence of U(VI).

Uchiyama *et al.* (1998a) studied the reduction kinetics of Np(VI) and Pu(IV) with aldehyde derivatives and concluded that *n*-butyraldehyde was promising as a selective reductant of Np(VI). They proposed an advanced Purex process for the separation of neptunium, technetium, plutonium, and uranium, which consisted of five steps for (1) co-decontamination of these elements, (2) Np oxidation with V(V) and TBP extraction of Np(VI), (3) Np separation by the reduction of Np(VI) to Np(V) with *n*-butyraldehyde, (4) Tc separation using highly acidic scrubbing solution, and (5) U/Pu partitioning by the selective reduction of Pu (IV) to Pu(III) with iso-butyraldehyde.

Taylor *et al.* (1998b) employed hydroxamic acids such as formohydroxamic acid and acetohydroxamic acid, and found that they selectively and rapidly reduced Np(VI) to Np(V). The investigators also reported that the reagent preferentially complexed Np(IV) and Pu(IV) in the aqueous solution. These characteristics may offer advantages in the control of neptunium in the advanced Purex process.

One way to control neptunium separation in the Purex process flowsheet is to extract all neptunium as Np(vi) together with U(vi) and Pu(iv) and then to separate neptunium from U(vi) as the reduced form, Np(v), along with Pu(iii). A suitable reductant to reduce Np(vi) to Np(v) and Pu(iv) to Pu(iii) efficiently and rapidly must be used. Hydroxylamine derivatives such as hydroxylamine and methyl-, dimethyl-, diethyl-, isopropyl-, and dibutyl-hydroxylamines, have been extensively examined for this purpose (Koltunov and Baranov, 1987). Koltunov *et al.* (1999) performed a kinetic study on the reduction of Np(vi) and Pu(iv) with the recently synthesized reductants *N*,*N*-ethyl(hydroxyethyl) hydroxylamine (EHEH). The reduction rates of Np(vi) and Pu(iv) with EHEH are among the highest of the salt-free reductants examined. This rapidity of the reduction makes EHEH particularly suitable for solvent extraction contactors such as centrifugal contactors of very short residence time in the advanced Purex process. A recent study by Koltunov *et al.* (2000) provides data on the rate of the reduction of Np(vi) and Pu(iv) with acetaldoxime in nitric acid solution, and suggests that Np(vi) and Pu(iv) are reductively stripped from 30% TBP (dodecane) phase in the presence of U(vi).

A photochemical procedure for the control of the oxidation state of the neptunium ion in the process solution is attractive due to its potential for minimization of secondary waste generation and simplicity of process design. Enokida and Suzuki (1989) used a KrF excimer laser to induce the reduction of Np(vi) to Np(v) in a 30% TBP (dodecane) phase, which was then stripped into the aqueous solution. Uchiyama *et al.* (1998b) studied the selective reduction of Np(vi) to Np(v) indirectly by nitrous acid produced photochemically with a low-pressure mercury lamp. Using a mixer-settler equipped with a photochemical reactor they demonstrated the applicability of this technique to the selective reduction and stripping of Np(v), leaving Pu(iv) and U(vi) in the 30% TBP (dodecane) phase. Photochemical processes were proposed (Wada *et al.*, 1996) for the selective extraction of Pu(vi) and Pu(iv) from Np(v), the oxidation states of which were controlled by 2 M HNO_3 + 10^{-2} M hydroxylamine nitrate + hydrazine under photoirradiation. A similar photochemical process was used for the coextraction of Pu(vi), Pu(iv), and Np(vi) prepared in 3 M HNO_3 + 10^{-2} M urea solution under irradiation.

(b) Partitioning of neptunium from high-level liquid wastes

The α emitters with a long half-life, such as ^{237}Np and other transplutonium nuclides contained in the HLW from the Purex process, are of great environmental concern. A considerable amount of work has been performed to develop methods for the partitioning of the actinides from the HLW. Several partitioning processes based on the solvent extraction technique using different extractants have been proposed as follows. Mathur *et al.* (1996a) proposed a method based on the TBP extraction for the removal of neptunium and plutonium together with U(VI). Quantitative extraction of Np(VI) and Pu(VI) from various kinds of simulated and real HLW was attained with 30% TBP (dodecane) after oxidizing neptunium and plutonium using 0.01 M $K_2Cr_2O_7$. More than 99% of neptunium and plutonium was stripped from the organic phase by reducing neptunium to Np(V) and plutonium to Pu(III) with 0.01 M ascorbic acid + 0.1 M H_2O_2 + 2 M HNO_3 solution, leaving most of the uranium in the organic phase. Feasibility of this method was confirmed by counter-current experiments using mixer-settlers with simulated HLW (Chitnis *et al.*, 1998). Pentavalent vanadium ion, VO_2^+, is also effective to adjust the oxidation state at Np(VI) and Pu(VI).

CMPO has been evaluated to be one of the best reagents for the partitioning strategy because of its high ability to extract hexavalent, tetravalent, and trivalent actinide ions from an acidic solution of relatively wide range of acid concentrations. The well-known TRUEX process for the recovery of all actinides from various types of nuclear waste solutions is based on CMPO extraction. Kolarik and Horwitz (1988), Wisnubroto *et al.* (1991), and Mathur *et al.* (1996b) accumulated the extraction data of neptunium ion of various oxidation states using TRUEX solvent. Np(V) is inextractable and must be oxidized to Np(VI) with $K_2Cr_2O_7$ or HNO_2 or reduced to Np(IV) with Fe(II) sulfamate or H_2O_2. Wisnubroto *et al.* (1991) showed that Np(V) readily disproportionated to Np(VI) and Np(IV) and the extraction efficiency of neptunium present initially as Np(V) in the sample solution increased, when the acid concentration of the aqueous solution was high enough, e.g. >4 M HNO_3. Np(IV) extracted in the TRUEX solvent was stripped quantitatively into the diluted HNO_3 solution containing complexing agents such as HF, $(COOH)_2$, carbonate, or EDTA. Np(VI) in the organic phase was easily stripped with diluted HNO_3 in the presence of H_2O_2 through the reduction of Np(VI) to Np(V).

The solvent extraction with diisodecylphosphoric acid (DIDPA) was applied to the partitioning of actinides in HLW (Morita *et al.*, 1996). The DIDPA extraction exhibits an advantage in that trivalent actinide ions, Am(III) and Cm(III), can be extracted from an aqueous solution of fairly low acidity, e.g. 0.5 M HNO_3, together with tetravalent and hexavalent ions. Even Np(V) in the sample solution is extracted by DIDPA. The addition of H_2O_2 enhances the rate of the extraction of Np(V) (Morita and Kubota, 1988). Rapid reduction of Np(V) to Np(IV) occurs during the DIDPA extraction in the presence of H_2O_2. The back-extraction of Np(IV) is achieved with 1 M $(COOH)_2$.

Trialkyl(C_6–C_8) phosphine oxides (TRPO) have been studied as an appropriate class of extractants for the recovery of Np, Pu, and Am from HLW (Zhu and Song, 1992). The optimum organic phase is 30 vol% TRPO (kerosene), and >99% of Np(IV) and Np(VI) with U(VI), Pu(VI), and Pu(IV) and >95% of trivalent actinide and lanthanide ions were extracted from 0.2 to 1 M HNO_3. The neptunium ion extracted is stripped with the plutonium ions into 0.5 M $(COOH)_2$ solution. In the recommended flowsheet, the oxidation state of neptunium is adjusted at 4+ by electrolytic reduction.

6.5.2 Chromatography using various resins

(a) Chromatography with ion-exchange resin

Various methods based on ion-exchange chromatography have been used for the separation of neptunium ions (Burney and Harbour, 1974). Cation-exchange chromatography of NpO_2^{2+}, NpO_2^{+}, and Np^{4+} with dilute acid solutions has been developed. The adsorption of ions of different oxidation states differ from each other so that the distribution ratio follows the order $Np^{4+} \gg NpO_2^{2+} \gg NpO_2^{+}$, which enables the mutual separation of neptunium ions of different oxidation states. Utilization of cation-exchange methods is limited because NpO_2^{2+} and NpO_2^{+} are often reduced to Np^{4+} when in contact with the resin; the adsorption behavior of Np^{4+} is not so selective from other coexisting cations.

Np(vi) and Np(iv) form anionic chloride or nitrate complexes in aqueous solutions containing high concentration of chloride or nitrate ions, and the anionic complexes formed are strongly adsorbed on anion-exchange resins. Well-established anion-exchange chromatographic methods are available and have been utilized for the isolation of neptunium from other actinides and fission product elements. From the viewpoint of the selectivity among neptunium ions and the other ions, nitrate media are preferable to chloride media. One such example is the procedure shown in Fig. 6.1 for the separation of ^{237}Np from environmental analytical samples, which consists of anion-exchange chromatography after solvent extraction with HTTA. The common procedure consists of the adjustment of neptunium ion at Np(iv) and the adsorption of Np(iv) nitrate complex, i.e. $Np(NO_3)_6^{2-}$, on the anion-exchange resin from 7 to 8 M HNO_3 solution. The anionic nitrate complexes of Pu(iv) and Th(iv) are also adsorbed on the resin. Pu(iv) is eluted as Pu(iii) with a mixture of 6 M HNO_3 + 0.05 M Fe(ii) sulfamate + 0.05 M hydrazine. Th(iv) is eluted with 8 M HCl. Np(iv) is then recovered by elution with 0.3 M HNO_3. Maiti *et al.* (1992) developed another method for the sequential separation of actinides by anion-exchange chromatography. Np(iv), Pu(iv), and U(vi) in 9 M HCl–0.05 M HNO_3 solution are adsorbed on the anion-exchange resin and Am(iii) is not adsorbed under these conditions. Pu(iv), Np(iv), and U(vi) are eluted successively using 9 M HCl–0.05 M NH_4I, 4 M HCl–0.1 M HF, and 0.5 M HCl–1 M HF, respectively. The Pu(iv) is eluted by the reduction of Pu(iv) to Pu(iii).

(b) Chromatography using chelate resins

Extraction chromatography using porous chelate resin loaded with an extractant is useful for the separation of actinides. A large number of theoretical plates of solvent extraction process is achieved during the column operation, which leads to an improvement of the selectivity in the separation. Maxwell (1997) developed a rapid method for the separation of neptunium using a resin loaded with Aliquat™ 336, which is called TEVA resin. Flowsheet is shown in Fig. 6.5. The oxidation states of neptunium and plutonium are adjusted to Np(IV) and Pu(III) by reducing them in a solution of Fe(II) sulfamate and ascorbic acid. Np(IV) is retained on the resin while >99.9% Pu(III) is eluted and removed. This method can be applied to such samples as nuclear materials process samples, waste solutions, and environmental samples.

TnOA-loaded Teflon resin was used for the rapid and simple separation of ^{237}Np from environmental samples (Ji *et al.*, 2001). Np(IV) in 2 M HNO_3 solution was adsorbed on the resin and eluted with 0.02 M $(COOH)_2$ + 0.16 M HNO_3 at 368 K. The decontamination factor for U(VI) was $>10^5$, allowing direct determination of ^{237}Np by ICP-MS.

Kimura (1990b) and Seranno and Kimura (1993) developed an extraction chromatographic method with TBP-loaded Amberlite XAD-4 resin for the

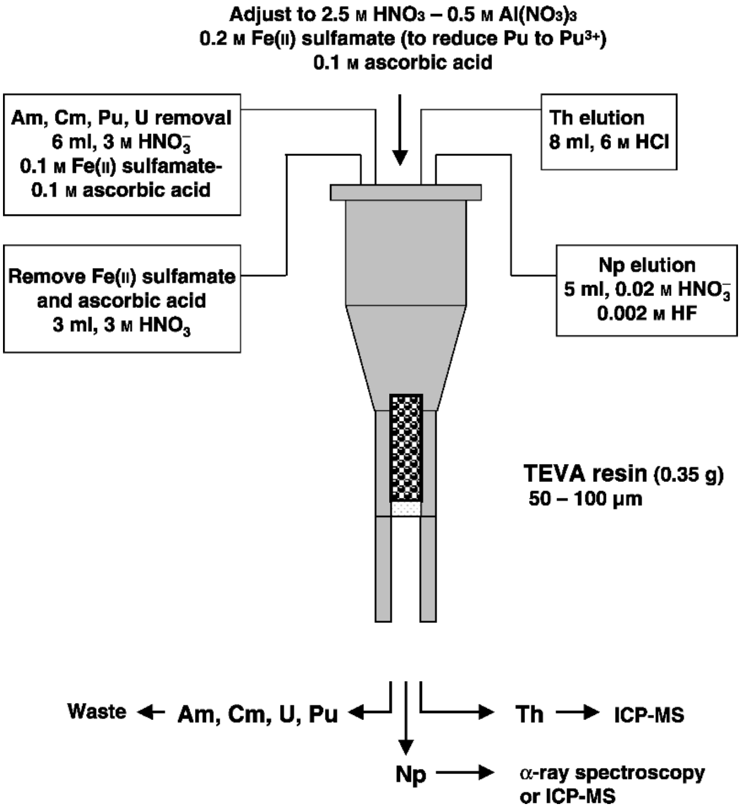

Fig. 6.5 *Procedure for the separation of neptunium ion from other actinide ions using TEVA resin.*

sequential separation of uranium, neptunium, plutonium, and americium. Np(vi) prepared by oxidizing neptunium ion in 3 M HNO_3 with 0.001 M $KBrO_3$ adsorbs on the resin and is eluted as Np(v) with the reductive effluent of 3 M HNO_3 + 0.05 M $NaNO_2$.

Heinrich and Klaus (1999) developed an automatic separation system, that is based on the extraction chromatography with silica gel particles loaded by TOPO, for the pretreatment of samples for nuclear material safeguards analysis. Np(iv), U(vi), and Pu(iv) in 3 M HNO_3 solution adsorb on the resin and are separated from Am(iii), Cm(iii), and fission products. Neptunium is eluted from the column as Np(v) with 0.1 M HNO_3 + 0.3 M H_2O_2 solution, plutonium is then eluted as Pu(iii) with formic acid + ascorbic acid, and finally U(vi) is eluted with $(NH_4)_2CO_3$ solution.

Diphonix resin combines methylenediphosphonate, carboxylate, and sulfonate functional groups in a cross-linked polystyrene resin. This resin has strong affinity toward actinide and lanthanide ions of various oxidation states (Chiarizia *et al.*, 1994). Horwitz *et al.* (1994) obtained data of the adsorption of Np(iv), U(vi), and Am(iii). One of the most distinguished features of this resin is its high adsorption ability of actinide ions from aqueous solutions even of high acidity.

6.5.3 Coprecipitation

Coprecipitation methods are traditional, well-established, and widely used for the separation of trace amounts of radioactive elements and the recovery of actinides such as neptunium. A typical example is the coprecipitation method for the preconcentration of ^{237}Np from a large volume of seawater for analytical purposes. Simplicity, rapidness, and applicability to treat large volumes of sample solution are the main advantages of this method. On the other hand, poor selectivity of coprecipitation often requires additional separation processes by solvent extraction or ion-exchange chromatography for the isolation of neptunium ions.

Several kinds of precipitates such as LaF_3, $BiPO_4$, $BaSO_4$, $Fe(OH)_3$, and MnO_2 have been used as a matrix. Np(iv) coprecipitates quantitatively with LaF_3 together with Pu(iii), Pu(iv), Th(iv), and lanthanide (iii). Because Np(vi) as well as Np(v) do not coprecipitate on LaF_3, neptunium can be separated from these metal ions by adjusting the oxidation state at Np(vi) or Np(v) before the coprecipitation procedure. U(vi) does not coprecipitate on LaF_3 from sulfate medium; therefore, U(vi) can be removed from the coprecipitated ions. Np(iv), Ce(iii), Ba(ii), and lanthanides (iii) coprecipitate on $BiPO_4$ very efficiently. Kimura *et al.* (1986) developed a sequential separation procedure utilizing the coprecipitation of neptunium, plutonium, and americium ions with $BiPO_4$. Hoelgye (1998) employed the $BiPO_4$ coprecipitation method for the separation of neptunium from urine samples.

6.5.4 Electrodeposition methods

The electrodeposition reaction of a metallic actinide at a cathode in a eutectic mixture of LiCl + KCl (ca. 700–900 K) was applied as the separation method for the actinide. This method has been expected to be a novel technology for pyrometallurgical reprocessing of nuclear spent fuels or partitioning of the HLW. Electrolytic reaction reduces an actinide (III) to actinide (0) in LiCl + KCl melt and deposits the metallic actinide at the surface of the solid cathode such as tungsten or dissolves the actinide in the liquid cathode such as bismuth or cadmium melt. There have been fundamental studies on the electrode process between Np(III) and Np(0) to obtain thermodynamic data including the equilibrium redox potential of Np(III)/Np(0), the activity coefficient and the diffusion coefficient of Np(III) in LiCl + KCl (Roy *et al.*, 1996; Sakamura *et al.*, 1998, 2000; Shirai *et al.*, 2001). Martinot (1991) developed a method for the preparation of metallic neptunium of high purity by electrodeposition in LiCl + KCl (723 K). The metal product contained a total of 500 ppm impurities.

6.5.5 Biotechnology

Biotechnological methods exhibit the potential of removal of neptunium from the solution. Lloyd *et al.* (2000) proposed a procedure utilizing a combination of two microbial activities that reduce Np(V) in the sample solution to Np(IV) using the reductive capability of *Shewanella putrefaciens* followed by the formation of Np(IV) precipitate with a phosphate ligand enzymatically liberated by *Citrobacter species*. Immobilized cells of a *Citrobacter species* were prepared and employed for the removal of neptunium and plutonium ions from the sample solution (Macaskie and Basnakova, 1998).

6.6 THE METALLIC STATE

6.6.1 Neptunium metal

Although tracer quantities of neptunium were first produced by McMillan and Abelson (1940), it was not until 1945 that microgram quantities of metallic neptunium were synthesized by Magnusson and LaChapelle (1948). Their method reacted NpF_3 with barium at 1473 K. Several methods are currently used to produce gram-sized quantities of metallic neptunium. The first of these reacts NpF_4 with a stoichiometric excess of calcium and 0.15 mol of iodine 'booster' per mole of neptunium (Haire, 1986). A second method uses NpO_2 as a starting material, although other compounds such as $Cs_2NpO_2Cl_4$ and $Cs_3NpO_2Cl_4$ can be used as starting materials, and applies molten salt electrochemistry (Reavis *et al.*, 1985). A salt of LiCl/KCl is used as the electrolyte maintained at 723 K and the material is subjected to stream of HCl and H_2 gas

(Martinot, 1984). The neptunium produced can be collected either as a solid cathodic deposit on a tungsten mandrel or through use of a vitreous magnesia crucible suspended in the salt and positioned around the tungsten cathode to harvest the drops of neptunium from the cathode. The second method of collection is more challenging due to a higher operating temperature of 1023 K but can yield gram-sized quantities. A third method for producing neptunium is the reduction of NpC using tantalum followed by distillation of the neptunium metal (Spirlet and Vogt, 1984). The purity of the neptunium produced from the methods mentioned above is high, typically 99.95%, although the method involving calcium may require further electrorefining to obtain such an elevated level of purity. Recently, Hasegawa *et al.* (1998) developed a new method for the preparation of metallic neptunium based on the electrodeposition from aqueous solution. Neptunium is amalgamated by electrolysis at a mercury cathode with electrolyte solution of 1 M CH_3COOH + 0.3 M CH_3COONa (pH = 3.5) containing 0.05 M neptunium and then separated from mercury by evaporation at 1523 K.

Metallic neptunium is silvery in appearance and forms a thin oxide layer when exposed to air at ordinary temperatures. The reaction to form oxide is more pronounced at higher temperatures. The metallic form is similar to uranium in physical workability. The accepted values for melting point and density are (912 ± 3) K and 19.38 $cm^3\ g^{-1}$ (Lemire *et al.*, 2001, pp 85–87), respectively. Boiling point has not been determined experimentally; however, a value of 4447 K has been obtained via extrapolation of vapor pressure results (Eick and Mulford, 1964).

The thermodynamic properties of neptunium have been compiled by Oetting *et al.* (1976). Metallic neptunium exists in three crystalline forms (allotropes): α-form (orthorhombic), β-form (tetragonal), and γ-form (body-centered cubic (bcc)). The accepted transition temperatures, obtained by several independent groups (Zachariasen, 1952; Lee *et al.*, 1959; Wittenberg *et al.*, 1970), for the transitions are: $\alpha \rightarrow \beta$ (553 ± 5 K) and $\beta \rightarrow \gamma$ (849 ± 5 K). The enthalpies and entropies of transition for the three allotropes are: (1) for the $\alpha \rightarrow \beta$ transition, 5607 J mol^{-1} (ΔH°) and 10.1 J $K^{-1}mol^{-1}$ (ΔS°) and (2) for $\beta \rightarrow \gamma$ transition, 5272 J mol^{-1} (ΔH°) and 6.23 J $K^{-1}mol^{-1}$ (ΔS°). A later determination of these temperatures and enthalpies of transition using differential thermal analysis has yielded slightly different values: (1) for the $\alpha\rightarrow\beta$ transition (555 K), 4730 J mol^{-1} (ΔH°) and (2) for $\beta \rightarrow \gamma$ transition (856 K), 2990 J mol^{-1} (ΔH°) (Foltyn, 1990). The largest difference between the latter values and earlier set are in the enthalpies of transition. It is reasonable to state that improvement in methods and instrumental techniques could account for this ‘refinement’ of the values of ΔH°. Some mention of a possible fourth allotrope has been advanced in the literature but without conclusive proof at this time (Foltyn, 1990).

The pertinent thermodynamic values at 298 K for metallic neptunium are: entropy, 50.5 J K^{-1} mol^{-1}, heat capacity, 29.6 J $K^{-1}mol^{-1}$, and the enthalpy component, $\{H^\circ(298) - H^\circ(0)\}$ 6.60 kJ mol^{-1}. The enthalpy and entropy of

Table 6.3 *Lattice parameters and space groups for allotropes of neptunium.* (*Lemire* et al., 2001)

[b] at 873 K.

fusion for neptunium are 5.19 kJ mol^{-1} and 5.69 J $K^{-1}mol^{-1}$, respectively (Wittenberg, 1970).

The fundamental studies of the crystallography of metallic neptunium were performed by Zachariasen (1952). This work was repeated, to a certain extent and with a different emphasis, by Mardon and Pearce (1959) as a portion of their study of the neptunium–uranium equilibrium diagram. The complete phase diagram for the allotropes of neptunium was first published by Stephens (1966). The lattice parameters for the allotropes are listed in Table 6.3.

The α allotrope of Np is orthorhombic and resembles a highly deformed bcc cell (Zachariasen, 1952). The coordination in this configuration has been reduced from 8 to 4 with a bond length of approximately 2.60 Å. The β allotrope of neptunium is a distorted tetragonal close-packed cell with 4 atoms per unit cell and a bond length of 2.76 Å. The bond length in the γ allotrope of neptunium is 2.97 Å. The phase diagram, fully developed by Stephens (1966), allows for several observations. The region of γ allotrope stability diminishes as the pressure is increased. The melting point of neptunium increases as the pressure is increased. The triple point of β-phase/γ-phase/liquid occurs at 998 K and 3200 MPa.

6.6.2 Neptunium alloys and intermetallic compounds

The past two decades have seen a resurgence of interest in the basic chemistry of neptunium in the area of alloys and intermetallic compounds (Hill, 1971; Aldred *et al.*, 1975; Elliot and Giessen, 1982; Potzel *et al.*, 1983, 1993; Gal *et al.*, 1987; Spitsyn and Ionova, 1987; Schafer *et al.*, 1989; Foltyn, 1990; Kalvius *et al.*, 1992, 1994; Yaar *et al.*, 1992; Gibson and Haire, 1993; Kitazawa *et al.*, 1993; Ogawa, 1993; Sanchez *et al.*, 1993, 1995; Wastin *et al.*, 1993; Zwirner *et al.*, 1993; Gibson *et al.*, 1994, 1996, 1999; Oddou *et al.*, 1994; Rodriguez *et al.*, 1994; Stewart *et al.*, 1994; Seret *et al.*, 1995; Jeandey *et al.*, 1996; Akabori *et al.*, 1997; Keiser *et al.*, 2000; Meresse *et al.*, 2000). The interest in intermetallic compounds in particular has been keen with the focus being the interesting and complex behavior observed due to the presence of f-shell electrons. The actinides and their intermetallic compounds exhibit magnetic behavior ranging from itinerant, band-like character, similar to transition metals, to local moment behavior, similar to the rare earths. The variety of behavior stems from either the overlap of the 5f wave functions or the hybridization of f electrons with the ligand orbitals. For contrasting example, $NpAl_3$ is a ferromagnet, no ordering was found in $NpGe_3$, and $NpSn_3$ was thought to exhibit heavy fermion behavior (Sanchez *et al.*, 1993). The observation of heavy fermion behavior for compounds of several actinides (U, Np, Pu) has been reported by several groups (Potzel *et al.*, 1983, 1993; Gal *et al.*, 1987; Spitsyn and Ionova, 1987; Schafer *et al.*, 1989; Kalvius *et al.*, 1992, 1994; Yaar *et al.*, 1992; Sanchez *et al.*, 1993, 1995; Wastin *et al.*, 1993; Zwirner *et al.*, 1993; Gibson *et al.*, 1994; Oddou *et al.*, 1994; Rodirguez *et al.*, 1994; Seret *et al.*, 1995; Jeandey *et al.*, 1996; Meresse *et al.*, 2000). To restate this unusual behavior in other (more chemical) terms, the 5f electrons of neptunium are relatively unshielded from the crystalline electric field interaction, unlike the rare earths where the 4f electrons are very well shielded thus quenching the angular momentum term leading J to be a good quantum number. In metallic neptunium and other actinides, the spin–orbit coupling is on the same order as the crystalline electric field interaction, leading to possible mixing of the J multiplet and a metallic solid that does not strictly adhere to Hund's rule (Potzel, 1983).

The primary instrumental methods for investigating the various neptunium intermetallics have been: specific heat measurements (Stewart *et al.*, 1994), Mössbauer spectroscopy (Gal *et al.*, 1987; Yaar *et al.*, 1992; Potzel *et al.*, 1993; Sanchez *et al.*, 1993, 1995; Kalvius *et al.*, 1994; Oddou *et al.*, 1994; Jeandey *et al.*, 1996), electrical conductivity (Seret *et al.*, 1995), X-ray diffraction (Wastin *et al.*, 1993; Meresse *et al.*, 2000), magnetization measurements (Yaar *et al.*, 1992; Kitazawa *et al.*, 1993; Sanchez *et al.*, 1993), and neutron diffraction (Oddou *et al.*, 1994).

The investigations of magnetic properties of the intermetallic compounds of neptunium has primarily focused on crystalline compounds, however, some early work was also performed on metallic glasses by Elliott and Giessen (1982). They conducted a study of some 13 metallic glasses containing Np, U, and Pu using X-ray diffraction to determine the interatomic distances. The primary experimental focus has been in the area of crystalline compounds of several types: (1) ternary compounds of composition RMt_2X_2 (R is either Th, Np or Pu, Mt is a 3d, 4d, or 5d transition metal, and X is Si or Ge) (Potzel *et al.*, 1993; Wastin *et al.*, 1993; Jeandey *et al.*, 1996); (2) ternary compounds such as AnT_2Al_3 (where An is either Np or Pu and T is Ni or Pd) or Np_2T_2Sn (where T is Ni, Pd, or Pt) (Zwirner *et al.*, 1993; Sanchez *et al.*, 1995; Seret *et al.*, 1995); (3) binary compounds of composition NpX_3 (where X is Al, Ga, Ge, In, or Sn) (Sanchez *et al.*, 1993; Kalvius *et al.*, 1994; Oddou *et al.*, 1994; Meresse *et al.*, 2000); (4) binary compounds of composition $NpCd_{11}$ (Stewart *et al.*, 1994); (5) binary compounds such as $NpBe_{13}$, $NpRu_2$, $NpOs_2$, and $NpIr_2$ (Gal *et al.*, 1987); (6) ternary compounds of the composition $AnFe_4Al_8$ (where An is Th, U, or Np) (Schafer *et al.*, 1989); and (7) binary compounds of the composition NpM_2 (where M is Al, Cr, Mn, Fe, Co, Ni, Cu, Os, Ir, Ru, or Zn) (Spitsyn and Ionova, 1987).

The effort in the nuclear industry to minimize the amount of the long-lived heavy isotopes of Np, Am, and Pu present in spent fuel so as to make the disposal of the spent fuel more environmentally and economically palatable has led to the efforts in the field of alloying Np with Zr, U, Am, and Pu (Gibson and Haire, 1993; Rodriguez *et al.*, 1994). Modeling efforts have also been employed to better understand the alloying behavior of neptunium with U, Am, Pu, Zr, and Fe (Ogawa, 1993; Gibson *et al.*, 1999). The intent of these efforts is to take long-lived actinides that have been separated from light water reactor spent fuel and recast them into fuel for irradiation in either an accelerator or a breeder reactor and thus transform the long-lived heavy isotopes into shorter-lived isotopes. This work is still underway and the success or failure of these efforts may play a pivotal role in the needed capacity of future geologic repositories for spent fuel in the world.

The formation of binary compounds with stainless steel components such as Fe, Ni, Mn, and Co has been studied from two distinct vantage points. There has been some interest in their magnetic properties (Aldred *et al.*, 1975). More recently intermetallic neptunium compounds (with Fe, Cr, Ni, and Zr) have been formed in a HLW produced from cladding hulls of spent breeder reactor fuel (Keiser *et al.*, 2000). Some neptunium is left in the cladding hulls after electrometallurgical processing for recovery of the uranium. The neptunium that is left forms Laves-type intermetallics with iron, from the stainless steel cladding, and the zirconium, from the metallic alloy fuel, U/10 wt% Zr. More extensive investigations in the general behavior of neptunium with a variety of transition metals have been undertaken by Gibson *et al.* (1994) and Akabori *et al.* (1997).

With the continued interest in making the most economic and environmentally conscious use of the geologic repository for spent fuel and the focus on materials that exhibit possible superconducting properties this area of neptunium chemistry promises to be a lively one for years to come.

6.7 IMPORTANT CLASSES OF COMPOUNDS

Since the discovery of neptunium in 1940 several important activities have directed the synthesis and characterization of neptunium compounds. These activities include the importance of neptunium compounds to fundamental research, as source material for producing Pu-238, and recently neptunium's role as an environmental concern in waste disposal or as a 'burnable' component in future nuclear reactor fuels. As a result of these activities numerous publications are found in the open literature. Synthetic methods, crystal structure, chemical behavior, and thermodynamic properties have been reviewed in a number of books and publications as follows: *The Chemistry of the Transuranium Elements*, Verlag Chemie, Weinheim, Keller (1971); *Gemlin Handbuck der Anorganischen Chemie*, Suppl. Work 8th edn, Transuranium, Verlag Chemie, Weinheim, vol. 4 part C, Compounds (1972); *The Chemical Thermodynamics of Actinide Elements and Compounds*, Part 4, Part 6, Part 8, Part 9 (ed. F. L. Oetting), International Atomic Energy Agency, Vienna, *Comprehensive Inorganic Chemistry* (ed. A. F. Trotman-Dichinson), Pergamon Press, Oxford, vol. 10, pp. 141–429 (1975); *Handbook on the Physics and Chemistry of the Actinides*, vol. 3 (eds. A. J. Freeman and C. Keller), Elsevier Science Publishers B.V., Amsterdam; (1985); *Handbook on the Physics and Chemistry of the Actinides*, vol. 6 (eds. A. J. Freeman and C. Keller), Elsevier Science Publishers B.V., Amsterdam; (1991); *Synthesis of Lanthanide and Actinide Compounds* (eds G. Meyer and L. R. Morss), Kluwer Academic Publishers, Dordrecht, The Netherlands (1991); and *Chemical Thermodynamics of Neptunium and Plutonium* (Lemire, R. J. *et al.*), Elsevier, Amsterdam (2001).

6.7.1 Hydrides

The reaction of neptunium with hydrogen results in the formation of hydrides similar to those produced by the reaction of hydrogen with plutonium (Fried and Davidson, 1948). Two hydrides, NpH_{2+x} and NpH_3, were synthesized and characterized by Mulford and Wiewandt (1965). Mintz *et al.* (1976) and recently Ward *et al.* (1987) confirmed the existence of these phases. A phase diagram proposed by Ward *et al.* (1987) for the neptunium–hydrogen system is shown in Fig. 6.6.

Mulford and Wiewandt (1965) found NpH_{2+x} to be face-centered cubic (fcc) and isostructural with PuH_{2+x} but with increasing lattice constants as hydrogen content increases. This trend is opposite of that expected when compared to the lattice constants for the plutonium–hydrogen system (Mulford and Wiewandt, 1965). Ward *et al.* (1987) confirmed this trend in neptunium–hydrogen lattice constants. A comparison of the lattice constants from the two investigations is given in Table 6.4. Both studies show the NpH_3 phase is hexagonal and isostructural with PuH_3. The lattice parameters found by Ward *et al.* (1987) are $a_0 = 6.5338$ Å and $c_0 = 6.7204$ Å.

Pressure–composition isotherms generated by Mulford and Wiewandt (1965) and later by Mintz *et al.* (1976) show flat plateaus to a [H]/[Np] value of approximately 2.16 in contrast to other actinides and lanthanides that show a phase boundary at 1.90. Another anomalous behavior found by Mulford and Wiewandt (1965) is increasing hydrogen content with increasing temperature as opposed to decreasing hydrogen with increasing temperature in the plutonium–hydrogen system. In addition to the anomalous behaviors described above, a comparison of the two reports show contrasting and conflicting thermodynamic values calculated from the pressure–composition isotherms. Ward *et al.* (1987) gives a detailed review of the two studies.

Thermodynamic data taken from Ward *et al.* (1987) are presented here. These data are selected for reporting because Ward re-examined the neptunium–hydrogen system using ultrapure, double-refined neptunium metal, and a

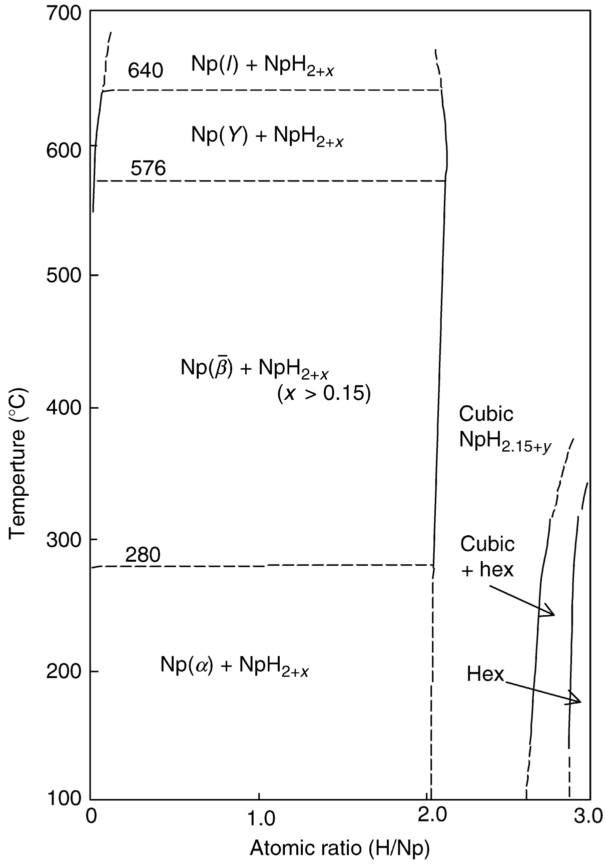

Fig. 6.6 *Partial phase diagram for the neptunium–hydrogen system. Reprinted from Ward* et al. (1987) *with permission from Elsevier Science.*

sophisticated Sievert's type apparatus. The pressure for hydrogen above $NpH_{2.13}$ below 849 K is given by:

$$\ln p \,(\text{pascals}) = 25.043 - 13421T^{-1} \tag{6.10}$$

From this equation enthalpies and entropies of formation for the reaction 0.94 $Np + H_2 = 0.94\ NpH_{2.13}$ are −118.8 kJ mol^{-1} (−28.38 kcal mol^{-1}) and −119.7 J K^{-1} mol^{-1} (−28.6 cal K^{-1} mol^{-1}), respectively. Ward calculated the enthalpy and entropy of formation for NpH_3 to be −153.9 kJ mol^{-1} (−36.78 kcal mol^{-1}) and −174.0 J $K^{-1}mol^{-1}$ (−41.63 cal K^{-1} mol^{-1}), respectively. Ward tabulated calculated partial and integral enthalpies and entropies and compared the data vs the data of Mulford and Wiewandt (1965) and Mintz *et al.* (1976).

There are no known heat capacity data for neptunium hydrides. Flotow *et al.* (1984) estimated the heat capacity of $NpH_2(s)$ from the data of Mulford and

Wiewandt (1965) and Mintz *et al.* (1976). The estimated C_p° at 298 K is 47.279 J K^{-1} mol^{-1}. Flotow *et al.* (1984) lists estimated heat capacities from 298 to 900 K in tabular form.

There are few published data describing chemical behavior of neptunium hydrides. Haschke (1991) reviews the practical aspects of actinide hydrides focusing on safety, compound purity, reaction rates, and preparatory procedures. Recognizing the well-known pyrophoricity of both plutonium and uranium and the fact that neptunium hydride decomposes above 573 K in vacuum, yielding finely divided pyrophoric elemental neptunium, one must take great care in handling neptunium hydrides.

6.7.2 Oxides, hydrated oxides, and hydroxides

Given that neptunium has five oxidation states, it is surprising that there are only two known anhydrous oxides, NpO_2 and Np_2O_5. Attempts to synthesize higher oxides have not been successful (Katz and Gruen, 1949) and the early reported existence of Np_3O_8 has been shown to be the neptunium pentoxide (Sudakov *et al.*, 1972; Fahey *et al.*, 1976a,b). Richter and Sari (1987) on the basis of their work and recent new information on the two-phase boundaries between Np and NpO_{2-x} experimentally determined by Bartscher and Sari (1986) proposed modifications to the partial phase diagram constructed by Belyaev (1983). Their phase diagram, shown in Fig. 6.7, shows the effects of the three metal phases and the substoichiometric range, NpO_{2-x}, first noted by Ackerman *et al.* (1966). However much important work remains to be done to fully understand the neptunium–oxygen system. Recently, Beauvy *et al.* (1998) did not find neptunium metal in their investigation of the preparation of actinide compounds for actinide transmutation, contrary to the data shown in the neptunium–oxygen phase diagram.

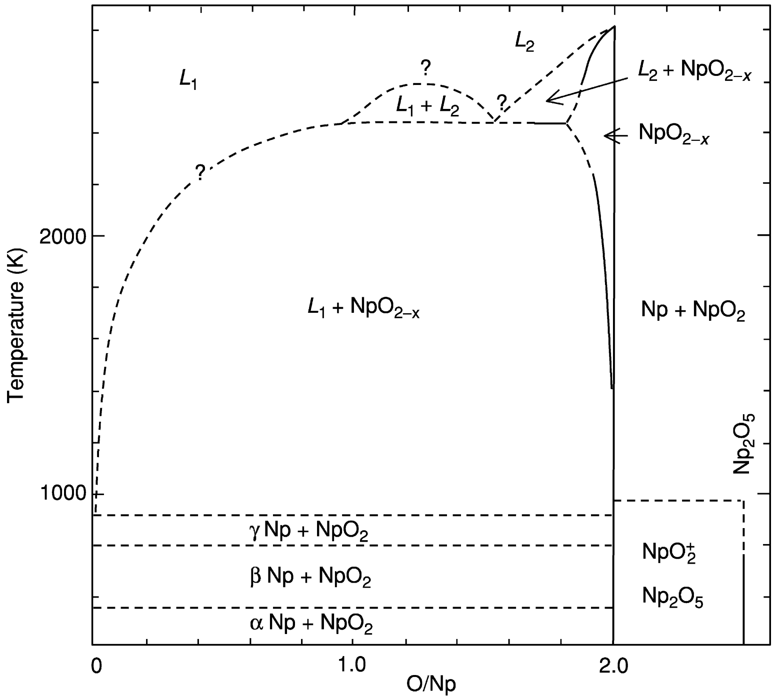

Fig. 6.7 *Phase relation of the neptunium–oxygen system. Reprinted from Richer and Sari* (1987), *with permission from Elsevier Science.*

NpO_2 is synthesized by the thermal decomposition of many neptunium compounds of any oxidation state. The oxide has a fluorite structure with a lattice parameter of (5.4334 ± 0.0003) Å and is isostructural with other actinide oxides (Fahey *et al.*, 1974). Martinot *et al.* (1970) grew single crystals of NpO_2 electrochemically. Spirlet *et al.* (1980) prepared single crystals of NpO_2 by means of a chemical transport reaction using tellurium tetrachloride as a transporting agent in a quartz ampoule at 1233 to 1323 K. X-ray diffraction characterization of the single crystals showed a fluorite lattice parameter of (5.433 ± 0.001) and (5.434 ± 0.001) Å, respectively, in relatively good agreement with literature data of Fahey *et al.* (1974, 1976a,b). Recently, Finch (2002) reported the crystallization of NpO_2 during corrosion experiments in which neptunium-doped U_3O_8 is reacted with humid air at 423 K for several weeks.

NpO_2 is extremely stable over a wide range of temperatures and pressures. The compound does not show a phase transition at low temperatures (Marples, 1975). Benedict *et al.* (1986) studied NpO_2 at pressures up to 50 GPa. Their study shows a phase transition from the fluorite fcc structure to orthorhombic between 33 and 37 GPa. The phase returned to the fcc structure on releasing pressure. The compound is stable at oxygen pressures and temperatures to 2.84 MPa and 673 K (Fahey, 1986). Non-destructive assay standards require materials of known purity for calibration and certification of instruments. Starting with impure NpO_2 and metal, Yarbro *et al.* (1991) synthesized rather pure NpO_2 and metal using two different procedures. Following dissolution, double peroxide precipitations, ion exchange, and an oxalate precipitation of the impurities in the resulting oxides were below 100 ppm each.

The identification of Np_2O_5 and its position in the neptunium–oxygen system result from several investigations of earlier contradictory information (Fahey *et al.*, 1976a,b; Richter and Sari, 1987). Cohen (1963) and Cohen and Walter (1964) obtained Np_2O_5 by precipitation of the compound by bubbling ozone through molten $LiClO_4$ containing NpO_2^+. Bagnall and Laidler (1964) prepared the compound by the thermal decomposition of $NpO_3 \cdot H_2O$ and Sudakov *et al.* (1972) prepared the compound by the decomposition of NpO_2OH(am). Investigations by Fahey *et al.* (1976a,b) and Sudakov *et al.* (1972) provided clarification of early reported contradictory information. Bessonov *et al.* (1989a) reported the synthesis of Np_2O_5 from neptunium(IV) peroxide, double nitrate, and oxalate, apparently contradicting previously published reports. Neptunium peroxide was quantitatively converted to the pentoxide by heating at 573 to 623 K for 2 to 3 h or by heating in an ampoule at 453 to 473 K under a layer of water. The preparation of Np_2O_5 from the double nitrate and oxalate was complex involving several steps for the double nitrate. Attempts to prepare Np_2O_5 by oxidation of NpO_2 at temperatures between 700 and 970 K and oxygen pressures at 0.3 MPa were not successful (Richter and Sari, 1987). Brown Np_2O_5 is monoclinic with the following lattice parameters: $a_0 = (4.183 \pm 0.003)$ Å, $b_0 = (6.584 \pm 0.005)$ Å, and $c_0 = (4.086 \pm 0.003)$ Å, and $\beta = (90.32 \pm 0.03)^\circ$ (Fahey *et al.*, 1976a,b). Np_2O_5 is not very stable decomposing to NpO_2 and O_2 at 693 to 970 K (Bagnall and Laidler, 1964; Richter and Sari, 1987).

Neptunium hydrated oxides and hydroxides are very important in the context of the disposition of nuclear waste. Considerable interest has been devoted to Np(V) since it is the most stable valence of neptunium in the environment. Recent publications reporting the results of studies particularly on chemical thermodynamics have been exhaustively reviewed and summarized by Lemire *et al.* (2001), pp 105–29.

Heptavalent neptunium hydroxide has been precipitated from acidic solutions containing Np(VII) by addition of NaOH or LiOH to a pH at approximately 10 (Krot *et al.*, 1968a; Chaikhorskii and Leikina, 1972). Both studies reported a formula of $NpO_2(OH)_3$. Later, Musikas *et al.* (1974) reported the formula to be $NpO_3(OH)$ based on a titration study showing one hydroxyl ion per Np(VII) ion. Chaikhorskii *et al.* (1972) obtained Np(VII) hydroxide by passing ozone through a suspension of Np(V) hydroxide. The reaction was carried on at 363 K for 5 h or by passing ozone over dried Np(V) hydroxide at 368 to 373 K for 5 h. Nikonov *et al.* (1994) investigated the oxidation of Np(V) hydroxide to form a compound containing Np(VII). The investigators reported the preparation of $(NpO_2OH)(NpO_4) \cdot 4H_2O$.

Several preparations for the synthesis of neptunium(VI) hydrates and hydroxides have been developed. LaChapelle *et al.* (1947) reported the precipitation of neptunium(VI) hydroxide by the addition of ammonia and sodium hydroxide to sulfuric acid solutions containing Np(VI). Cohen (1963) reported the preparation of $NpO_3 \cdot 2H_2O$ by oxidation of Np(V) in a molten $LiNO_3/KNO_3$ eutectic at 423 K with ozone. Bagnall and Laidler (1964), Chaikhorskii *et al.* (1974), and Belyaev *et al.* (1975) precipitated $NpO_3 \cdot H_2O$ and $NpO_3 \cdot 2H_2O$ by adding ozone to aqueous suspensions of neptunium(V) hydroxide. $NpO_2(OH)_2$ was prepared by bubbling ozone into an aqueous solution of NpO_2ClO_4 at $pH = 5$ and 363 K (Belyaev *et al.*, 1979). Kato *et al.* (1996) prepared $NpO_3 \cdot H_2O$ from an acidic solution. The X-ray diffraction pattern and infrared spectrum for their compound was different from that found by Bagnall and Laidler (1964). Recently, Saito *et al.* (1999), to prevent the formation of Np(VII), developed several methods to prepare neptunyl hydroxides. The authors prepared a starting solution containing $NpO_2(NO_3)_2 \cdot xH_2O$. Anhydrous $NpO_2(OH)_2$ and $NpO_2(OH) \cdot H_2O$ (orthorhombic) were precipitated by the addition of pyridine at 373 and 343 K, respectively. $NpO_2(OH) \cdot H_2O$ (hexagonal) and $NpO_2(OH)_2 \cdot xH_2O \cdot yNH_3$ $(x + y = 1)$ were prepared by the addition of LiOH and ammonia water, respectively. The formula reported for the monohydrate has been reported variously as $NpO_3 \cdot H_2O$ and $NpO_2(OH)_2$ (Bagnall and Laidler, 1964; Kato *et al.*, 1996; Saito *et al.*, 1999). The recent review by Lemire *et al.* (2001), p 118 assigns the formula, $NpO_2(OH)_2$, to the dried solid of Bagnall and Laidler (1964) and the formula, $NpO_3 \cdot H_2O$, to the solid of Kato *et al.* (1996). In summary, Lemire *et al.* (2001), p 118 and Saito *et al.* (1999) describe the chemistry of the hydrated oxides and hydroxides of hexavalent neptunium to be a complicated system.

Interest in the solubility and hydrolysis reactions of Np(V) results from the stability and mobility of this oxidation state in the natural environment, the relatively long half-life of ^{237}Np (2.144×10^6 years), and its abundance in nuclear waste (Lierse *et al.*, 1985). Investigators obtained neptunium(V) hydroxide by adding ammonia, NaOH, or LiOH to slightly acidic or basic solutions containing Np(V) (LaChapelle *et al.*, 1947; Chaikhorskii *et al.*, 1974; Neck, 1992; Merli and Fuger, 1994). Neck *et al.* (1992) reported that freshly prepared green NpO_2OH in 1 M $NaClO_4$ turned to a gray-white precipitate with a lower solubility upon aging. The aged precipitate has a lower solubility than that obtained by the addition of ammonia water to a slightly acidic nitrate and $NaClO_4$ solutions containing NpO_2^+. Their preparations did not show any diffraction lines.

Neptunium(IV) hydroxides are formed in the manner of LaChapelle *et al.* (1947). There are apparently very few data on the hydrates/hydroxides of Np(IV) and Np(III) oxides. Keller (1975) reported that hydrous oxides, $MO_2(aq)$ have varying amounts of absorbed water rather than forming distinct compounds such as $M(OH)_4$. In contrast, Rai *et al.* (1987), studying the solubility of $NpO_2 \cdot xH_2O(am)$, reported that hydrous oxides are thermodynamically reproducible material over a period of 2 days to several months when maintained at 298 K. Lemire *et al.* (2001), pp 114–5 however, suggests that the compound is not thermodynamically stable representing a reproducible compound formed under different experimental conditions. Further research is required to fully characterize neptunium oxide hydrates.

Available thermodynamic data for the oxides, hydrates, and hydroxides have been extensively reviewed (Lemire *et al.*, 2001, pp 105–29). Table 6.5 lists the entropies, enthalpies, and Gibbs energies selected from the review Lemire *et al.* (2001).

Ternary oxides are primarily obtained by the reaction of NpO_2 with oxides of many different elements or by precipitation from alkaline solutions. The syntheses and characterization of these oxides have been extensively reviewed (Keller, 1972; Morss, 1982; Tabuteau and Pagès, 1985). Recently Morss *et al.* (1994) reviewed the pioneering work of Keller and co-workers in the synthesis and characterization of alkali neptunates and the importance of these compounds because of their bonding and electronic properties.

The known alkali and alkaline earth Np(VII) ternary oxides include: Li_5NpO_6, $Ba_3(NpO_5)_2$, Ba_2LiNpO_6, Rb_3NpO_5, K_3NpO_5, Cs_3NpO_5, $RbNpO_4$, $KNpO_4$, and $CsNpO_4$ (Keller and Seiffert, 1969; Awasthi *et al.*, 1971; Pages *et al.*, 1971; Mefod'eva *et al.*, 1976). Keller and Seiffert (1969) prepared Li_5NpO_6 by reacting Li_2O with NpO_2 at 673 K for 16 h. Awathi *et al.* (1971) reacted Li_2O_2 with $NpO_3 \cdot H_2O$ at 673 K for 16 h in a quartz tube in flowing oxygen at ambient pressure to obtain the compound. The compound was reported to be Li_5ReO_6 hexagonal structure with lattice parameters: $a_0 = (5.21 \pm 0.03)$ Å and $c_0 = (14.61 \pm 0.05)$ Å, the results of Awasthi *et al.* (1971) differing only slightly from those of Keller and Sieffert (1969). Recently Morss *et al.* (1994) reinvestigated the compound using X-ray and neutron diffractions. The objective of their

Table 6.5 *Thermodynamic properties of neptunium oxides and hydrated oxides at* 298.15 K.

$NpO_2 \cdot$ (hyd,am)			-957.3 ± 8.0	

investigation was the redetermination of the structure based on the earlier finding that Li_5ReO_6 was monoclinic and not in the $R3m$ space group (Betz and Hoppe, 1984). The investigators found the X-ray diffraction patterns to be consistent with past data. However, they did not confirm the originally suggested space group, $R3m$, or any other structure using any plausible model.

$Ba_3(NpO_5)_2$, Ba_2NaNpO_6, and Ba_2LiNpO_6 were obtained by solid state reactions of alkali and alkaline peroxides with $NpO_3 \cdot H_2O$ at temperatures between 673 and 873 K for 15 to 30 h (Awasthi *et al.*, 1971). Interestingly, the reaction between Na_2O_2 and $NpO_3 \cdot H_2O$ was incomplete under the conditions of the experiment. The authors reported the presence of both Np(VI) and Np(VII) absorption spectra in dilute NaOH solution of the dissolved product. Furthermore, X-ray examination of the product showed evidence of unreacted Na_2O_2. Attempts to produce K_5NpO_6 and Ba_2KNpO_6 using the appropriate reactants under similar conditions were not successful. Pagès *et al.* (1971) obtained K_3NpO_5, Rb_3NpO_5, and Cs_3NpO_5 by the general reaction:

$$NpO_2 + 3MO_2 \rightarrow M_3NpO_5(M = K, Cs, Rb) \qquad (6.11)$$

Mefod'eva *et al.* (1976) precipitated $KNpO_4$, $RbNpO_4$, and $CsNpO_4$ from alkaline solutions containing the appropriate alkali metal nitrate, ozone, and Np(VII). Alkali metal to neptunium ratios for these compounds ranged from 1.07 to 1.19. The overestimation of the alkali metal content was explained by an admixture of nitrates.

A large number of hexavalent neptunium ternary oxides are obtained by solid state reactions of NpO_2 and alkali or alkaline earth oxides in a stream of oxygen. These oxides, generally isostructural, with uranates of the same chemical formula include: rhombohedral $Na_2Np_2O_7$, orthorhombic α-Na_2NpO_4 and β-Na_2NpO_4, tetragonal Li_4NpO_5 and α-Na_4NpO_5, orthorhombic β-Na_4NpO_5, Li_6NpO_6, and Na_6NpO_6 (Keller *et al.*, 1965a). Heating a 2:1 mixture of NpO_2 and Na_2O at temperature >673 K results in the formation of $Na_2Np_2O_7$. The heating of $Na_2Np_2O_7$ at >773 K gives α-Na_2NpO_4, which if heated to 1073 K results in the formation of β-Na_2NpO_4. Heating a 1:2 mixture of NpO_2 and Na_2O in an oxygen atmosphere at 673 K produces cubic α-Na_4NpO_5. Heating to >773 K may result in the formation of β-Na_4NpO_5. Further heating to 1073 K β-Na_4NpO_5 decomposes to β-Na_2NpO_4. When a 1:3 mixture of NpO_2 to Na_2O is heated to 773 K Na_6NpO_6 results. Heating a 1:2 mixture of NpO_2 and Li_2O at 673 to 773 K results in Li_4NpO_5 and heating a 1:3 mixture to 673 to 773 K results in Li_6NpO_6. $NaNp_2O_7$ is precipitated from molten salts containing either Np(V) or Np(VI) by reaction with BrO_3^- (Carnall *et al.*, 1965). Keller (1963) synthesized and characterized the following hexavalent Np(VI) alkaline earth oxides: $MNpO_4$ and M_3NpO_6 (where M = Ba, Ca, Sr). Appel *et al.* (1990) using crystallographic and spectroscopic techniques as well as magnetic susceptibility measurement and Mössbauer spectroscopy investigated the structure of $BaNpO_4$. The authors reported that structure to be isostructural with $BaUO_4$ with the lattice contants $a_0 = 5.726$ Å, $b_0 = 8.072$ Å, and $c_0 = 8.165$ Å. Hoekstra and Gebert (1977) synthesized M_2NpO_4 and M_2NpO_7 (where M = K, Rb, and Cs), $Cs_4Np_5O_{17}$, $Cs_2Np_3O_{10}$, and Li_2NpO_4. The researchers obtained the compound by two methods: (1) thermal decomposition of coprecipitated alkali-actinide nitrates and (2) reaction of alkali hydroxides with Np_2O_5.

Compounds of the types $K_2Np_2O_7$, K_2NpO_4, and $BaNpO_4$ have crystal structures made up of linear NpO_2^{2+} groups arranged in layers. By contrast, no NpO_2^{2+} groups are found in the crystal lattice of Li_6NpO_6 (Morss, 1982). Coordination, crystal chemistry, and thermochemistry of these oxides have been reviewed by Morss (1982) and Mössbauer studies have been reported by Jovè *et al.* (1988a,b).

Ternary oxides containing pentavalent neptunium include: Li_3NpO_4, Na_3NpO_4, and Li_7NpO_6 (Keller *et al.*, 1965b). Li_3NpO_4 is obtained by heating Li_6NpO_6 at 1173 to 1273 K apparently in a stream of argon. Na_3NpO_4 results from the heating of a mixture of Na_6NpO_6 and NpO_2 in vacuum at 773 K for 8 h. Li_3NpO_4 is obtained by heating Li_6NpO_6 in vacuum at 1173 to 1273 K for 4 h.

Ternary oxides with Np(IV) compounds with the formula $BaNpO_3$ and $SrNpO_3$ are prepared by reacting NpO_2 with BaO and SrO in an inert and reducing atmosphere between 1373 and 1573 K (Keller, 1963). Mössbauer spectra and magnetic susceptibility of these compounds have been investigated by Kanellakopulos *et al.* (1980a,b), Konig *et al.* (1983), and Bickel and Kanellakopulos (1986).

Neptunium forms a number of ternary oxides with the oxides of group III through group VII elements. Synthesis conditions, structural properties, and phase diagrams have been reviewed by Tabuteau and Pagès (1985). Self-assembled uranyl peroxide nanosphere clusters of 24, 28, and 32 polyhedra (some containing neptunyl) that crystallize from alkaline solution have been characterized (Burns *et al.*, 2005).

6.7.3 Halides, halide complexes, and oxyhalides

The preparation and characterization of neptunium binary halides, oxyhalides, and complex halides have not been as extensively studied with respect to other actinides such as uranium and plutonium and more attention has been given to neptunium–fluorine compounds.

(a) Fluorides, fluoride complexes, and oxyfluorides

There are four known neptunium binary fluorides: NpF_3, NpF_4, NpF_5, and NpF_6. The lower valent neptunium fluorides can be prepared by the following reactions as initially reported by Fried and Davidson (1947):

$$NpO_2 + 1/2H_2 + 3HF \rightarrow NpF_3 + 2H_2O\,(773\,K) \qquad (6.12)$$

$$NpF_3 + 1/4O_2 + HF \rightarrow NpF_4 + 1/2H_2O\,(773\,K) \qquad (6.13)$$

The tetravalent fluoride can also be prepared by the reaction of HF directly with the oxide by the following reaction:

$$NpO_2 + 4HF \rightarrow NpF_4 + 2H_2O \tag{6.14}$$

Trevorrow *et al.* (1968) prepared NpF_4 by treating NpO_2 with a gaseous mixture of HF(75 v/o) and oxygen (25 v/o) at 773 K at approximatetly 101.3 kPa pressure. More recently, Kleinschmidt *et al.* (1992a) prepared NpF_4 by heating NpO_2 between 553 and 603 K in flowing fluorine. Neptunium is apparently transported downstream as NpF_6 and collected as NpF_4. An amorphous NpF_4 can be precipitated from a solution of Np(iv). Fried and Davidson (1947) did report that NpF_4 was not attacked by concentrated HNO_3. The crystal structures for NpF_3 and NpF_4 are shown in Table 6.6.

The preparation of NpF_5 has proved to be difficult. A number of preparations of NpF_5 are reported in the earlier literature (Cohen *et al.*, 1970; Drobyshevskii *et al.*, 1975, 1978; Baluka *et al.*, 1980). These preparations depend on the reaction of I_2 in IF_5 and KrF_2 or PF_3 in anhydrous HF with NpF_6, NpF_4, and NpF_6, respectively. Recently there have been two investigations searching for simpler alternatives to obtain NpF_5 in a pure form. Brown *et al.* (1982) reinvestigated the use of I_2 in IF_5 medium to reduce Np(vi) as shown in the following equation:

$$10NpF_6 + I_2 \rightarrow 10NpF_5 + 2IF_5 \tag{6.15}$$

The authors reported the precipitation of a cream-white precipitate which was determined to be 70.25 wt% Np. NpF_5 is 71.35 wt% Np. There was no evidence of Np(iv) in contrast to the reported contaminant by a similar method employed by Cohen *et al.* (1970). Malm *et al.* (1993) investigated several preparations for NpF_5. NpF_5 is prepared from the reaction of $NONpF_6$ with LiF

and BF_3. NpF_6 reacts with CO and light to produce a fine white powder presumed to be a mixture of NpF_5 and unidentified material. NpF_5 did not result from the reaction of NpF_6 with PF_3 in anhydrous HF in contrast to an earlier report (Baluka *et al.*, 1980). Both investigators studied some of the chemical behavior of NpF_5. In summary, NpF_5 does not react with BCl_3 in contrast to UF_5, NpF_5 hydrolyzes in $HClO_4$, NpF_5 reacts with LiF in anhydrous hydrogen fluoride to produce $LiNpF_6$, and NpF_5 thermally decomposes at 591 K to produce NpF_4 and NpF_6. Interestingly, UF_5 decomposes at 423 K into UF_6 and then in a orderly fashion to U_2F_9, U_4F_{17}, and UF_4. The product of both investigations were examined by X-ray diffraction and the patterns were similar to those in the literature (Baluku *et al.*, 1980) and similar to α-UF_5. From the study by Malm *et al.* (1993) the lattice parameters for the tetragonal compound are $a_0 = 6.5358$ Å and $c_0 = 4.4562$ Å (see Table 6.6). Significant differences in the IR data reported by Brown *et al.* (1982) and IR data reported by Drobyshevskii *et al.* (1975, 1978) have apparently not been resolved.

The volatility of NpF_6, presenting possible separation schemes to recover Np from spent nuclear fuel, led to early interest in preparations and characterization of NpF_6 (Malm *et al.*, 1958; Seaborg and Brown, 1961; Trevorrow *et al.*, 1968). The volatility of NpF_6 is similar to that of UF_6 and PuF_6. Florin (1943) first prepared NpF_6 by reacting NpF_3 with fluorine at high temperatures. Malm *et al.* (1958) achieved the preparation of gram quantities of NpF_6 in specially designed fluorination reactors which dripped liquid fluorine onto heated NpF_4. Convection currents moved NpF_6 to a condenser. Trevorrow *et al.* (1968) studied the fluorination of NpF_4 and NpO_2 with fluorine, BrF_3, and BrF_5. The reaction of both BrF_3 and BrF_5 with NpF_4 produced NpF_6 and bromine. The reaction of fluorine with NpF_4 confirmed the production of NpF_6. The researchers identified an intermediate solid, NpF_4, in the preparations of NpF_6 from NpO_2. Similar reactions with UO_2 show an intermediate as UO_2F_2. Later, Henrion and Leurs (1971) reported NpO_2F_2 as an intermediate in the fluorination of NpO_2 with fluorine. The investigators suggest that the NpF_4 identified by Trevorrow *et al.* (1968) was the result of a secondary reaction.

The use of KrF_2 as a fluorinating agent to prepare NpF_6 at low temperatures has been reported by several investigators (Drobyshevskii *et al.*, 1975, 1978; Peacock and Edelstein, 1976; Asprey *et al.*, 1986). Low-temperature fluorinations avoid the safety and material concerns intrinsic to high-temperature fluorinations with F_2. Peacock and Edelstein (1976) reported that NpF_6 resulted when $NpOF_4$ was contacted with KrF_2 at 213 K. Asprey *et al.* (1986) showed that NpF_6 is prepared by the reaction of gaseous KrF_2 and as well KrF_2 dissolved in anhydrous hydrogen fluoride with neptunium substrates.

Eller *et al.* (1998a) investigated the reaction of O_2F_2 with neptunium oxides and fluorides. NpF_6 is prepared by gas–solid reactions as shown below:

$$NpF_4(s) + xO_2F_2(g) \rightarrow NpF_6(g) + xO_2 + (x-1)F_2(g) \qquad (6.16)$$

$$NpO_2(s) + xO_2F_2 \rightarrow NpF_6(g) + (x+1)O_2(g) + (x-3)F_2(g) \qquad (6.17)$$

Both reactions proceed almost quantitatively at ambient temperatures. Reaction (6.16) is >95% complete after 45 min and reaction (6.17) is >95% complete after 30 min. Neptunium hexafluoride is produced by reaction with excess O_2F_2 in anhydrous hydrogen fluoride at 195 K with both NpO_2 and NpF_4, but the reactions are much slower. Reaction with NpF_4 was >95% complete after 2 h and reaction with NpO_2 was >95% complete after 3 h. Under both conditions, NpO_2 is converted to NpF_6 with NpO_2F_2 as one of the intermediates. The investigators attempted to study the reaction of the two substrates by condensing O_2F_2 directly on the solid and allowing the mixture to warm to 195 K. Using this procedure, the reaction became uncontrollable with total decomposition of the O_2F_2 and no detectable NpF_6 was produced.

Neptunium hexafluoride is an orange solid melting at 327.8 K to a liquid. Both solid and liquid evaporate to reddish-brown gas. The crystal structure of NpF_6(s) is orthorhombic and the lattice parameters are given in Table 6.6. The vapor pressure is given by the following:

$$\log p(\text{torr}) = A - B(T(\text{K})) + \text{C} \log(T(\text{K})) \tag{6.18}$$

For the temperature range 273–328.1 K, $A = 18.48130$, $B = 2892.0$, and $C = -2.6990$. For the temperature range 328.1–349.82 K, $A = 0.01023$, $B = 1191.1$, and $C = 2.5825$ (Keller, 1982). Keller (1982) pointed out that NpF_6 has a higher vapor pressure than either UF_6 or PuF_6. As with other volatile radionuclides and radionuclide-containing compounds, $^{237}NpF_6$ is a radiological as well as a chemical hazard and engineered safety precautions are required.

NpF_6 like UF_6 and PuF_6 is a very reactive compound. The chemical behavior has been studied by a number of investigators (Malm *et al.*, 1958; Trevorrow *et al.*, 1968; Peacock and Edelstein, 1976; Eller *et al.*, 1998b). Malm *et al.* (1958) studied the reaction of NpF_6 with both BrF_3 and water. The reaction of NpF_6 with BrF_3 was very slow resulting in a non-volatile product presumed to be NpF_4 in contrast to PuF_6 which reacts very rapidly with BrF_3. Similar to UF_6 and PuF_6, the authors report that NpF_6 reacts vigorously with water to form NpO_2^{2+}. Trevorrow *et al.* (1968) studied the reaction of NpF_6 with sodium fluoride. In this reaction, NpF_6 reacts reversibly with sodium fluoride at 523 to 673 K according to the following reaction:

$$Na_3NpF_8(s) + 1/2F_2(g) \leftrightarrow 3NaF(s) + NpF_6(g) \tag{6.19}$$

This investigaton shows that hexavalent Np is reduced to pentavalent Np; in contrast hexavalent U reacted with NaF under the same conditions results in a hexavalent compound Na_2UF_8. Peacock and Edelstein (1976) investigated the hydrolysis of NpF_6 in anhydrous hydrogen fluoride to form $NpOF_4$. Attempts to oxidize $NpOF_4$ to Np(VII) with KrF_2 were not successful. In the same study, the investigators attempted to produce higher chlorides by an exchange reaction with BCl_3 similar to exchange reactions with uranium and tungsten. In their study, Np(VI) was reduced to Np(IV) by the following reaction:

$$3NpF_6 + 2BCl_3 \rightarrow 3NpF_4 + 3Cl_2 + 2BF_3 \tag{6.20}$$

The investigators reported that NpF_6 reacts with CsF at 298 K to produce $CsNpF_6$. Recently Eller *et al.* (1998b) studied the reactions of neptunium hexafluorides with nitrogen oxides and oxyfluorides. NpF_6 reacts with excess NO. X-ray powder diffraction pattern of a resulting green product indicated NpF_4. NpF_6 reacts with FNO under a UV lamp to produce $(NO)[NpF_6]$ confirming the earlier work of Malm *et al.* (1993). The authors did not observe any reaction between NpF_6 and FNO_2 and F_3NO even when the reaction was carried out under irradiation by UV lamp.

Np(IV), (V), (VI), and (VII) form a number of fluoro complexes. Tetravalent fluoro complexes with Li, Na, K, Rb, NH_3, Ca, Sr, and Ba have all been prepared and are well-characterized. Brown (1972) reviewed and summarized a number of preparatory methods. Examples of these compounds are shown in Table 6.7. Known pentavalent fluoro hexavalent complexes include $CsNpF_6$, Rb_2NpF_7, Na_3NpF_8, and $K_3NpO_2F_5$. Reduction of NpF_6 in contact with alkali metal fluorides or fluorination of tetravalent compounds mixed with the appropriate univalent fluoride leads to the pentavalent compounds. A selection of typical compounds of this class taken in part from a table by Brown (1972) is shown in Table 6.8. Additional information on these complexes is given by Keller (1971) and Penneman *et al.* (1973).

The known or inferred neptunium oxyfluorides are NpO_2F, $NpOF_3$, NpO_2F_2, and $NpOF_4$ (Bagnall *et al.*, 1968a; Henrion and Leurs, 1971; Drobyshevskii *et al.*, 1975, 1978; Peacock and Edelstein, 1976; Holloway and Laycock, 1984; Asprey *et al.*, 1986; Kleinschmidt *et al.*, 1992b; Eller *et al.*, 1998a). These compounds have not been extensively studied and characterized. Fried (1954) first reported the preparation of NpO_2F_2 by reacting $NaNpO_2Ac_3$ with anhydrous hydrogen fluoride at 573 to 625 K. Bagnall *et al.* (1968a) reported the preparation of the compound by reacting $NpO_3 \cdot H_2O$ and Np_2F_5 with anhydrous hydrogen fluoride at 523 to 548 K and fluorine at 603 K, respectively. The authors also reported the preparation of NpO_2F_2 by the reaction of $NpO_3 \cdot H_2O$ with fluorine at 603 K and BrF_3 at 298 K. Henrion and Leurs (1971) reported that NpO_2F_2 was an intermediate compound in the fluorination of NpO_2 with fluorine to produce NpF_6. Kleinschmidt *et al.* (1992b) prepared NpO_2F_2 by reacting NpO_2 with fluorine at 603 K and by the controlled hydrolysis of NpF_6 with trace H_2O in anhydrous hydrogen fluoride. Recently, Eller *et al.* (1998a) inferred that NpO_2F_2 was a dominant intermediate species in the preparation of NpF_6 by the reaction of O_2F_2 with NpO_2 at ambient temperature. NpO_2F_2 is a pink solid that is soluble in water and mineral acid. The crystal structure is rhombohedral and the lattice constants are shown in Table 6.6.

Peacock and Edelstein (1976) investigated the preparation of $NpOF_4$ by hydrolysis of NpF_6 with water in anhydrous hydrogen fluoride. Drobyshevskii *et al.* (1975) prepared $NpOF_4$ by reacting NpO_2 with KrF_2 in anhydrous hydrogen fluoride at ambient temperatures. Malm *et al.* (1993) reported that $NpOF_4$ was an impurity in all reported preparations of Np_2O_5.

$NpOF_3$ has been prepared by reacting Np_2O_5 with anhydrous hydrogen fluoride at 313 to 333 K and dehydrating the resulting $NpOF_3$ hydrate at 373 to 423 K or by treating NpO_2 with KrF_2 in anhydrous HF (Bagnall *et al.*, 1968a; Drobyshevskii *et al.*, 1978). Compounds similar to NpO_2F have been obtained by reduction of NpO_2F_2 in hydrogen or the existence of the compound has been inferred as an intermediate in the reaction of NpO_2 with KrF_2 in anhydrous HF, respectively (Bagnall *et al.*, 1968a; Drobyshevskii *et al.*, 1975).

Neptunium tetrachloride has been prepared by at least two methods. One method is to react either neptunium oxalate or neptunium dioxide with CCl_4 at approximately 773 K (Fried and Davidson, 1951). Under these conditions, $NpCl_4$ forms and sublimes and is collected by condensation. Using a modification of this method Choporov and Chudinov (1968) reacted NpO_2 with a stream of CCl_4 vapor at lower temperatures, 553 to 673 K, to obtain $NpCl_4$. Apparently sublimation is minimal at these temperatures. Sublimation under vacuum at 633 to 653 K was used to purify their product. In the second method Bagnall and Laidler (1966) reacted $NpO_2 \cdot OH$ with hexachloropropene to obtain $NpCl_4$. They purified their product by sublimation at 923 K. $NpCl_4(g)$ condenses as a dark red or orange red deposit.

There is still uncertainty in the melting point of $NpCl_4$. Several melting points for $NpCl_4$ have been reported. Fried and Davidson (1951) reported that $NpCl_4$

melts sharply at 811 K. Later, Choporov and Chudinov (1968) using both air and salt baths reported the melting point to be (790.5 ± 2.5) K. More recently, Gruen *et al.* (1976) reinvestigated the melting point of $NpCl_4$. Using data obtained from the spectroscopically measured vapor pressures, the investigators determined that 802.9 K is the best value.

As with most of the early man-made element investigations, $NpCl_4$ was initially identified by X-ray powder diffraction. Fried and Davidson (1951) reported that the crystal structure was tetragonal with lattice parameters $a_0 = (8.25 \pm 0.01)$ Å and $c_0 = (7.46 \pm 0.01)$ Å. Recently, Spirlet *et al.* (1994) performed a complete X-ray examination of single crystals of $NpCl_4$. They confirmed that the crystal structure is tetragonal and the lattice parameters are $a_0 = 8.229$ Å and $c_0 = 7.437$ Å in reasonably close agreement with the earliest work and the crystal structure data shown in Table 6.6.

Neptunium trichloride is prepared by several methods. Fried and Davidson (1951) obtained $NpCl_3$ by reduction of NpO_2 with a mixture of hydrogen and CCl_4 at 623 to 673 K. Brown and Edwards (1972) reported the quantitative synthesis of $NpCl_3$ by reducing $NpCl_4$ with an excess of zinc. In this method, $NpCl_4$ and zinc are sealed under vacuum in a quartz tube. The reactants are heated at 823 to 873 K for 12 to 24 h. After conversion, excess zinc and $ZnCl_2$ are purified by sublimation under high vacuum away from the $NpCl_3$. $NpCl_3$ is sublimed into a clean quartz tube at 1223 to 1273 K. Attempts by Brown and Edwards (1972) to reduce $NpCl_4$ with aluminum were not successful; conversions ranged from 15 to 60%. Recently, Foropoulus *et al.* (1992) prepared anhydrous $NpCl_3$ from aqueous solutions. In their patented method, neptunium is reduced to Np(III) in a chloride solution. The solution is evaporated and the resulting residue, $NpCl_3$ hydrate, is dehydrated by contacting with thionyl chloride. The authors report that an essentially pure $NpCl_3$, ca. 98%, is obtained by their method.

Efforts to prepare higher neptunium chlorides have been unsuccessful. Heating $NpCl_4$ in chlorine at 101.3 kPa does not result in the formation of $NpCl_5$. Efforts were also made to observe the possible formation of $NpCl_5$ spectroscopically in the vapor phase by heating $NpCl_4$ in a chlorine atmosphere. At temperatures up to 1273 K no new features in the absorption spectrum were found (Fried and Davidson, 1951).

Fried and Davidson (1948) reported the preparation of neptunium tetrabromide by reaction of NpO_2 with aluminum bromide at 623 K:

$$3NpO_2 + 4AlBr_3 \rightarrow 3NpBr_4 + 2Al_2O_3 \qquad (6.21)$$

Brown and Edwards (1972) in a method identical to the method described above for the synthesis of $NpCl_3$ reported the quantitative synthesis of $NpBr_3$ by reacting $NpBr_4$ with excess zinc. Brown *et al.* (1970) prepared $NpBr_4$ by direct action of metallic neptunium and bromine. Neptunium metal and bromine were vacuum-sealed in a quartz tube. One end of the tube containing neptunium metal was heated between 673 and 698 K. $NpBr_4$ sublimed and condensed in a cooler section of the tube.

Brown *et al.* (1968) investigated the preparation of $NpBr_3$ by dehydration of $NpBr_3$ hydrates. The authors prepared the hydrates by exposing the anhydrous tribromide to oxygen-free water vapor resulting in $NpBr_3$ hexahydrate. By controlling the temperature and vacuum, the hydrate was easily converted to the anhydrous form. Previously unknown $NpBr_3$ hexahydrate was characterized using X-ray powder diffraction, radioanalytical, and gravimetric methods.

Neptunium triiodide was prepared by Fried and Davidson (1951) with aluminum iodide. Another, perhaps more convenient, method for the preparation of these halides is the direct action of hydrogen bromide/hydrogen iodide on NpO_2 at 773 K. Because the anhydrous gases (HBr and HI) are available in small, easily handled cylinders, this reaction is advantageous for laboratory preparations. The reaction products can be readily purified from unreacted NpO_2 by sublimation at the appropriate temperature. Brown and Edwards (1972) prepared the triiodide by reacting neptunium metal with excess iodine. The reactants were sealed in a tube under vacuum. The reactants were then heated at 773 K. Excess iodine was sublimed from the product, which was identified as NpI_3. Neptunium tetraiodide is predicted to be unstable (Brewer *et al.*, 1949). NpI_3 has been studied by X-ray powder diffraction and the crystal structure and lattice paramters are shown in Table 6.6.

For the synthesis of $NpBr_3$ and NpI_3 described above using aluminum halide, the aluminum halide required for these syntheses is conveniently prepared *in situ* from the elements. This method has the convenience that on the laboratory scale it is unnecessary to handle small amounts of the extremely hygroscopic aluminum halides. In this method, however, if excess aluminum is present, $NpBr_3$ is formed rather than $NpBr_4$. The reaction between NpO_2 and aluminum halide is best carried out in a sealed vessel at 623 to 673 K. Any excess aluminum halide is easily sublimed away at about 523 K. The crystal structures and lattice parameters of neptunium bromides are shown in Table 6.6.

Neptunium oxyhalides have been prepared and characterized. Fried and Davidson (1951) reported $NpOCl_2$ results when $NpCl_4$ was heated in sealed and evacuated capillary. They hypothesized that the compound was the product of the reactions of the tetrachloride with either oxygen or water impurities. The compound was investigated by X-ray powder diffraction and reported to be isostructural with $UOCl_2$. The crystal structure is shown in Table 6.6. Bagnall *et al.* (1968b) reported the synthesis of $NpOCl_2$ by reacting $NpCl_4$ and antimony sesquioxide at 673 K in a vacuum. $NpOCl_2$ can be sublimed at 823 K in vacuum. The synthesis of NpOCl has been observed during efforts to prepare $NpCl_3$ (Brown and Edwards, 1972). Pentavalent neptunium oxychlorides, $NpOCl_2$ and NpO_2Cl, are prepared by the dehydration of a solution containing chloride ions and Np(v) (LaChapelle, 1964). Brown *et al.* (1977) prepared and characterized NpOI. The oxyhalide was prepared by reacting Sb_2O_3 and NpI_3 stoichiometrically in a sealed and evacuated tube at 573 to 773 K. Product SbI_3 was sublimed away from NpOI. The crystal structure is shown in Table 6.6.

Np(III), (IV), (V), and (VI) halide complexes with both alkali metal and alkaline earth elements and ammonia are known and have been characterized (Bagnall and Laidler, 1966; Fuger and Brown, 1971; Jove and Cousson, 1977; Magette and Fuger, 1977; Abazli *et al.*, 1979; Fuger, 1979; Tomilin *et al.*, 1986; Schoebrechts *et al.*, 1989). A selection of compounds collected from the above references is shown in Table 6.7. More recently, Lemire *et al.* (2001, pp 148–53) reviewed the available chemical and thermodynamic data of the following neptunium halide complexes: Na_3NpF_8, Cs_2NpCl_6, $Cs_3NpO_2Cl_4$, $Cs_2NpO_2Cl_4$, $Cs_2NaNpCl_4$, and Cs_2NpBr_6. The information and references therein should be consulted for additional information.

Measured thermodynamic data for the halides is limited. Recently the Nuclear Energy Agency (NEA) published the exhaustive review of the published thermodynamic data (Lemire *et al.* (2001), pp 131–53) and Table 6.8 gives some of the data. In summary much of the thermodynamic data are interpolated from those of the corresponding thorium, uranium, and plutonium compounds. The thermodynamic data are collected from the recommended values in Lemire *et al.* (2001) and those adopted in Chapter 19.

6.7.4 Chalcogenides, pnictides, and carbides

Neptunium pnictides and chalcogenides have been extensively investigated primarily to understand their electronic and magnetic properties. These properties have been studied by magnetic susceptibility, Mössbauer spectroscopy, electrical resistivity, neutron and low-temperature X-ray diffraction experiments (Aldred *et al.*, 1974; Rossat-Mignod *et al.*, 1984, 1989; Burlet *et al.*, 1989; Vogt and Mattenberger, 1994; Lander and Burlet, 1995). The rock salt-type monopnictides and monochalcogenides form ideal models for studying the magnetic properties of the 5f electrons.

(a) Chalcogenides

The known sulfides and oxysulfides are NpS, NpS_3, Np_2S_5, Np_3S_5, Np_2S_3 (α-, β-, and γ-) Np_3S_4, NpOS, Np_4O_4S, and Np_2O_2S (Marcon, 1967, 1969).

NpS has been synthesized by several methods. The compound can be prepared by heating Np_2S_3 and neptunium metal at 1873 K (Marcon, 1967, 1969; Charvillat *et al.*, 1976). Bihan *et al.* (1997) prepared NpS by reacting stoichiometric amounts of the pure elements by vapor reaction in a sealed tube. Details of this method are described by Spirlet and Vogt (1984). A more facile method for preparing the compound was patented by Van Der Sluys *et al.* (1992). In their method NpS was synthesized by heating an admixture of an organometallic precursor, a suitable solvent, and a protic Lewis acid at temperature and for sufficient time to form an intermediate neptunium complex. The complex is then heated at a specific temperature and time to form the monosulfide. NpS is isostructural with PuS and US, exhibiting the NaCl-type structure with lattice parameter $a_0 = (5.532 \pm 0.001)$ Å. Bihan *et al.* (1997)

investigated the compressibility of NpS up to 60 GPa. The authors reported no phase transformation from NaCl to CsCl over the pressure range investigated.

Np_2S_3 was first prepared by treating NpO_2 with a mixture of hydrogen sulfide and carbon disulfide at 1278 K (Fried and Davidson, 1948, 1951). This compound was reported to be isostructural with U_2S_3 with lattice parameters $a_0 = (10.3 \pm 0.1)$ Å, $b_0 = (10.6 \pm 0.1)$ Å, $c_0 = (3.86 \pm 0.5)$ Å (Zachariasen, 1949a, b). Marcon (1967) obtained α-Np_2S_3 by thermal dissociation of Np_3S_5 at 1200 K. The compound is orthorhombic and isotypic with α-Pu_2S_3 and α-Ce_2S_3 with lattice parameters $a_0 = (3.98 \pm 0.01)$ Å, $b_0 = (7.39 \pm 0.02)$ Å, $c_0 = (15.50 \pm 0.03)$ Å. At about 1500 K, α-Np_2S_3 transforms into tetragonal β-Np_2S_3, isotypic with β-Pu_2S_3 and Ce_5S_7, $a_0 = (14.94 \pm 0.02)$ Å, $c_0 = (19.84 \pm 0.02)$ Å. Finally, around 1800 K, change to the cubic Np_2S_3 (γ) with the structure of the Th_3P_4-type occurred ($a_0 = 8.440 \pm 0.001$ Å) (Marcon, 1967). The γ-form can also have the composition of Np_3S_4 (Damien and Berger, 1976). Np_3S_4 was obtained after the heat treatment described above by Charvillat *et al.* (1976). Np_3S_4 is cubic with a lattice parameter of $a_0 = 8.440$ Å.

Np_3S_5 was obtained by thermal decomposition of NpS_3 at 773 K (Marcon, 1967, 1969; Marcon and Pascard, 1968). Blaise *et al.* (1982) reported the preparation of Np_3S_5 by reaction of the appropriate chalcogen and neptunium hydride at 923 K. Np_3S_5 is isostructural with U_3S_5 with lattice parameters $a_0 = (7.42 \pm 0.01)$ Å, $b_0 = (8.07 \pm 0.01)$ Å, $c_0 = (11.71 \pm 0.02)$ Å.

Np_2S_5 is prepared by heating mixtures of Np_3S_5 and sulfur at 773 K (Marcon, 1967, 1969). The crystal structure is tetragonal ($a_0 = (10.48 \pm 0.01)$ Å, $c_0 = (9.84 \pm 0.1)$ Å), and isotypic with Th_2S_5, Th_2Se_5, and U_2S_5.

NpS_3 was prepared from the elements at 773 K by Marcon (1967, 1969). NpS_3 is monoclinic with lattice parameters $a_0 = (5.36 \pm 0.01)$ Å, $b_0 = (3.87 \pm 0.01)$ Å, $c_0 = (18.10 \pm 0.05)$ Å, $\beta = 99.5°$ and isostructural with US_3, USe_3, UTe_3, $NpSe_3$, and $NpTe_3$.

The three oxysulfides NpOS, Np_2O_2S, and $Np_4O_4S_3$ have been reported (Zachariasen, 1949b; Marcon, 1969). Only NpOS has been extensively studied (Thevenin *et al.*, 1985; Collard *et al.*, 1986). Thevenin *et al.* (1985) prepared NpOS by vacuum sealing and heating NpO_2, Np_3S_5, and sulfur in a quartz tube to 1073 K for 1 week. NpOS is tetragonal with lattice parameters $a_0 = b_0 = 3.808$ Å and $c_0 = 6.627$ Å. $Np_4O_4S_3$ and Np_2O_2S were prepared and characterized by Marcon (1969) and Zachariasen (1949b). Hexagonal Np_2O_2S is isostructural with the actinide and lanthanide oxysulfides of the same composition (Zachariasen, 1949b; Haire and Fahey, 1977). Hoffman and Kleykamp (1972) have presented an extensive review of the preparation and properties of these sulfides and oxysulfides.

Known neptunium selenides and oxyselenides are NpSe, Np_3Se_4, γ-Np_2Se_3, Np_2Se_5, Np_3Se_5, $NpSe_3$, NpOSe, and Np_2O_2Se. These compounds have been prepared and characterized by Mitchell and Lam (1971), Damien and Wojakowski (1975), Damien *et al.* (1973), Charvillat *et al.* (1976), and Thevenin and Pagès (1982).

Damien and Wojakowski (1975) and Charvillat *et al.* (1976) obtained NpSe by reacting neptunium hydride with a stoichiometric amount of selenium metal. The reactants, sealed in a quartz tube under vacuum, were heated at 800 K for 24 h. The investigators reported that NpSe crystallizes in the NaCl-type structure with lattice constant $a_0 = (5.804 \pm 0.002)$ Å for samples heated between 1593 and 1783 K. Gensini *et al.* (1993) reported that the selenide transforms from the NaCl to CsCl structure at 23 GPa.

Mitchell and Lam (1971) investigated the alloying behavior of neptunium and selenium and obtained Np_3Se_4. Neptunium and selenium were sealed, in vacuum, in a quartz ampoule. The reactants were heated to the melting point of selenium, 494 K, then heated to and maintained at 1273 K for 5 to 24 h. The final steps in the procedure held the ampoule at 773 K for 15 to 22 days followed by furnace cooling and X-ray diffraction analysis. Damien *et al.* (1973) obtained this phase by decomposition of Np_3Se_5 at 1123 K at high vacuum. After heating at 1323 K and apparently cooling, the lattice parameter decreased from $a_0 = (8.8242 \pm 0.0002)$ to (8.8223 ± 0.0003) Å similar to the cubic structure lattice constant $a_0 = (8.8261 \pm 0.00\,02)$ Å reported by Mitchell and Lam (1971). Damien *et al.* (1973) could not determine if the composition of their product was γ-Np_2Se_3 or Np_3Se_4.

Damien *et al.* (1973) obtained Np_3Se_5 by thermal dissociation of $NpSe_3$ at 693 K in vacuum. Blaise *et al.* (1982) prepared Np_3Se_5 by heating the appropriate amounts of chalcogen with neptunium hydride at 923 K. The crystal structure is orthorhombic and the lattice parameters are $a_0 = (7.75 \pm 0.01)$ Å, $b_0 = (8.43 \pm 0.01)$ Å, and $c_0 = (12.24 \pm 0.02)$ Å. The compound is isostructural with U_3S_5, U_3Se_5, and Np_3S_5.

Np_2Se_5 is prepared either by thermal decomposition of $NpSe_3$ at 823 K for 2 weeks or by reaction of neptunium hydride and selenium metal at 753 K. Both preparations are performed in sealed and evacuated quartz tubes (Thevenin and Pagaès, 1982). The compound has an orthorhombic (pseudotetragonal) crystal structure with lattice parameters $a_0 = b_0 = 7.725$ Å and $c_0 = 10.6225$ Å.

$NpSe_3$ was synthesized by Damien *et al.* (1973) by reaction of neptunium hydride with excess selenium sealed in a quartz tube under vacuum and heating at 620 K for 1 week. Blaise *et al.* (1982) prepared $NpSe_3$ by reacting chalcogen with neptunium hydride at 1273 K. The investigators identified $NpSe_3$ by X-ray powder diffraction pattern to be analogous to that of USe_3. The triselenide crystal structure is monoclinic with lattice constants: $a_0 = (5.64 \pm 0.02)$ Å, $b_0 = (4.01 \pm 0.01)$ Å, $c_0 = (19.06 \pm 0.07)$ Å, $\beta = (79.60 \pm 20)°$.

The known oxyselenides are NpOSe and Np_2O_2Se (Marcon, 1969). Only NpOSe has been investigated (Thevenin *et al.*, 1985). Thevenin *et al.* (1985) prepared NpOSe by vacuum sealing and heating NpO_2 and Np_2Se_5 to 1073 K for 1 week. NpOSe is tetragonal with lattice parameters $a_0 = b_0 = 3.869$ Å and $c_0 = 6.911$ Å. The known neptunium tellurides and oxytellurides are NpTe, Np_3Te_4, $NpTe_3$, $NpTe_{2-x}$, $\eta\gamma$-Np_2Te_3, and Np_2O_2Te.

Damien and Wojakowski (1975) and Charvillat *et al.* (1976) obtained a two-phase NpTe product by reacting neptunium hydride with a stoichiometric amount of tellurium metal sealed in a quartz tube under vacuum at 800 K for 24 h. The product formed was made into a pellet, heated at 1563 K for 4 h in a sealed quartz tube under vacuum, cooled, and examined by X-ray diffraction. Under these circumstances the investigators determined that NpTe crystallizes in the NaCl-type structure with lattice constant $a_0 = (6.197 \pm 0.0001)$ Å. Dabos-Seignon *et al.* (1990) investigated X-ray diffraction patterns of NpTe at pressures up to 51 GPa. The investigators reported that NpTe maintains the NaCl structure to 12 GPa where CsCl-type structure began to appear. Only the CsCl-type structure exists above 20 GPa.

Mitchell and Lam (1971), investigating the alloying behavior of neptunium and tellurium, obtained Np_3Te_4. Neptunium and tellurium were vacuum-sealed in a quartz ampoule. The reactants were heated to the melting point of tellurium, 494 K, then heated to and maintained at 1273 K for 5 to 24 h. The final step in the procedure held the ampoule at 772 K for 15 to 22 days. The lattice constant for the cubic structure was reported to be $a_0 = (8.8261 \pm 0.0002)$ Å (Mitchell and Lam, 1971).

Blaise *et al.* (1976), investigating magnetic properties of some neptunium chalcogenides, prepared $NpTe_3$ by reacting tellurium with neptunium hydride at 628 K. $NpTe_3$ is isostructural with rare earth tritellurides with the lattice parameters $a_0 = b_0 = 4.355$ Å and $c_0 = 25.40$ Å in agreement with literature values (Damien and Berger, 1976).

Thevenin *et al.* (1985) investigated the preparation and crystal structure of Np_2O_2Te. The investigators obtained Np_2O_2Te by reacting Np_2Te_3 and NpO_2 in a vacuum-sealed quartz tube at 1273 K for 1 week. The black compound is tetragonal with lattice constants $a_0 = b_0 = 4.003$ Å, $c_0 = 12.73$ Å and is isostructural with U_2O_2 Te and Pu_2O_2Te.

(b) Pnictides

Neptunium pnictides have been studied because of their solid state properties and relationship to advanced reactor fuels. Neptunium nitride, NpN, was prepared by Sheft and Fried (1953) who reacted ammonia gas and neptunium hydride at 1023 to 1048 K in a quartz X-ray capillary tube. Later preparations by Olson and Mulford (1966), De Novion and Lorenzelli (1968), and Aldred *et al.* (1974) reacted neptunium metal with a mixture of nitrogen and hydrogen at temperatures to 1773 K, NpH_{2+x} with nitrogen at temperatures to 1873 K, and NpH_3 with nitrogen at temperatures between 573 and 623 K, respectively.

In the method of Olson and Mulford (1966) neptunium filings were heated in a tungsten vee with nitrogen 0.5% in hydrogen as a catalyst. The reaction started at 873 K and upon apparent completion the temperature was brought to 1783 K. Gaseous neptunium hydride and neptunium were removed by pumping. De Novion and Lorezelli (1968) directly reacted nitrogen with NpH_{2+x} at 673 K, while Aldred *et al.* (1974) reacted NpH_3 with nitrogen at 573 to 623 K for 5 h. The powder product was formed into pellets and heated at 1273 K for 2.5 h. More recently, Suzuki *et al.* (1994) synthesized NpN by a high temperature, 1823 K, carbothermic reduction of NpO_2 in a stream of N_2 gas. The crystal structure is NaCl-type (fcc) and the lattice parameter is $a = (4.8968 \pm 0.005)$ Å which agrees well with values reported in the literature (Olson and Mulford, 1966; De Novion and Lorenzelli, 1968). NpN is isomorphous with UN and PuN, reacts slowly with dilute hydrochloric and nitric acids, and appears to be relatively inert toward water (Sheft and Fried, 1953). The melting point of NpN has been determined to be 3103 K under a nitrogen pressure of ca. 1 MPa (Olson and Mulford, 1966). There is very little thermodynamic data reported for NpN. Arai *et al.* (1994) derived the following equation for the heat capacity of NpN: $C_p\,(\text{J mol}^{-1}\,\text{K}) = 52.85 + 2.55 \times 10^{-3}T - 8.37 \times 10^{5}T^{-2}$. Suzuki and Arai (1998) reviewed and investigated some thermal and thermodynamic properties of NpN. They reported the free energy of formation to be $\Delta G_f\ (\text{J mol}^{-1}) = 427\,000 - 98.88T(1700\text{–}2100\ \text{K})$.

Lander *et al.* (1973) prepared neptunium monophosphide by a hydriding, dehydriding, and nitriding technique. First the metal is converted to powder by hydriding and dehydriding. Then the powder reacted with phosphine gas at 623 K. NpP is single-phase fcc. The lattice parameter is (5.614 ± 0.001) Å. A compound with the formula, Np_3P_4, is formed by reacting an excess of red phosphorus with neptunium metal at 1013 K in an evacuated and sealed quartz tube (Sheft and Fried, 1953). Excess phosphorus is removed by sublimation in vacuo at 1073 K. The compound does not react with water but does react with 6 M HNO_3 to yield dark-green Np(IV) solution.

$NpAs_2$ and NpAs are prepared by reacting stoichiometrically arsenic and neptunium hydride in a vacuum-sealed tube for 1 week (Charvillat and Damien, 1973; Blaise *et al.*, 1981). In this method NpAs was synthesized at 923 K and $NpAs_2$ synthesized at 723 K. Dabos *et al.* (1986) synthesized NpAs by reacting arsenic vapor and neptunium metal turnings in a vacuum-sealed quartz tube. In this method, the reactants are separated by a quartz membrane and heated to just below the melting point of neptunium metal: arsenic sublimes at 886 K and the melting point of neptunium is 903 K. X-ray studies show that NpAs has the cubic NaCl structure with the lattice parameter $a_0 = (5.8338 \pm 0.0002)$ Å (Charvillat and Damien, 1973). $NpAs_2$ is tetragonal, anti-Fe_2As type with lattice parameter $a_0 = (3.962 \pm 0.001)$ Å, $b_0 = (8.115 \pm 0.002)$ Å (Charvillat and Damien, 1973; Blaise *et al.*, 1981). Wojakowski and Damien (1982) reported the preparation of single crystals of both $NpAs_2$ and Np_3As_4 using iodine as a transporting agent in a transport reaction process in sealed quartz tubes. The investigators reported that $NpAs_2$ single crystals are more stable in air than powder material. $NpAs_2$ crystals are brown to gold and Np_3A_4 are black in color. The reported lattice parameters are in agreement with literature values.

NpSb was prepared by an isothermal annealing technique (Mitchell and Lam, 1971). In this technique, equal atomic percentages of neptunium and 99.999%

pure antimony were sealed in a quartz tube under vacuum, and the mixture was heated at the melting temperature of antimony. The temperature was then raised to 1000°C, held at this temperature for 16 days, and then cooled. In all samples, traces of Np_3Sb_4 were present (Aldred *et al.*, 1974).

There are limited reports for the preparation and characterization of NpBi. Aldred *et al.* (1974) attempted to prepare the compound by reaction of the elements at 1273 K for 16 days and was not successful. Attempts to prepare single crystals of NpBi by Burlet *et al.* (1992) using the mineralization method described by Spirlet and Vogt (1984) were successful.

(c) Carbides

The neptunium compounds NpC, Np_2C_3 and NpC_2 have been reported in the literature with limited characterization. This is unfortunate because of the importance of carbides as advanced reactor fuels. Holley *et al.* (1984) reviewed the earlier literature and determined that two phases had been identified and that the identification of NpC_2 was tentative. Nevitt (1963) reported that the monocarbide exists in the range of $NpC_{0.82}$ to $NpC_{0.96}$. De Novion and Lorenzelli (1968) prepared $NpC_{0.95}$ by heating a mixture of neptunium hydride and graphite to 1673 K. Sandenaw *et al.* (1973) prepared $NpC_{0.91}$ by arc melting the elements using a tungsten electrode. Sheft and Fried (1953) reported the syntheses of NpC_2 by heating NpO_2 at various temperatures between 2933 and 3073 K in a graphite crucible. When an attempt is made to prepare neptunium metal by reaction of lithium vapor on NpF_3 in a graphite crucible at 1373 K, the reaction yields a mixture of NpC and Np_2C_3. When NpC reacts with excess carbon it forms a pure phase with the composition of Np_2C_3 (Lorenzelli, 1968). Sandenaw *et al.* (1973) measured the heat capacity of $NpC_{0.91}$. Holley *et al.* (1984) and Lemire *et al.* (2001), pp 201–2 reviewed the very limited thermodynamic properties of neptunium carbides.

6.7.5 Other inorganic compounds

Many other inorganic neptunium compounds have been synthesized and characterized. Interest has been shown in the preparation and characterization of phosphates, sulfates, and carbonates. The stability of phosphates makes them a candidate for immobilizing radioactive waste (Bamberger *et al.*, 1984; Volkov *et al.*, 1994). Bamberger *et al.* (1984) reported the preparation of green neptunium pyrophosphate, α-NpP_2O_7, by reacting NpO_2 and BPO_4 at 1373 K. The lattice parameter for the cubic compound was (8.593 ± 0.002) Å. Attempts to prepare $Np_3(PO_4)_4$ by a similar reaction were unsuccessful. Volkov *et al.* (1994) studied a series of double phosphate of neptunium with the formula $NpA_2(PO_4)_3$ where A = Li, Na, K, Rb, Cs. The compounds were synthesized by heating the appropriate mixtures of NpO_2, LiOH, $N(K)H_2PO_4$, $Rb(Cs)NO_3$, and H_3PO_4 at 373 to 573 K for 5 h followed by annealing in air from 773 to

1923 K. Monoclinic and trigonal crystalline structures were identified for the double phosphates containing the cations Li^+, Na^+, and K^+. Transitions from the monoclinic to trigonal phases for $NaLi_2(PO_4)_3$, $NaNa_2(PO_4)_3$, and $NaK_2(PO_4)_3$ occurred at 1723, 1623, and 1423 K, respectively. Only the trigonal phase was reported for both $NpRb_2(PO_4)_3$ and $NpCs_2(PO_4)_3$ and the latter compound formed an unidentified high-temperature phase.

A number of neptunium sulfates have been synthesized and characterized. The most recent studies of solid neptunium sulfates are by Weigel and Hellmann (1986) and Budantseva *et al.* (1988). Neptunium hydroxysulfate was synthesized and characterized by Wester *et al.* (1982).

Preparation and characterization of neptunium carbonates is essential to research conducted to understand neptunium behavior in geologic repositories and the environment. Radionuclides placed in repository, particularly the long-lived radiotoxic actinides, may contact carbonate and bicarbonate containing water, forming soluble complexes. Recognizing this concern and the need for research, Clark *et al.* (1995) and Lemire *et al.* (2001, pp 203–83) have exhaustively reviewed the available literature on neptunium carbonates.

6.7.6 Coordination compounds

Interest in the coordination chemistry of neptunium compounds is enhanced by the unique properties of each of the five oxidation states of neptunium and by the changes in coordination chemistry caused by decreasing ionic size across the actinide series. Therefore a number of compounds of neptunium and various ligands have been prepared to characterize neptunium coordination chemistry. A selected listing of these compounds and some reported crystal structures and lattice parameters are given in Table 6.9.

There is little published information of Np(III) coordination compounds. According to Mefod'eva and Gel'man (1971) the reason is in the instability of Np(III) in aqueous solutions to atmospheric oxygen. These investigators, however, reported the reduction of Np(IV) to Np(III) by sodium formaldehyde sulfoxylate, $NaHSO_2 \cdot CH_2O \cdot 2H_2O$. Apparently this compound stabilizes Np(III) and allows the formation of sparingly soluble compounds such as $Np_2(C_2O_4)_3 \cdot nH_2O(n = 11)$, $Np_2(C_6H_5AsO_3)_3 \cdot H_2O$ and $Np_2[C_6H_4(OH)COO]_3$. These compounds were formed by the addition of oxalic acid, phenylarsonic acid, or ammonium salicylate to solutions containing Np(III) reduced by $NaHSO_2 \cdot Ch_2O \cdot 2H_2O$. Atmospheric oxygen was removed from reagent solutions by argon purges and/or covering solutions with benzene. The precipitates were dried with ether and/or acetone and streams of argon.

A number of Np(IV) coordination compounds have been reported. Al-Kazzaz *et al.* (1972) prepared $(Et_4N)Np(NCS)_8$, where Et_4N = tetraethyl ammonium, which is isostructural with the uranium analog. Cousson *et al.* (1985) obtained $CoNp_2F_{10} \cdot 8H_2O$ and $CuNp_2F_{10} \cdot 6H_2O$. The investigators, using the method of Abazli *et al.* (1984), mixed and powdered transition metal cobalt or copper

difluorides and NpF_4. The mixtures were placed into gold tubes with a few drops of 40% HF. The tubes were sealed, placed in an autoclave, the pressure was adjusted to 152 MPa, and temperature increased to the desired reaction temperatures. The cobalt- and copper-containing compounds are reportedly formed at 400 and 600 K, respectively. Bagnall *et al.* (1985) reported the preparation of $NpCl_2 \cdot P(i\text{-}C_4H_9)_3O$, $NpCl_4 \cdot CH_3CON(i\text{-}C_3H_7)_2$, $NpCl_4 \cdot 2.5HCON(CH_3)$, and $NpCl_4 \cdot 3.5P(CH_3)(C_6H_5)_2O$. These compounds were obtained by mixing suspensions of Cs_2NpCl_6 in dichloromethane with the appropriate phosphine oxides and amides by stirring for 7 days and evaporating the solution to dryness. Complex nitrate compounds have been formed. Grigor'ev *et al.* (1986a) prepared $Np(NO_3)_4 \cdot 2C_{10}H_{10}N_2(NO_3)_2 \cdot 2H_2O$ with the intent of investigating the separation of Np(IV) as a more complicated compound. Grigor'ev *et al.* (1987) also prepared the Np(IV) coordination compound $(C_{10}H_{10}N_2)[Np(NO_3)_6] \cdot 2H_2O$. In both nitrate complex studies, the investigators formed single crystals by slow ambient temperature evaporation of solutions of Np(IV) in concentrated HNO_3 and excess 2,2′-pyridine.

The coordination chemistry of Np(V) compounds was stimulated by the discovery of the so-called cation–cation interaction in the solid state by Cousson *et al.* (1984). Interestingly, cation–cation interactions with actinyl ions in solution have been known since 1961 (Sullivan *et al.*, 1961). Cousson *et al.* (1984) obtained the neptunyl dimer, $Na_4(NpO_4)_2C_{12}O_{12} \cdot 8H_2O$, by dissolving neptunyl hydroxide in an aqueous solution of benzenehexacarboxylic acid (mellitic acid). The resulting solution was adjusted with NaOH to a pH of approximately 6.5 and was slowly evaporated, producing green crystals. The investigators reported, based on diffraction studies, the distance between the two neptunium atoms to be 3.4824 Å. Krot *et al.* (1993) and Grigor'ev *et al.* (1993a,b) synthesized and characterized Np(V) malonates and neptunyl malonate hydrates; $(NpO_2)_2CH_2(CO_2)_2 \cdot xH_2O$ where $x = 1, 3, 4$ and $MNpO_2CH_2(CO_2)_2$ where $M = NH_4$ or Cs and $NaNpO_2CH_2(CO_2) \cdot 2H_2O$. Grigor'ev *et al.* (1989) and Logvis' *et al.* (1994) prepared neptunyl formate, $NpO_2OOCH \cdot H_2O$, by reacting NH_4OOCH and HCOOH with a neptunyl(V) nitrate solution. Charushnikova *et al.* (1995) and Grigor'ev *et al.* (1995) prepared neptunyl glycolate by dissolving freshly prepared neptunyl hydroxide into excess glycolic acid and evaporation of the resulting solution until green crystals formed. In the same study Charushnikova *et al.* (1995) precipitated neptunyl trichloroacetate by dissolving the freshly prepared neptunyl hydroxide in equimolar amounts of trichloroacetic acid. The acetate, $NpO_2OOCCH_3 \cdot H_2O$, was obtained either by dissolving freshly prepared neptunyl(V) hydroxide in excess glacial acetic acid and collection of a resulting green precipitate by filtration or by the addition of $NaOOCH_3$ to a solution of Np(V) which had been adjusted to a pH of 4 to 5 with ammonia and collection of the resulting precipitate by filtration (Bessonov *et al.*, 1989b). Charushnikova *et al.* (1992) obtained neptunyl benzoate in a similar manner to the acetate. Ammonium benzoate was added to a solution of Np(V) which had been adjusted to a pH of 4 to 5 with ammonia water. Several oxalate compounds have been prepared and characterized (Jones and Stone, 1972; Tomilin *et al.*, 1984). Grigor'ev *et al.* (1991a) reported the results of their study on two complex neptunium(V) oxalates; $[Co(NH_3)_6][NpO_2(C_2O_4)_2] \cdot nH_2O$ where $n = 3$ and 4. Single crystals of each compound formed were a function of the concentrations of $C_2O_4^{2-}$ and Np(V). Budantseva *et al.* (1989) synthesized and studied some of the properties of neptunyl sulfamate monohydrate. The air-stable compound, $NpO_2SO_3NH_2 \cdot H_2O$, was obtained by eluting Np(V) from a cation-exchange resin in the neptunyl form with sodium sulfamate. The eluent was evaporated in a stream of air at 298 K. Attempts to prepare single crystals were not successful. Simple and complex neptunyl sulfate complexes have been prepared and characterized (Grigor'ev *et al.*, 1991b,c, 1993c). The lattice parameter for these compounds are given in Table 6.9. Saeki *et al.* (1999) studied the correlation between isomer shifts of ^{237}Np Mössbauer spectra and coordination numbers of neptunium atoms in some Np(V) compounds.

Np(VI) coordination compounds include simple compounds such as $NpO_2C_2O_4$ (Mefod'eva *et al.*, 1969) and complex compounds such as $(NH_4)_4NpO_2(CO_3)_3$ (Marquart *et al.*, 1983). The oxalate was obtained by adding oxalic acid to a nitric acid solution of Np(VI) containing $KBrO_3$. The resulting compound is not stable, Np(VI) is reduced to Np(IV) after storage even at cold temperatures. Green $(NH_4)_4NpO_2(CO_3)_3$ was prepared by adding an excess of $(NH_4)_2CO_3$ to a nitric acid solution containing Np(VI). Hexavalent actinide complexes of the formula $M_4AnO_2(CO_3)_3$ (An=U, Np, Pu; M = single valent cation) have been extensively studied (Clark *et al.*, 1995).

Since the discovery of Np(VII) (Krot and Gel'man, 1967) several Np(VII) coordination compounds have been prepared and studied. Krot *et al.* (1968b,c) reported the preparation of a compound with the formulation $Co(NH_3)_6NpO_5 \cdot nH_2O$. Later, Burns *et al.* (1973) suggested the formulation should be $[Co(NH_3)_6][NpO_4(OH)_2] \cdot 2H_2O$ following their efforts to experimentally demonstrate the existence of $[NpO_4(OH)_2]^{3-}$ as the form of Np(VII) in alkaline solution. The investigators, using the method proposed by Krot *et al.* (1968a), precipitated $[Co(NH_3)_6][NpO_4(OH)_2] \cdot 2H_2O$ by the simultaneous dropwise addition of solutions of $Co(NH_3)_6Cl_3$ and Np(VII) in LiOH to a stirred solution of LiOH. In the same study Burns *et al.* (1973) reported the preparation of $LiCo(NH_3)_6Np_2O_8(OH)_2 \cdot 2H_2O$ by slowly diffusing a LiOH solution of Np (VII) into a solution of $Co(NH_3)_6Cl_3$. The investigators also prepared an analog containing sodium from NaOH solution of Np(VII) but attempts to prepare a potassium analog from Np(VII) in KOH was unsuccessful. Apparently, the formation of $[Co(NH_3)_6][NpO_4(OH)_2] \cdot 2H_2O$ or $LiCo(NH_3)_6Np_2O_8(OH)_2 \cdot 2H_2O$ is dependent on rapid precipitation vs slow diffusion, respectively. Grigor'ev *et al.* (1986b) obtained large single crystals of $Co(NH_3)_6NpO_4(OH)_2 \cdot 2H_2O$ by mixing a LiOH solution of Np(VII) with a LiOH solution containing small excess of $Co(NH_3)_6Cl_3$ and placing the mixture into a cooler for several hours. The resulting prismatic crystals were dark green and a maximum length of the edge 0.15–0.4 mm. The crystal structure and lattice parameters are given in Table 6.9. Nakamoto *et al.* (1999) reported the ^{237}Np Mössbauer spectroscopic study of $Co(NH_3)_6NpO_4(OH)_2 \cdot 2H_2O$. The preparation and some properties of $[Pt(NH_3)_5Cl]NpO_5 \cdot nH_2O$ (where $n =$ ca. 1) were reported by Krot *et al.* (1968b). Blackish-green $[Pt(NH_3)_5Cl]NpO_5 \cdot nH_2O$ was obtained by adding a saturated solution of $[Pt(NH_3)_5Cl]Cl_3$ to a basic solution of Np(vii). Mefod'eva *et al.* (1970a,b) synthesized $[CoEn_3]NpO_5 \cdot 3H_2O$ (where En = ethylenediamine) using a method similar to the preparation described above for the preparation of $[Co(NH_3)_6][NpO_4(OH)_2] \cdot 2H_2O$ modified to use more concentration solutions because of the solubility of $[CoEn_3]NpO_5 \cdot 3H_2O$. The precipitates formed are thin green plate-like crystals, which decompose to a brown-colored material after stored for 5 to 6 days in a dry desiccator.

6.7.7 Important organometallic compounds

Neptunium organometallic compounds have been prepared and characterized, but not nearly to the extent of uranium organometallics. A survey of the literature produced a limited number of well-characterized neptunium organometallics. The radioactive hazard associated with neptunium and its scarcity are two reasons for the scarcity of published information. Most investigations reported to date deal with the preparation of neptunium cyclopentadienyl and cyclooctatetraenyl compounds and derivatives of these compounds. These compounds have been extensively reviewed (Gysling and Tsutsui, 1970; Hayes and Thomas, 1971; Legin, 1979; Marks and Ernest, 1982; Mishin *et al.*, 1986). The synthesis, characterization, and catalytic processes of organometallic actinides are discussed in Chapters 25 and 26.

(a) Cyclopentadienyl compounds

A trivalent neptunium cyclopentadienyl complex was synthesized and characterized by Karraker and Stone (1972). The complex is formed by the reduction of $Np(C_5H_5)_3Cl$ with sodium:

$$Np(C_5H_5)_3Cl + Na \rightarrow Np(C_5H_5) \cdot 3THF + NaCl \qquad (6.22)$$

Attempts to obtain $Np(C_5H_5)$ by heating and vacuum to remove tetrahydrofuran (THF) were unsuccessful.

Tetravalent neptunium tetracyclopentadienyl was prepared and characterized by Baumgartner *et al.* (1968). The complex was prepared by reacting $NpCl_4$ with KC_5H_5 in benzene under reflux for 160 h:

$$NpCl_4 + 4KC_5H_5 \rightarrow Np(C_5H_5)_4 + 4KCl \qquad (6.23)$$

The reddish-brown complex dissolved in benzene and THF. The authors reported that the compound is less sensitive to oxygen and water than $Pu(C_5H_5)_3$ and $Am(C_5H_5)_3$.

Other Np(IV) cyclopentadienyl compounds have been prepared and characterized. Two reactions have been reported for the preparation of tricyclopentadienyl chloride, $(C_5H_5)_3NpCl$. Fischer *et al.* (1966) prepared the compound by reacting NpX_4 (X = Cl, F) with potassium cyclopentadienyl, $3K(C_5H_5)$, in THF. Later Karraker and Stone (1972) prepared the compound by reacting $NpCl_4$ with beryllium cyclopentadienyl. Equations describing the two reactions are:

$$NpX_4 + 3K(C_5H_5)_4 \rightarrow Np(C_5H_5)_3X + 3KX \tag{6.24}$$

$$2NpCl_4 + 3BeC_5H_5 \rightarrow 2Np(C_5H_5)_3Cl + 3BeCl_2 \tag{6.25}$$

A number of derivatives can be prepared starting with tetrakiscyclopentadienyl Np(IV), $Np(C_5H_5)_4$, and tris(cyclopentadienyl)Np(IV) chloride, $(C_5H_5)_3NpCl$. These compounds have the general formula $(C_5H_5)_3NpL$ with either inorganic ionic ($L = Br^-$, I^-, $1/2SO_4^{2-}$, NCS^-, $ALCl_4$) or organic ligands ($L = NC_4H_4^-$, $N_2C_3H_3^-$, $C = CH^-$, $1/2C = C_2^-$, $C_2H_5^-$, $C_6H_5^-$) (Bohlander, 1986). An interesting and unusual synthetic method was reported by Baumgartner *et al.* (1965). These authors obtained $Np(C_5H_5)_3Cl$ by (γ,n) reaction with U-238 in $U(C_5H_5)_3Cl$.

(b) Cyclooctatetraene compounds

Karraker *et al.* (1970) prepared bis(cyclooctatetraenyl) Np(IV) by reacting $NpCl_4$ with a THF solution of $K_2(C_8H_8)$:

$$NpCl_4 + 2K_2(C_8H_8) \rightarrow Np(C_8H_8)_2 + 4KCl \tag{6.26}$$

After 16 h of stirring, the compound was precipitated by the addition of deaerated water and recovered by evaporation. The authors report that X-ray diffraction patterns indicate that $Np(C_8H_8)_2$ is isomorphous with $U(C_8H_8)_2$ and $Pu(C_8H_8)_2$. The chemical behavior of the three compounds are identical: the compounds are not sensitive to water or dilute base, they are air-sensitive, reacting quickly to form oxides, and they are very slightly soluble in organic solvents such as benzene and toluene.

Karraker (1973) synthesized both neptunium bis(ethylcyclotetraene) and bis (*n*-butylcyclotetraene) complexes by reacting the alkyl substitued potassium complex in THF with $NpCl_4$ as shown below:

$$2K_2RC_8H_7 + NpCl_4 \rightarrow Np(RC_8H_7)_2 + 4KCl \tag{6.27}$$

where R = ethanol, butanol.

A trivalent neptunium cyclotetraene complex was prepared and characterized by Karraker and Stone (1974) by reacting stoichiometric amounts of NpX_3 (X = Cl, Br, I) and $K_2(C_8H_8)$ in THF:

$$NpXr_3 + 2K_2(C_8H_8) \rightarrow KNp(C_8H_8) \cdot 2THF + 3KX \tag{6.28}$$

The compound is isostructural with $KPu(C_8H_8)_2 \cdot 2THF$ with an orthorhombic unit cell. Both compounds are reported to be air- and water-sensitive, converting to $Np(C_8H_8)_2$ by air oxidation and other trace amounts of oxidizing agents. The compound is soluble in THF but slightly soluble in benzene and toluene.

(c) Other organometallic compounds

Hydrocarbyl compounds of neptunium have been reported. Karraker and Stone (1976) reported the preparation of $Np(C_5H_5)_3R$ where R = *n*-butyl by reacting $Np(C_5H_5)_3Cl$ with RLi.

Recent investigations of suitable precursors for organometallic and inorganometallic compounds suggested the usefulness of solvated triiodide complexes for this purpose (Karraker, 1987; Zwick *et al.*, 1992). Karraker (1987) investigated the reaction of neptunium with diiodoethane. The reaction in THF is:

$$Np + 3/2C_2H_4I_2 \rightarrow NpI_3 \cdot x\mathrm{THF} + 3/2C_2H_4 \qquad (6.29)$$

The reaction was carried out in a dry argon. The mixture of reactants were stirred at ambient temperature at times up to 1 week. A yellow precipitate was mixed with thallous methylcyclopentadienide in THF. The reaction is complete in 5 to 10 min. Two pure products, $NpI_2(MeC_5H_5) \cdot 3THF$ and $NpI(MeC_5H_5)$ 2.3THF can be obtained by evaporation or precipitation with ether. Using $NpI_3(THF)_4$ Zwick *et al.* (1992) reported the preparation of $Np[N(SiMe)_2]_3$, $Np[O\text{-}2,6\text{-}(t\text{-}C_4H_9)_2C_6H_3]_3$, and $Np[CH(SiMe_3)_2]_3$, demonstrating that $NpI_3(THF)_4$ is a precursor to new and existing compounds.

6.8 NEPTUNIUM IN AQUEOUS SOLUTION

6.8.1 Oxidation states of neptunium ions

Neptunium exists in an aqueous solution as ions of oxidation states from 3+ to 7+. These oxidation states are liable to change through reduction and oxidation reactions and disproportionation reaction of Np(v). The stability of the oxidation state is strongly affected by factors such as oxidants or reductants, acidity of the solution, presence of a complex forming ligand, and the concentration of neptunium itself in the solution. The stability of each ion can be simply predicted from the redox potentials as described below.

Trivalent and tetravalent neptunium exist as hydrated Np^{3+} and Np^{4+} in acidic solutions without ligand, Np^{3+} is quickly oxidized to Np^{4+} by air. Even in moderately acidic solutions, Np^{4+} is significantly hydrolyzed. Np(III) and Np(IV) form insoluble hydroxides in aqueous solutions of low acidity and the hydroxide of Np(III) is readily oxidized to the hydroxide of Np(IV) by air. The pentavalent neptunium ion, which is the most stable oxidation state in solution, and hexavalent neptunium ion behave as strong Lewis acids and these ions form dioxo species, NpO_2^+ and NpO_2^{2+}, in acidic solution. NpO_2^{2+} is stable in acidic solution but is relatively easily reduced to NpO_2^+. Np(v) and Np(vi) form hydroxides in neutral and basic solutions. The solubilities of these hydroxides in the aqueous solution are higher than that of Np(iv) hydroxide. Np(vii) was first prepared by Krot and Gelman (1967) in basic solution. The chemical forms of Np(vii) in acidic and basic media are described in Section 6.8.2. NpO_3^+ is quickly reduced to NpO_2^{2+} by water (Spitsyn *et al.*, 1969).

(a) Redox potentials of neptunium ions

(*i*) *Acidic media*

Np(iii), Np(iv), Np(v), and Np(vi) ions exist in solutions of sufficiently high acidity or solutions containing ligands. Standard redox potentials are estimated from experimentally determined formal redox potentials by precise correction for activity coefficients. Alternatively, the standard redox potentials are calculated from standard enthalpies of formation and entropies of the ions. Chapter 19 of this work provides recommended values of the standard potentials of actinide ions as the following potential diagram:

$$\underbrace{\mathrm{NpO_2^{2+}} \xrightarrow{+1.159} \mathrm{NpO_2^{+}} \xrightarrow{+0.604}}_{+0.882} \mathrm{Np^{4+}} \underbrace{\xrightarrow{+0.219} \mathrm{Np^{3+}} \xrightarrow{-1.772} \mathrm{Np}}_{-1.274}$$

Recently, Kihara *et al.* (1999) critically evaluated the redox potentials of uranium, neptunium, and plutonium ions in acidic solutions by extrapolating the formal potentials to the state of zero ionic strength, referring mainly to the works by Riglet *et al.* (1987, 1989) and based on the Bronsted–Guggenheim–Scatchard specific ion-interaction theory (SIT) (Pitzer, 1979).

The $E°$ for such reversible redox couples as NpO_2^{2+}/NpO_2^+ and Np^{4+}/Np^{3+} proposed by Riglet *et al.* (1987, 1989) are reliable and most of the experimental data are in good agreement with these $E°$ if the activity coefficient is properly corrected in the conversion of the formal potential to $E°$. The formal potential for the redox couple between NpO_2^+ and Np^{4+} is difficult to determine by conventional voltammetry or polarography, because the electrode reaction between NpO_2^+ and Np^{4+} is slow or irreversible because Np–O bonds must be made or broken. The $E°$ for NpO_2^+/Np^{4+} couple in the diagram was evaluated from data of Gibbs energy of formation (Martinot and Fuger, 1985). Kihara *et al.* (1999) re-estimated the electromotive force (EMF) data (Cohen and Hindman, 1952) by the activity coefficient correction based on the SIT and obtained $+0.596$ for NpO_2^+/NP^{4+} couple. The $E°$ for NpO_3^+/NpO_2^{2+} estimated by Musikas *et al.* (1974) given in the diagram is recommended at the present time.

(*ii*) *Basic media*

Standard potentials or formal potentials for neptunium ions in basic media are less precise and less reliable than those in acidic media. For some redox reactions even chemical forms of hydrolytic species participating in the processes have not yet been fully understood. The potential diagram for neptunium ions in basic media by Martinot and Fuger (1985) is recommended:

$$\mathrm{NpO_5^{3-}} \xrightarrow{+0.58} \mathrm{NpO_2(OH)_2} \xrightarrow{+0.6} \mathrm{NpO_2OH} \xrightarrow{+0.3} \mathrm{NpO_2} \xrightarrow{-2.1} \mathrm{Np(OH)_3} \xrightarrow{-2.2} \mathrm{Np}$$

Recently a new method for the determination of formal potentials by the use of *in situ* X-ray absorption near-edge structure (XANES) spectroscopy was applied to the redox couples of neptunium ions in 1 M $HClO_4$ (Soderholm *et al.*, 1999). The relative concentrations of Np(VI)/Np(V) or Np(IV)/Np(III) after the controlled potential electrolysis were determined from XANES spectra using the principal component analysis technique. XANES spectra specific for the hydrated neptunium ions of different oxidation states are shown in Fig. 6.8.

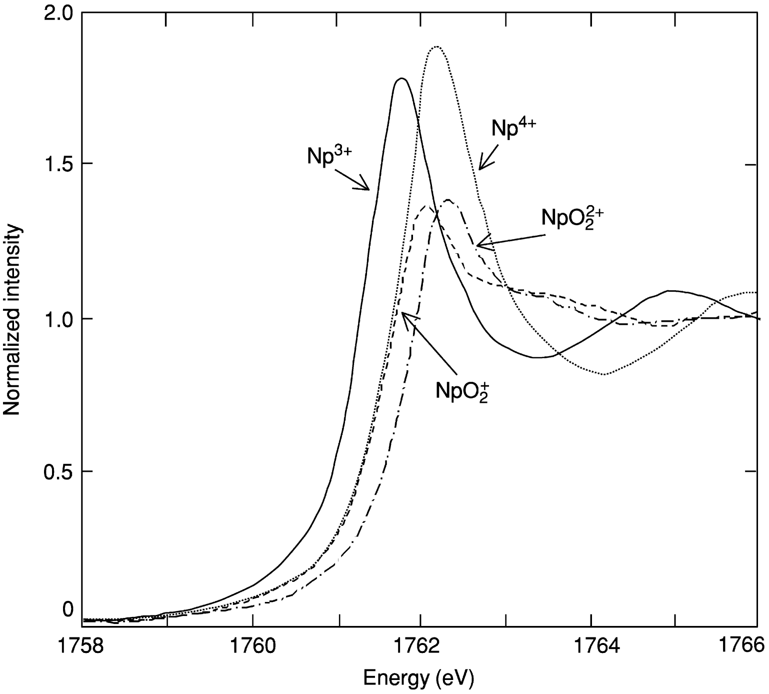

Fig. 6.8 *XANES spectra from the pure Np(III), Np(IV), Np(V), and Np(VI) ions in* $HClO_4$; *reprinted from Soderholm* et al. (1999) *with permission from American Chemical Society.*

The Nernstian plots between log([Np(VI)]/[Np(V)]) or log([Np(IV)]/[Np(III)]) and the applied potential lead to the precise determination of the formal potential, at which [Np(VI)]/[Np(V)] or [Np(IV)]/[Np(III)] equals unity. The formal potentials determined by this method are in good agreement with those determined by traditional voltammetry or polarography. An advantage of this method is that XANES is highly selective to the ion of interest that can interrogate a given redox couple in a complicated mixture such as the test solution containing multiple redox-active species.

(b) Electrolytic behavior of neptunium ions

(*i*) *Voltammetric behavior*

The measurements of current–potential relations by voltammetry, polarography, or related methods are important not only to elucidate the reaction mechanism and estimate the reaction rate but also to determine the formal potential for the evaluation of the standard redox potential. The voltammetric studies of the redox of neptunium ions, however, have not been conducted extensively enough.

Voltammetric data for the redox of neptunium ions in acidic media were provided by Niese and Vecernik (1981). The current–potential curves were recorded by cyclic voltammetry at a glassy carbon electrode with $HClO_4$, HNO_3, H_2SO_4, and acetate buffer solutions containing neptunium ion of a given oxidation state. Clear peaks due to one-electron redox reactions of NpO_2^{2+}/NpO_2^+ and Np^{4+}/Np^{3+} were observed. The peak potentials $E_{p,a}$ and $E_{p,c}$, at which the anodic and cathodic current peaks were observed, for the redox couples of NpO_2^{2+}/NpO_2^+ and Np^{4+}/Np^{3+} are summarized in Table 6.10. A difference between $E_{p,a}$ and $E_{p,c}$, ΔE_p, indicates that the redox processes of NpO_2^{2+}/NpO_2^+ and Np^{4+}/Np^{3+} in the 0.5 M $HClO_4$ or 1 M HNO_3 solutions are practically reversible and those in the H_2SO_4 or acetate buffer solutions are not reversible. The peak potential for NpO_2^{2+}/NpO_2^+ shifts more negatively with acetate buffer solution and the peak potential for Np^{4+}/Np^{3+} in HNO_3, H_2SO_4, and acetate buffer solution are more negative than that in $HClO_4$, which is due to stabilization of NpO_2^{2+} and Np^{4+} by the complex formation of NpO_2^{2+} with acetate ion and Np^{4+} with NO_3^-, SO_4^{2-}, and acetate ion.

The cathodic wave corresponding to further reduction of NpO_2^+ to Np^{4+} or Np^{3+} was not observed in the experiments by Niese and Vecernik (1981). The rate of the redox between Np^{4+} and NpO_2^+ as equation (6.30) is very slow, because the redox process involves formation or rupture of a Np–O bond which requires a large overpotential.

$$NpO_2^+ + 4H^+ + e^- \rightleftarrows Np^{4+} + 2H_2O \tag{6.30}$$

The potential for the reduction of NpO_2^+ to Np^{4+} is, therefore, more negative than that for the reduction of Np^{4+} to Np^{3+}, and the potential for the oxidation

Table 6.10 *Characteristics of voltammograms for redox of neptunium ions in $HClO_4$, HNO_3, H_2SO_4, or acetate buffer solutions.*

		Peak potentials (*V vs SSE*)		
Redox reactions	*Electrolyte*	*Anodic peak,* $E_{p,a}$	*Cathodic peak,* $E_{p,c}$	E_p
$NpO_2^{2+} + e^- = NpO_2^+$	0.5 M $HClO_4$	+1.01	+0.95	0.060
	1 M HNO_3	+1.04	+0.98	0.060
	0.5 M H_2SO_4	+1.02	+0.91	0.110
	0.5 M acetate buffer (pH = 4.2)	+0.84	+0.72	0.120
$Np^{4+} + e^- = Np^{3+}$	0.5 M $HClO_4$	+0.05	–0.02	0.070
	1 M HNO_3	–0.02	–0.08	0.070
	0.5 M H_2SO_4	–0.095	–0.23	0.135
	0.5 M acetate buffer (pH = 4.2)	–0.27	–1.06	0.790

of Np^{4+} to NpO_2^+ is more positive than that for the oxidation of NpO_2^+ to NpO_2^{2+} in $HClO_4$ and HNO_3 media.

Riglet *et al.* (1989) recorded voltammograms for the redox of Np(VI) and Np(V) in perchlorate media of various ionic strengths ($0.5 < I < 3$) for the precise determination of the formal redox potentials and re-evaluation of the standard redox potential at $I = 0$. The current–potential curves shown in Fig. 6.9 were recorded at rotating platinum disk electrode (2 mm in disk diameter) with rotation rate of 1500 rpm by scanning the potential at a rate of 0.002 V s^{-1}. The oxidation state of the neptunium ion in the test solution was controlled by the electrolysis so that NpO_2^+ initially present in the solution was partly oxidized to NpO_2^{2+} step by step (curves 2 to 5). The anodic wave developing at more positive potential and the cathodic wave at more negative potential than ca. +0.77 to +0.78 V correspond to the oxidation of NpO_2^+ and the reduction of NpO_2^{2+}, respectively. The redox reaction between NpO_2^+ and NpO_2^{2+} is not fully reversible at the platinum electrode because the slopes of the logarithmic analysis of the diffusion controlled waves are ca. 0.080 V per log unit, which are larger than the theoretical value.

Voltammetry using a rotating platinum electrode was applied to study the redox behavior of neptunium ions in 0.5– 4 M NaOH solution (Peretrukhin and Alekseeva, 1974). The successive reduction and oxidation among Np(VII), Np (VI), Np(V), and Np(IV) were investigated. The redox behavior of the neptunium ions strongly depends on the concentration of NaOH, which is interpreted as a change of the chemical form of Np(VI) during the electrolytic reduction and oxidation depending on the NaOH concentration.

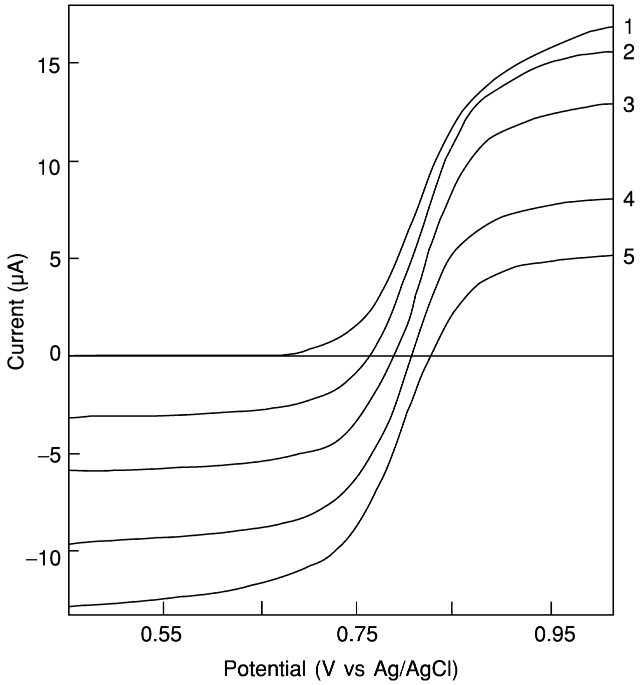

Fig. 6.9 *Current–potential curves for the redox couple of* NpO_2^{2+}/NpO_2^+ *in* 1 M $HClO_4$ + 1 M $NaClO_4$ *at rotating platinum disk electrode* (1500 rpm). *Concentration of Np*; 10^{-3} M, *Potential;* V *vs Ag/AgCl electrode* (E° = 0.3329 V *vs NHE*).

Electrochemical and spectroscopic studies of neptunium ions in concentrated aqueous carbonate and carbonate–hydroxide solutions were carried out by Varlashkin *et al.* (1984). The formal potential of the Np(VI)/Np(V) couple was determined as a function of pH of the solution. The redox reaction between Np(VI) and Np(V) was found to be quasi-reversible at a platinum electrode and the formal potential was estimated to be (+0.23 ± 0.01) V vs saturated calomel electrode (SCE).

(*ii*) *Coulometric behavior*

Flow coulometry using multi-step column electrodes is a powerful technique to investigate a redox reaction even if the reaction is irreversible, because the surface area of the working electrode of the column electrode is very large comparing with a volume of the solution in the column and a quantitative electrolysis can be achieved very rapidly. The electrolysis method using column electrode is also useful for the preparation of ions of a desired oxidation state as well as for the rapid determination or collection of various metals (Fujinaga and Kihara, 1977; Yoshida *et al.*, 1991).

Flow coulometry has been applied to the studies of overall redox behavior of the neptunium ions in acidic aqueous solution. Coulopotentiograms, which are current–potential curves observed by flow coulometry, were measured by using the multi-step column electrodes connected in series. Coulopotentiograms for the redox of neptunium ions of various oxidation states are shown in Fig. 6.10 after correction for the residual current. In the figure, the number of electrons involved in the redox reaction, *n*, converted from the current is plotted on the ordinate instead of the current.

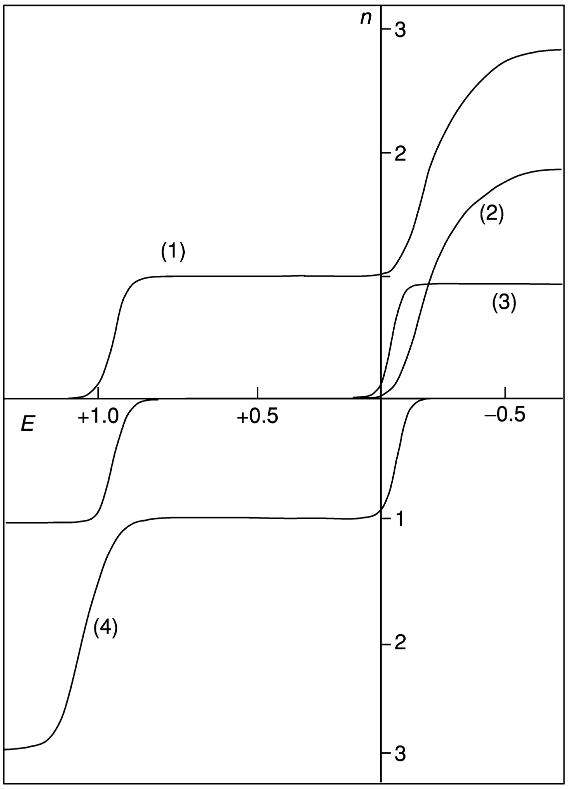

Fig. 6.10 *Coulopotentiograms for the redox of neptunium ions in* 1 M $HClO_4$ *solution.* n, *number of electrons involved in redox reaction;* E, *working electrode potential* (V *vs Ag–AgCl reference electrode*). (1) *Reduction of* NpO_2^{2+}, (2) *reduction and oxidation of* NpO_2^{+}, (3) *reduction of* Np^{4+}, (4) *oxidation of* Np^{3+}. *Sample solution;* 10^{-3} M *Np ion, flow rate,* 1.5 ml min^{-1}; *potential scan rate,* 0.002 V s^{-1}.

Coulopotentiogram 1 in Fig. 6.10 was recorded at a single column electrode with flowing 1 M $HClO_4$ solution containing 10^{-3} M NpO_2^{2+} and scanning the potential. The coulopotentiogram shows the reduction of NpO_2^{2+} to NpO_2^+ at more negative potential than +0.85 V vs Ag–AgCl reference electrode (SSE) and further to Np^{3+} at more negative potential than −0.6 V. Coulopotentiogram 2 was recorded with a two-step column electrode system with the first column electrode kept at +0.5 V and the second column at the scanned potential. Here, NpO_2^{2+} in the test solution is converted to NpO_2^+ quantitatively at the first column, and therefore, the redox behavior of NpO_2^+ can be examined at the second column electrode. Coulopotentiogram 2 shows one-electron oxidation of NpO_2^+ to NpO_2^{2+} at more positive potential than +1.1 V and two-electron reduction to Np^{3+} at more negative potential than −0.6 V. Coulopotentiograms 3 and 4 are recorded identically using two-step or three-step column electrode systems and show the reduction of Np^{4+} to Np^{3+} and the oxidation of Np^{3+} to Np^{4+} and further to NpO_2^{2+}.

(c) Disproportionation of NpO_2^+

NpO_2^+ disproportionates to Np^{4+} and NpO_2^{2+} through the following reaction. The extent of the disproportionation is promoted when the acidity of the solution and the concentration of NpO_2^+ are high:

$$2NpO_2^+ + 4H^+ \rightleftarrows Np^{4+} + NpO_2^{2+} + 2H_2O$$
$$K_{\text{dispro}} = [Np^{4+}][NpO_2^{2+}]/[NpO_2^+]^2[H^+]^4 \tag{6.31}$$

The equilibrium constant is increased by the addition of reagents that form complexes with Np^{4+} and NpO_2^2+ in the solution. For example, it was shown that $K_{\text{dispro}} = 4 \times 10^{-7}$ for Np(V) in 1 M $HClO_4$ and $K_{\text{dispro}} = 2.4 \times 10^{-2}$ for Np(V) 1 M H_2SO_4 solution (Keller, 1971). Hindman *et al.* (1954) suggested that the rate of the disproportionation reaction of equation (6.31) is expressed by equation (6.32).

$$-d[NpO_2^+]/dt = k[NpO_2^+][H^+]^2 \tag{6.32}$$

(d) Methods for the control of oxidation state of neptunium ions

(*i*) *Redox reagents*

The oxidation state of neptunium ions can be adjusted using various redox agents. The agent and chemical procedure feasible for the promotion of the redox between reversible couples such as NpO_2^{2+}/NpO_2^+ or Np^{4+}/Np^{3+} are chosen properly by referring to the redox potentials for neptunium ions and those for the agent as well as a ligand coexisting in the solution. Typical procedures for the control of the oxidation state of neptunium ions are shown

Table 6.11 *Procedures for adjusting the oxidation state of neptunium ion in aqueous solutions using redox agents.*

Oxidation states of neptunium ion		*Procedures*	
Before treatment	*After treatment*	*Agents*	*Conditions*
Oxidative treatment			
Np(iii), Np(iv), Np(v)	Np(vi)	Ce(iv)	HNO_3, H_2SO_4
		MnO_4^-	HNO_3, H_2SO_4
		Ag(ii)	1 M $HClO_4$
		BrO_3^-	
		$HClO_4$	fuming
		Cl_2	1 M HCl (348 K)
Np(iii)	Np(iv)	O_2 (air)	
Reductive treatment			
Np(v), Np(vi)	Np(iv)	Fe^{2+}	H_2SO_4
		I^-	5 M HCl (373 K)
Np(vi)	Np(v)	NH_2NH_2	1 M H^+
		NH_2OH	1 M H^+
		NO_2^-	1 M HNO_3
		H_2O_2	0.5 M HNO_3
		Sn^{2+}	HCl
		SO_2	H_2SO_4
Np(iv), Np(v), Np(vi)	Np(iii)	Zn(Hg)	
		H_2 (Pt black)	

in Table 6.11. The kinetic factors are required to be evaluated to complete slow processes between NpO_2^{2+} and Np^{4+} or between NpO_2^+ and Np^{4+} involved in the procedure for the oxidation state control. The kinetics of the redox reactions for Np(vi)–H_2O_2, Np(v)–V(iii), Np(v)–Cr(ii), and Np(vii)–Hg(i) systems were summarized by Newton (1975). Nakamura *et al.* (1992) proposed a method for the rapid reduction of Np(v) to Np(iv) by hydroxylamine nitrate in the presence of platinum black catalyst.

Recently much attention has been paid to the kinetics of the redox of neptunium ions by various organic agents for the development of an advanced Purex process. These studies aim at screening of the most suitable 'salt-free' redox agent, which enables precise control of the oxidation state of the neptunium ion in the process flowsheet. Taylor *et al.* (1997) reviewed the redox chemistry of neptunium ion in the proposed procedures.

Aldehyde derivatives such as *n*- and isobutyraldehydes are effective reductants for Np(vi) and Pu(iv) as reported by Kolarik and Dressler (1984) and Uchiyama *et al.* (1993). Hydroxylamine- and hydrazine derivatives have been suggested as effective reducing agents for Np(vi) and Pu(iv). Koltunov *et al.* (1993, 1999) investigated the reduction kinetics of Np(vi) by *N*,*N*-ethyl (hydroethyl)hydroxylamine ($HOC_2H_4(C_2H_5)NHOH^+$, EHEH) and *N*,*N*-diethyl hydroxylamine ($(C_2H_5)_2NHOH^+$, DEH) in nitric acid solution. The reduction reactions are expressed as follows.

$$4NpO_2^{2+} + HOC_2H_4(C_2H_5)NHOH^+ + 3H_2O \rightarrow 4NpO_2^+ + 2C_2H_5OH + HNO_3 + 9H^+ \tag{6.33}$$

$$8NpO_2^{2+} + (C_2H_5)_2NHOH^+ + 4H_2O \rightarrow 8NpO_2^+ + CH_3CHO + C_2H_5OH + HNO_3 + 5H^+ \tag{6.34}$$

The different characteristics of reactions by EHEH and DEH are explained by their different structures providing an availability of a hydroxyl group in the EHEH molecule. The kinetics of reactions (6.33) and (6.34) were studied in 0.3 – 2.0 M HNO_3 at ionic strength of 2.0. It was concluded that the reaction is first order relative to Np(VI) with excess reductants. The rate equations of reaction (6.33) and (6.34) are

$$-d[Np(VI)/dt = k[Np(VI)][EHEH][H^+]^{-0.8} \tag{6.35}$$

where k = (334 ± 12) $L^{0.2}\ mol^{-0.2}\ min^{-1}$ (298.6 K), and activation energy (E_A) = (42.3 ± 2.7) kJ mol^{-1}, and

$$-d[Np(VI)/dt = k[Np(VI)][DEH][H^+]^{-0.84} \tag{6.36}$$

where $k = (22.6 \pm 0.8)\ L^{0.16}\ mol^{-0.16}\ min^{-1}$ (298 K), and $E_A = (68.5 \pm 0.9)$ kJ mol^{-1}. Np(VI) and Pu(IV) are reduced faster by EHEH than by DEH, which suggests that the introduction of the hydroxyl group into the reductant molecule enhances the kinetics.

A comprehensive study on the reduction kinetics of Np(VI) and Pu(IV) by Taylor *et al.* (1998a) suggests that 1,1-dimethylhydrazine (DMHz) and *tert*-butylhydrazine (*tert*-BHz) are the most promising agents for the rapid reduction of Np(VI) with high selectivity over Pu(IV) reduction. For example, 99% of Np(VI) (initial concentration (1–2) × 10^{-4} M) in 1 M HNO_3 solution was reduced to Np(V) at 298 K by the addition of 0.1 M DMHz or *tert*-BHz within 1 or 8.7 min, respectively, and only 0.23 or 0.11% of Pu(IV) (initial concentration (2–10) × 10^{-3} M) was reduced to Pu(III) during 99% reduction of Np(VI) under the equivalent condition. It was found that formohydroxamic acid (Taylor *et al.*, 1998b) and acetaldoxime (Koltunov *et al.*, 2000) were also effective reductants for the rapid reduction of Np(VI) to Np(V) in acid solution.

(*ii*) *Electrochemical methods*

Controlled potential electrolysis is available to control the oxidation state of neptunium ions. For example, Np(V) in acidic solutions such as 1 M $HClO_4$ solution is oxidized to Np(VI) completely at +1.20 V vs Ag–AgCl (saturated KCl) reference electrode, Np(v) is quantitatively reduced to Np(iii) at −0.20 V, and Np(iii) is oxidized to Np(iv) at +0.40 V by controlled potential electrolysis using carbon or platinum working electrodes. Controlled potential electrolysis was applied to the preparation of carbonate complexes of neptunium ion of a given oxidation state in neutral or basic solutions (Li *et al.*, 1993).

The electrolytic technique using multi-step column electrodes of glassy carbon fiber working electrode as described in Section 6.8.1b is also useful to adjust the oxidation state of the neptunium ion in the flowing sample solution. The applied potential and the other electrolytic conditions can be chosen consulting with the current–potential relationship as shown in Fig. 6.10.

(*iii*) *Miscellaneous*

A sonochemical technique was applied to oxidize Np(v) efficiently (Nikitenko *et al.*, 1999). Np(v) in HNO_3 solution was found to be oxidized to Np(vi) in the presence of argon under the effect of power ultrasound (20 kHz, 1 W cm^{-2}). The addition of urea which exerts a buffering effect related to nitrous acid concentration helps to stabilize Np(vi) formed under sonification. The oxidation mechanism is related to the formation of HNO_2 by sonolysis of HNO_3, followed by the oxidation of Np(v) with HNO_3 catalyzed by HNO_2.

Photochemical reaction is feasible to oxidize and reduce Np(v) and Np(vi) in nitric acid solution (Fukasawa *et al.*, 1991). Np(vi) is reduced to Np(v) by HNO_2 generated by the photolysis of HNO_3 and is shown in reactions (6.37) to (6.39).

$$HNO_3(\text{photo irradiation}) \rightarrow OH + NO_2 \qquad (6.37)$$

$$2NO_2 + H_2O \rightarrow HNO_2 + HNO_3 \qquad (6.38)$$

$$NpO_2^{2+} + HNO_2 + H_2O \rightarrow 2NpO_2^+ + 3H^+ + NO_3^- \qquad (6.39)$$

Addition of a scavenger for HNO_2, such as urea, allows the oxidation of Np(v) to Np(vi) by the action of OH radical as given by reactions (6.40) and (6.41).

$$2HNO_2 + CO(NH_2)_2 \rightarrow 2N_2 + CO_2 + 3H_2O \qquad (6.40)$$

$$NpO_2^+ + OH + H^+ \rightarrow NpO_2^{2+} + H_2O \qquad (6.41)$$

The kinetics of the photochemical reduction of Np(vi) to Np(v) in HNO_3 solution were investigated (Wada *et al.*, 1995) as a function of irradiation wavelength, the acidity of nitric acid, and the nature of the coexisting agents. It was concluded that the higher the irradiation rate and the HNO_3 concentration, the easier the oxidation reaction of Np(v) progressed.

6.8.2 Optical spectroscopy of neptunium

Optical spectroscopy has been extensively applied to neptunium to better understand the electronic structure of the aquo ions Np(iii) through Np(vii), and of coordination complexes that occur in solution (Gruen, 1952; Waggener, 1958; Dukes and Shuler, 1960; Krot *et al.*, 1968a; Stafsudd *et al.*, 1969; Varga *et al.*, 1970; Chaikhorskii, 1971; Chaikhorskii and Leikina, 1972; Rykov and Frolov, 1972; Tsivadze and Krot, 1972; Kharitonov and Moskvin, 1973; Rykov *et al.*, 1973; Hessler *et al.*, 1980; Kanellakopulos *et al.*, 1980a,b; Lahalle *et al.*, 1986; Carnall *et al.*, 1987; Tait *et al.*, 1995; Matsika and Pitzer, 2000; Neck *et al.*, 2001). An excellent review article has been published by Gruen (1992) describing the development of the knowledge base for the f-electron elements, especially neptunium. Fig. 6.11 shows the visible absorption spectra for the neptunium ions (iii, iv, v, and vi) in 2 M perchloric acid. Optical spectroscopy has been applied in both the visible and infrared portions of the spectrum with a wealth of information being gathered.

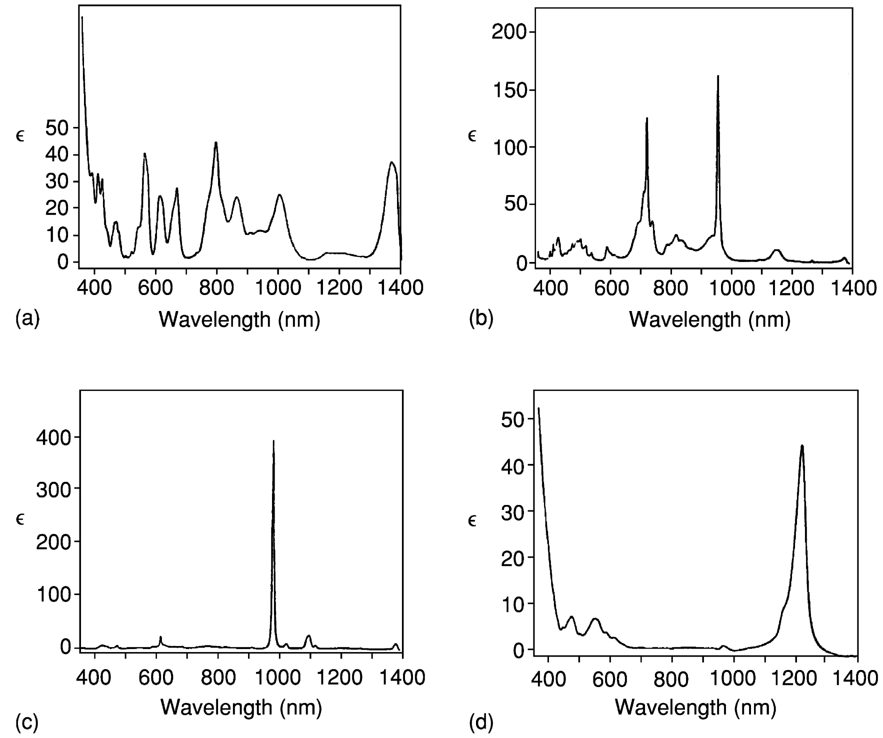

Fig. 6.11 *The absorption spectra of neptunium ions in* 2 M *$HClO_4$ solution:* (*a*)*Np*(*iii*); (*b*) *Np*(*iv*); (*c*) *Np*(*v*); (*d*) *Np*(*vi*).

One of the earliest studies on the subject (Gruen, 1952) used optical means to obtain information on the spin–orbit coupling for NpO_2^{2+} species. A value of 950 cm^{-1} for the spin–orbit coupling energy provided the best agreement between calculated and experimentally observed results for the $5f^2$ configuration. This 'best fit' was obtained by using the intermediate case of mixing the pure spin–orbit coupling and the pure electrostatic case.

The absorption spectrum of neptunium has often been measured in nitric acid solution. This provides straightforward identification of what valence states are present as was shown by Dukes and Shuler (1960). Np(IV) displays a strong absorption band at 715 nm, while Np(V) displays a somewhat weaker band at 617 nm and Np(VI) displays a strong band in the region below 400 nm. The concentration of nitric acid was determined not to be a significant factor in the absorption spectrum from 1 to 6 M.

Absorption spectroscopy of the Np(VII) species is somewhat more difficult in that it can be observed only under basic conditions (Krot *et al.*, 1968a; Williams *et al.*, 2001) in a steady-state manner. The actual form of the Np(VII) in solution is as NpO_6^{5-} in basic solutions and NpO_2^{3+} in acidic solutions. The tetraoxo Np(VII) compound exhibits four 'short' bonded oxygen (~1.85 Å) and two 'long' bonded oxygen (~2.2 Å) in basic solutions. The acidic form can only be observed at room temperature for a matter of minutes before it is reduced to the Np(VI) state. The hydroxide, $NpO_2(OH)_3$ is assumed to have amphoteric properties in solution.

The absorption spectrum for Np(VII) in solution was investigated in more detail by Chaikhorskii (1971). They prepared Np(VII) species in the cationic form and then precipitated it for their study. It was determined that fine structure could be observed in the visible absorption bands (412 and 620 nm). This fine structure was attributed to two causes, electron transfer (oxygen $\pi \rightarrow 5f$) and vibrational states. Several vibrational states were identified with energies between 681 and 2338 cm^{-1}. The vibrational bands identified were consistent with the predicted symmetry of a compound involving the NpO_2^{3+} species.

The infrared spectroscopy study by Chaikhorskii (1971) was extended by Tsivadze and Krot (1972) to include several compounds of Np in the Np(VII) state. Their work validated the earlier work of Chaikhorskii (1971) and furthered the knowledge base in that they determined the neptunium in the solid compounds that contained no isolated NpO_2 groups but that there were chains of 'infinite' length which connected the NpO_6 octahedra.

Stafsudd *et al.* (1969) studied Np(VI) by doping NpO_2^{2+} into a matrix of $Cs_2UO_2Cl_4$ and applying infrared and visible spectroscopies. They identified several pure electronic levels at 6880, 13 277, 15 426, 17 478, and 19 358 cm^{-1}. The ground state and the 6880 cm^{-1} state belong to the $5f^1$ configuration, whereas the other energy levels were thought to likely belong to an excited configuration involving electrons in the non-bonding 5f shell.

A more recent theoretical effort sought to improve the assignments of the electronic states for both Np(VI) and Np(V) species (Matsika and Pitzer, 2000).

This work is more complete than the much earlier effort of Eisenstein and Pryce (1965, 1966). Their work resulted in the calculation of the energy levels of 15 excited states for NpO_2^{2+} and 19 for NpO_2^{+}, as well as their respective wave functions. Their methods used relativistic spin–orbit coupling configuration interactions based on effective core potentials.

Work on the Np(v) species with a focus on its interaction with polyvalent species in different solvents was reported by Rykov and Frolov (1972). Visible spectroscopy of solutions of NpO_2^{+} in several different mixed solvents (water–methanol, water–ethanol, water–acetone) were obtained at room temperature in the presence of Fe^{3+}. The interaction of Fe^{3+} with Np^{5+} ion in mixed solvents was studied and it was reported that the formation of a complex involving both ions mirrored that of the electron exchange for Fe^{2+} and Fe^{3+} for aqueous solutions kinetically. The degree of interaction between the two ions being inversely dependent on the effective dielectric constant of the solvent.

Varga *et al.* (1970) performed an extensive spectroscopic study of the Np(iv) species from 300 to 1800 nm using NpF_4 either dissolved in $CsF \cdot 2HF$ (300–1300 nm) and in a fluorocarbon mull (1300–1800 nm). This study allowed for the assignment of 17 excited-state transitions for Np^{4+}. The experimental values for these transitions were compared to calculated values with good agreement. Infrared spectroscopy was also applied to a Np(iv) species in the form of several oxalate compounds formed with neptunium in the 4+ state (Kharitonov and Moskvin, 1973). This work identified several vibrational bands and their respective force constants and bond lengths (Np–O). The bond length was reported as 1.78 Å, which agreed well with the literature value for this quantity based on the vibrational band of approximately 825 cm^{-1} (Kharitonov and Moskvin, 1973).

Rykov *et al.* (1973) investigated the complexation behavior of Np(iv) in nitrate solutions of varying concentrations. A total of three types (A–B–C) of complexes were observed depending on whether there was very little nitrate present (type 'A' spectra observed) or nitrate solutions with very little free water present (type 'C' spectra observed). Type 'B' spectra were considered as intermediate to 'A' and 'C'. The fundamental distinction between the three types of complexes was assigned to the structure of the first coordination sphere. The type 'A' were thought to be of the M_{aq}^{4+} formula whereas the type 'C' were assigned to be a neptunium ion coordinated with six nitrates. The type 'B' complex had been thought to be an intermediate nitrate complex (less than six coordination) but their results were shown to be consistent with change in the aqueous coordinated complex and did not involve complexation by nitrate at all.

A later study of Np(iv) utilized low temperature spectroscopy (4.2 K) and two different crystalline hosts, $ThSiO_4$ and ThO_2 (Lahalle *et al.*, 1986). The latter of the two crystalline hosts had been used in an earlier study by Gruber and Menzel (1969) and was used for comparison purposes. Their study identified 29 excited-state transitions in the $ThSiO_4$ host and 19 in the ThO_2 host for

Np(IV) using both absorption and fluorescence spectroscopies over the temperature range of 4.2–300 K. Work of a similar nature on alkali and alkaline earth neptunates involving Np(VI) was performed by Kanellakopulos *et al.* (1980a,b).

A spectroscopic investigation of Np(III) was undertaken by Hessler *et al.* (1980) using low-temperature, high-resolution absorption, and fluorescence spectroscopies. A crystalline host of $LaCl_3$ was used. The temperature dependence of the homogeneous linewidth of D_1 to Z_1 (671.51 nm) and the D_1 to Z_2 (677.18 nm) transitions were obtained.

Carnall *et al.* (1987) investigated the interpretation of the spectra of neptunium obtained in silicate glasses with a focus on determining the valence state of the neptunium present. This work was undertaken to assist in the understanding of the local environment of neptunium in waste glasses bound for disposal in a geologic repository. Another spectroscopic investigation that has ramifications in the nuclear waste community is that of Neck *et al.* (2001) which utilized absorption spectroscopy, laser-induced photoacoustic spectroscopy (LIPAS), and laser-induced breakdown spectroscopy to study the colloids formed by neptunium in solution. An aqueous solution of $HClO_4$–$NaClO_4$ with Np(IV) present was used to obtain the solubility product constant of $Np(OH)_4$ at a wide range of pH. Kihara *et al.* (1996) also applied LIPAS to the study of neptunium species in Purex solutions.

A rather extensive study of Np(IV) and Np(V) in hydrolysis and carbonate reactions using optical and NMR spectroscopies was performed by Tait *et al.* (1995). Chaikhorskii and Leikina (1972) had earlier performed a similar study on Np(VII) during hydrolysis using optical spectroscopy.

With the relative importance of neptunium in the field of nuclear waste disposal, due to its long half-life, it is anticipated that the field of optical spectroscopy will continue to be an active one for many years with a particular emphasis on determining its local environment *in situ*.

6.8.3 Hydrolysis behavior

The hydrolysis reaction as a particular case of complex formation is the primary common property of all actinide ions in aqueous solution. The tendency for neptunium ions to undergo hydrolysis is in the order of $Np^{4+} > NpO_2^{2+} > Np^{3+} > NpO_2^+$, following the effective charge of the ions. The pentavalent NpO_2^+ ion is the most stable ion in solution and is not hydrolyzed appreciably at pH below 7. The trivalent Np^{3+} and hexavalent NpO_2^{2+} ions are the predominant species in solution at pH below 4–5 and 3–4, respectively, reflecting that the NpO_2^{2+} ion has an effective charge greater than the Np^{3+} ion. The tetravalent Np^{4+} ion shows a strong tendency towards hydrolysis and considerable hydrolysis is expected at pH 1 or above. Representative equilibrium constants for hydrolysis of neptunium ions, Np^{3+}, Np^{4+}, NpO_2^+, and NpO_2^{2+}, are listed in Table 6.12, together with some solubility products of the oxide or hydroxide.

Table 6.12 *Experimental equilibrium constants for hydrolysis of neptunium ion.*

Ion	*Method*	*Temp.* (°C)	*Medium*	*Equilibrium constants*	*References*
Np^{3+}	pot	25	0.3 M $NaClO_4$	$\log{}^*K_{11} = -7.43 \pm 0.11$	Mefod'eva *et al.* (1974)
Np^{4+}	sp	25	1.0 M	$\log{}^*K_{11} = -1.90$	Paul (1970)
	sol	25	0.0	$\log{}^*K_{14} = -9.8 \pm 0.11$	Rai *et al.* (1987)
				$\log{}^*K_s = 1.5 \pm 1.0$; $NpO_2(s) + 4H^+ \rightleftarrows Np^{4+} + 2H_2O$	Lemire *et al.* (2001)
NpO_2^+	sol	25	0.1 M $NaClO_4$	$\log{}^*K_{11} = -11.36 \pm 0.16$ $\log{}^*K_{12} = -23.50 \pm 0.12$	Neck *et al.* (1992)
			1.0 M $NaClO_4$	$\log{}^*K_{11} = -11.13 \pm 0.20$ $\log{}^*K_{12} = -23.19 \pm 0.14$ $\log{}^*K_s = 4.50 \pm 0.06$; $NpO_2OH(s) + H^+ \rightleftarrows NpO_2^+ + H_2O$	
NpO_2^{2+}	pot	25	1.0 M $NaClO_4$	$\log{}^*K_{11} = -5.17 \pm 0.03$ $\log{}^*K_{22} = -6.68 \pm 0.02$ $\log{}^*K_{35} = -18.25 \pm 0.02$	Cassol *et al.* (1972a)
	sol	25	0.1 M $NaClO_4$	$\log{}^*K_s = 5.87 \pm 0.17$; $NpO_3H_2O(s) + 2H^+ \rightleftarrows NpO_2^{2+} + 2H_2O$	Kato *et al.* (1996)

* K_{mn} is the hydrolysis constant for the equilibrium: $m\mathrm{M}^{a+} + n\mathrm{H_2O} \rightleftarrows \mathrm{M}_m(\mathrm{OH})_n^{am-n} + n\mathrm{H}^+$.

(a) Neptunium(III)

The trivalent Np^{3+} ion is sufficiently stable in acidic solution to allow spectrophotometric studies, but it is rapidly oxidized by air to the tetravalent state. Therefore, Np^{3+} will be stable in the presence of strong reductants and/or in an oxygen-free atmosphere. The tendency of an ion to undergo hydrolysis increases with charge and with decreasing ionic radius. The order of the trivalent actinide ions for ease of hydrolysis should be as follows: $U^{3+} < Np^{3+} < Pu^{3+} < Am^{3+}$, because the stability of hydrolyzed ions increases as z/r_{ion} increases.

As only one experimental study for the equilibrium,

$$Np^{3+} + H_2O \leftrightarrows NpOH^{2+} + H^+ \tag{6.42}$$

Mefod'eva *et al.* (1974) determined $\log {}^*K_{11} = -7.43$ for 298 K and 0.3 M $NaClO_4$ from potentiometric measurements in the pH range 6–8. The Np^{3+} ion was produced by electrolysis of 0.022 M $Cs_2NpCl_6(aq)$ in 0.1 M HCl using a mercury cathode in an inert atmosphere. The titration curves of Np^{3+} were compared with those of Pr^{3+} and Nd^{3+} under the similar conditions to obtain the ratios of the hydrolysis constants.

There has been no systematic study to determine the solubility product for Np(III) and no usable experimental data for $Np(OH)_3(s)$ is available.

(b) Neptunium(IV)

From the same reasons as in the case of the trivalent state, the tendency of the tetravalent actinide ions to undergo hydrolysis follows the order: $Th^{4+} < U^{4+} < Np^{4+} < Pu^{4+}$. There are three reports of the first hydrolysis step of Np^{4+}.

$$Np^{4+} + H_2O \leftrightarrows NpOH^{3+} + H^+ \tag{6.43}$$

Sullivan and Hindman (1959) and Paul (1970) reported $\log {}^*K_{11} = -2.30$ ($I = 2.0$ M) and -1.90 ($I = 1.0$ M), respectively, in aqueous perchlorate solutions by spectrophotometry. From extraction experiments, Duplessis and Guillaumont (1977) reported $\log {}^*K_{11} = -0.50$ in 1.0 M $LiClO_4$. Two values $\log {}^*K_{12}$ for $Np(OH)_2^{2+}$ have been reported with a large discrepancy (three order of magnitude) (Duplessis and Guillaumont, 1977; Schmidt *et al.*, 1980), while there is no experimental evidence for the formation of $Np(OH)_3^+$.

Several groups (Ewart *et al.*, 1985; Rai and Ryan, 1985; Pratopo *et al.*, 1989; Eriksen *et al.*, 1993) measured the solubility of Np(IV) hydrated oxide or hydroxide in neutral to basic solutions at room temperature in the presence of reducing agents, e.g. $Na_2S_2O_4$, Fe, or Zn, and reported a limiting neptunium concentration of $10^{-8.5}$ to $10^{-8.1}$ M. The pH-independence of the solubility indicates that the main species in equilibrium with Np(IV) solids is uncharged $Np(OH)_4^0$ and that $Np(OH)_5^-$ is not an important species for Np(IV) hydrolysis. Rai *et al.* (1987) studied the solubility of $NpO_2 \cdot xH_2O$ in the presence of Cu(I)/Cu(II) buffer and in the pH range from 1.5 to 2.5. Based on the measured redox potentials, pH, and calculated activities of Np^{4+} and NpO_2^+, the thermodynamic equilibrium constants were determined. After recalculation of the results in the NEA/TDB neptunium and plutonium volume (Lemire *et al.*, 2001), $\log{}^*K_s = 1.5$ and $\log{}^*K_{14} = -9.8$ were reported for the following reactions, respectively:

$$NpO_2(s) + 4H^+ \leftrightarrows Np^{4+} + 2H_2O \tag{6.44}$$

$$Np^{4+} + 4H_2O \leftrightarrows Np(OH)_4^0 + 4H^+ \tag{6.45}$$

The experimental $\log{}^*K_s$ values of Th(IV) (Ryan and Rai, 1987), Np(IV) (Rai *et al.*, 1987), and Pu(IV) (Rai, 1984) hydrous oxides show a linear relationship with the inverse square of the M^{4+} ionic radii.

(c) Neptunium(V)

The pentavalent NpO_2^+ ion is stable and disproportionates only at rather high acidities. Many groups have reported the formation constants of the hydroxo species by using various experimental methods (see Lemire *et al.*, 2001). The recent hydrolysis studies by solubility measurements (Lierse *et al.*, 1985; Itagaki *et al.*, 1992; Neck *et al.*, 1992) show smaller constants than found in earlier studies (Kraus and Nelson, 1948; Moskvin, 1971; Sevost'yanova and Khalturin, 1976; Schmidt *et al.*, 1980; Maya, 1983; Bidoglio *et al.*, 1985), which is probably due to the effect of carbonate complexation.

Neck *et al.* (1992) studied the hydrolysis behavior of the NpO_2^+ ion at 298 K by solubility experiments in the pH range 7–14 in 0.1, 1.0, and 3.0 M $NaClO_4$ solutions under CO_2-free argon atmosphere. In 0.1 M $NaClO_4$ Np(V) hydroxide precipitate remained amorphous (green) over several months, while in 1.0 M $NaClO_4$ the precipitate changed from an amorphous to a more stable-aged state (white) within a relatively short time. In 3.0 M $NaClO_4$ the aged modification of $NpO_2OH(s)$ is formed from the beginning. As shown in Table 6.12, the hydrolysis constants and solubility product for aged $NpO_2OH(s)$ were reported for the following reactions:

$$NpO_2^+ + H_2O \leftrightarrows NpO_2OH^0 + H^+ \tag{6.46}$$

$$NpO_2^+ + 2H_2O \leftrightarrows NpO_2(OH)_2^- + 2H^+ \tag{6.47}$$

$$NpO_2OH(s) + H^+ \leftrightarrows NpO_2^+ + H_2O \tag{6.48}$$

The solids (fresh and aged NpO_2OH) were not analyzed for possible incorporation of sodium ions, however the parallel solubility curves obtained for the two solids in 1.0 M $NaClO_4$ strongly suggest that they have similar stoichiometries.

(d) Neptunium(VI)

The hexavalent NpO_2^{2+} ion is not as stable as the UO_2^{2+} and PuO_2^{2+} ions. Cassol *et al.* (1972a) studied the hydrolysis of the NpO_2^{2+} ion in 1 M $NaClO_4$ at 298 K by potentiometric titrations. The NpO_2^{2+} solution was prepared by electrolytic oxidation of a NpO_2^+ solution. The hydrolysis constants shown in Table 6.12 were reported for the following equilibria:

$$NpO_2^{2+} + H_2O \leftrightarrows NpO_2OH^+ + H^+ \tag{6.49}$$

$$2NpO_2^{2+} + 2H_2O \leftrightarrows (NpO_2)_2(OH)_2^{2+} + 2H^+ \tag{6.50}$$

$$3NpO_2^{2+} + 5H_2O \leftrightarrows (NpO_2)_3(OH)_5^+ + 5H^+ \tag{6.51}$$

The value $\log{}^*K_{11} = -5.17$ is consistent with the value ($\log{}^*K_{11} = -5.45$) reported by Schmidt *et al.* (1983), while the hydrolysis scheme proposed by Moskvin (1971) based on solubility measurements is rather different. Comparison of the results (Cassol *et al.*, 1972a) with some available data on the hydrolysis of U(VI) (Rush *et al.*, 1962; Rush and Johnson, 1963) and Pu(VI) (Cassol *et al.*, 1972b) indicates a close analogy in hydrolysis behavior for the three ions. The tendency in acidity with increasing atomic number is in the order of $UO_2^{2+} > NpO_2^{2+} > PuO_2^{2+}$.

Kato *et al.* (1996) have determined the solubility product of neptunium trioxide monohydrate at 298 K in acidic 0.1 M $NaClO_4$ solution prepared with ozone in air.

$$NpO_3H_2O(s) + 2H^+ \leftrightarrows NpO_2^{2+} + 2H_2O \tag{6.52}$$

The solid was characterized to be $NpO_3 \cdot H_2O$, not $NpO_2(OH)_2$, by X-ray diffraction and Fourier transform infrared spectroscopy (FTIR).

(e) Neptunium(VII)

A cationic Np(VII) species in acidic solutions (Shilov *et al.*, 1991) and an anionic species in strongly alkaline solutions (Chaikhorskii *et al.*, 1975) have been reported, but no thermodynamic data are available. Np(VII) hydroxide or hydrated oxide has been prepared by several groups (Chaikhorskii *et al.*, 1974; Nikonov *et al.*, 1994) using different methods. No thermodynamic data for Np(VII) hydroxide and oxide are available.

6.9 COORDINATION COMPLEXES IN SOLUTION

Representative equilibrium constants and the experimental conditions at which they were determined are collected in Tables 6.13 and 6.14 for neptunium complexes with inorganic and organic ligands, respectively. Data on complex formation of neptunium and of other actinides have been compiled in the literature, e.g. Gel'man *et al.* (1962), Degischer and Choppin (1975), Fuger *et al.* (1992), Lemire *et al.* (2001), Smith and Martell (2002), etc., and are reviewed in Chapters 19 and 23.

In Tables 6.13 and 6.14, the following abbreviations are used in experimental methods: cix, cation exchange; dis, distribution between two phases; em, electromigration; emf, electromotive force; ise, ion selective electrode; pot, potentiometry; red, emf with redox electrode; sol, solubility; sp, spectrophotometry. The stepwise stability constants K_i and overall constants β_i are defined for the reaction of a cation M with a ligand L as follows:

$$K_1 = \beta_1 = [\mathrm{ML}]/[\mathrm{M}][\mathrm{L}], K_2 = [\mathrm{ML_2}]/[\mathrm{ML}][\mathrm{L}], K_3 = [\mathrm{ML_3}]/[\mathrm{ML_2}][\mathrm{L}], \mathrm{etc.}$$

$$\beta_2 = [\mathrm{ML_2}]/[\mathrm{M}][\mathrm{L}]^2, \beta_3 = [\mathrm{ML_3}]/[\mathrm{M}][\mathrm{L}]^3, \mathrm{etc.}$$

Therefore

$$\beta_2 = \mathrm{K_1K_2}, \beta_3 = \mathrm{K_1K_2K_3}, \text{ etc.} \qquad (6.53)$$

The other equilibrium constants are indicated in Tables 6.13 and 6.14.

6.9.1 Complexation with inorganic ligands

All of the equilibrium constants listed in Table 6.13 are for complexes of Np (IV), Np(V), and Np(VI). Only a few studies have been carried out on complexes of Np(III) and Np(VII). Shiloh and Marcus (1966) studied the $\mathrm{Np^{3+}}$–halide system quantitatively by measurement of the absorption spectra. The stability constants for $\mathrm{NpX^{2+}}$ and $\mathrm{NpX_2^+}$ ($\mathrm{X = Cl^-, Br^-}$) were obtained in concentrated LiCl and LiBr solutions, respectively. Mefod'eva *et al.* (1970a,b) reported the complex formation of Np(VII)($\mathrm{NpO_2^{3+}}$) with sulfate ion in acid solution. The stability constants obtained for $\mathrm{NpO_2SO_4^+}$ and $\mathrm{NpO_2(SO_4)_2^-}$ were greater than those of $\mathrm{NpO_2^{2+}}$.

The tendency of a neptunium ion for complex formation, as well as the hydrolysis reaction, depends on its ionic potential, i.e. its formal charge divided by its ionic radius. In analogy with neighboring uranium and plutonium, the order of decreasing ability for complex formation is

$$\mathrm{Np^{4+} > NpO_2^{2+} \geq Np^{3+} > NpO_2^+}$$

The relative complex-forming ability of $\mathrm{Np^{3+}}$ and $\mathrm{NpO_2^{2+}}$ may depend on the ligand and/or the solvent with which these ions are associated. It is difficult to

compare the data listed in Table 6.13 because of the wide range of experimental conditions used and the lack of data for a given oxidation state of the ions with some ligands. However, the stability sequence for complexes of Np(IV), Np(V), or Np(VI) with monovalent inorganic ligands is seen to be

$$F^- > H_2PO_4^- > SCN^- > NO_3^- > Cl^- > ClO_4^-$$

For divalent inorganic ligands, the sequence is

$$CO_3^{2-} > HPO_4^{2-} > SO_4^{2-}$$

as would be expected from the relative strengths of the corresponding acids. Divalent ligands are more strongly complexing than monovalent ligands.

In addition to the data in Table 6.13, Np(V) (NpO_2^+) is known to form 'cation–cation' complexes with some multiply charged cations. The dioxo cation NpO_2^+ in perchloric acid solution forms complex ions with trivalent cations of Al, Ga, Sc, In, Fe, Cr, and Rh (Sullivan, 1962, 1964). The relative strength of the interaction between NpO_2^+ and M^{3+} was found to follow the following order: Fe > In > Sc > Ga > Al. Some of these polynuclear complexes such as $[NpO_2^+Cr^{3+}]$ and $[NpO_2^+Rh^{3+}]$ have been isolated by using an ion-exchange method, while the others were detected by spectrophotometry. The $[NpO_2^+Cr^{3+}]$ complex is also formed by the reduction of NpO_2^{2+} with Cr^{2+}. The formation of the complex between NpO_2^+ and UO_2^{2+} has extensively been studied by the use of potentiometry, spectrophotometry, Raman spectroscopy, and large-angle X-ray scattering (Sullivan *et al.*, 1961; Guillaume *et al.*, 1982, 1983; Stout *et al.*, 1993).

6.9.2 Complexation with organic ligands

With some exceptions, most of the data in Table 6.14 are for complexes of Np(V) with organic ligands. The following presents the results on several selected systems.

Stability data for complexes of M(VI) ions MO_2^{2+} (M = U, Np, and Pu) with monocarboxylic ligands L (L = acetate, propionate, monochloroacetate, and β-chloropropionate) have been reported and discussed by Cassol *et al.* (1969) and Portanova *et al.* (1970). In the range of ligand concentrations examined, complexes are formed in which the highest average ligand number is three. The stability order of complexes of the various ligands examined is $UO_2^{2+} > NpO_2^{2+} > PuO_2^{2+}$. The stability of complexes of a given MO_2^{2+} ion increases with increasing ligand basicity (pK_a), which suggests a strong 'hard' ionic character of these oxycations.

The stability constants of Np(V) complexes with a series of α-hydroxycarboxylates (e.g. glycolate and lactate) have been obtained by spectrophotometry (Eberle and Schaefer, 1969; Rizkalla *et al.*, 1990a) and solvent extraction (Tochiyama *et al.*, 1992). The stability of the α-hydroxycarboxylate complexes appears to increase a little with pK_a of the ligand, although the stability of these complexes is not much different. The stability of Np(V) complexes with aliphatic dicarboxylates (e.g. oxalate and malonate) has also been studied by potentiometry (Magon *et al.*, 1972), spectrophotometry (Stout *et al.*, 1989), and solvent extraction (Tochiyama *et al.*, 1992). The stability of the complexes is controlled mainly by the size of the chelate ring. In spite of the increase in the basicity of the ligand, the stability of the complexes decreases with increasing the number of carbon atoms between two carboxylate groups in the ligand.

The complexation of Np(v) with aromatic polycarboxylates has been studied by spectrophotometry (Choppin *et al.*, 1998). The stability constants of the 1:1 complexes decreases in the order: hemimellitate > mellitate > pyromellitate > trimellitate≃phthalate. After correction for the number of chelating binding (bidentate) sites, the stability constants with all ligands except hemimellitate are approximately the same. The greater strength of hemimellitate complexation is attributed to an increase in electron density at the binding site through induction from the non-chelating carboxylate group.

With aliphatic aminopolycarboxylate ligands, the complexation of Np(iv) or Np(v) has been studied by spectrophotometry (Eberle and Paul, 1971; Eberle and Wede, 1970). The logarithms of the stability constants of the Np(iv) complexes increase linearly with the number of bound donor atoms of the ligands. On the other hand, the Np(v) ion forms protonated and normal chelates of 1:1 stoichiometry. In addition, at high pH chelate hydroxides with one ligand molecule and one hydroxyl group per NpO_2^+ are formed. The nature of the ligand has only slight or no influence on the stability constants of normal chelates or chelate hydroxides, respectively, suggesting that not more than two carboxylic groups and one amine-nitrogen are bound from one ligand to the central neptunium.

6.10 ANALYTICAL CHEMISTRY AND SPECTROSCOPIC TECHNIQUES

The concentration of ^{237}Np and the radioactivity arising from this nuclide in the environment is extremely low compared to most other α emitters. The background concentration of ^{237}Np in seawater due to global fallout was estimated to be at a level of 10^{-15} to 10^{-14} g L^{-1} (Novikov *et al.*, 1989; Jha and Bhat, 1994). However, with the increase in nuclear power generation, this nuclide has become one of the most important from the viewpoint of long-term disposal of the radioactive waste. In fact, the analytical results showing contamination of ^{237}Np in seawater from nuclear fuel reprocessing plants have been reported, e.g. the concentrations of ^{237}Np were $3 \times 10^{-12} - 5.5 \times 10^{-11}$ g kg^{-1} in some samples from Irish sea (Pentreath and Harvey, 1981), 3×10^{-12} g kg^{-1} from Goury near La Hague, France (Germain *et al.*, 1987), $(2.3 \pm 0.4) \times 10^{-11}$ g kg^{-1} from English disposal area (May *et al.*, 1987), and $2 \times 10^{-12} \sim 2 \times 10^{-11}$ g L^{-1} in a waste discharge point at Trombay, India (Jha and Bhat, 1994). More sensitive methods for measuring such low levels of ^{237}Np must be developed and applied. Novikov *et al.* (1989) reviewed the analytical methods to be applied to

^{237}Np in the environmental samples. Hursthouse *et al.* (1992) performed a comparative study to evaluate the practical advantages and disadvantages of the methods. Lee *et al.* (1995) reported the result of an intercomparison study by eight laboratories of low-level ^{237}Np determination in artificial urine samples in order to evaluate and establish the optimal method for a routine *in vivo* radioassay program. In addition, precise determination of the ^{237}Np in the nuclear spent fuel or HLW from the reprocessing process is still a major concern in the field of nuclear engineering as well as the related research and development works.

6.10.1 Radiometric methods

Radiometric methods that are based on counting of alpha particles from ^{237}Np and neutron activation of ^{237}Np have been widely employed for the quantitative analysis of trace amount of ^{237}Np in environmental samples. The alpha-particle counting method is useful for the rapid and low-cost determination of trace quantity of ^{237}Np (specific radioactivity = 2.6×10^{7} Bq g^{-1}). A recent report by Pavlotskaya (1997) reviewed critically the radiochemical analysis methods for the determination of a trace quantity of neptunium in environmental samples.

(a) Alpha- and gamma-ray spectrometry

Alpha spectroscopy with solid state detectors enables the determination of ^{237}Np in a thin sample of a mixture with other α emitters such as ^{239}Pu and ^{241}Am. A preparation of sufficiently thin counting source is a key in the measurement of a reproducible spectrum without a disturbance from the self-absorption of alpha particles in the source. A simple method adopting an evaporation of the sample solution on the source substrate such as a plate of stainless steel or platinum is typically employed. Methods based on the electrodeposition of neptunium directly on the source substrate are useful to prepare thinner sources. Coprecipitation methods are simple and feasible for the preparation of counting sources but may not yield a sufficiently thin source for energy discrimination. Kimura (1990a) utilized $BiPO_4$ precipitate for the quantitative recovery and the preparation of alpha-counting sources for the simultaneous determination of Np, Pu, Am, and Cm.

Holm *et al.* (1987) applied alpha spectroscopy to the determination of the fallout level of ^{237}Np in large volume samples of seawater. They employed a method for the isolation of ^{237}Np by a hydroxide coprecipitation, ion-exchange chromatography, a LaF_3 coprecipitation, and a solvent extraction with HTTA. Yamamoto *et al.* (1989) developed a method for determination of low levels of ^{237}Np in soil and sediment samples. The separation scheme they developed is shown in Fig. 6.12 and consists of leaching of neptunium by aqua regia, separation and purification by TnOA extraction, LaF_3 coprecipitation, and

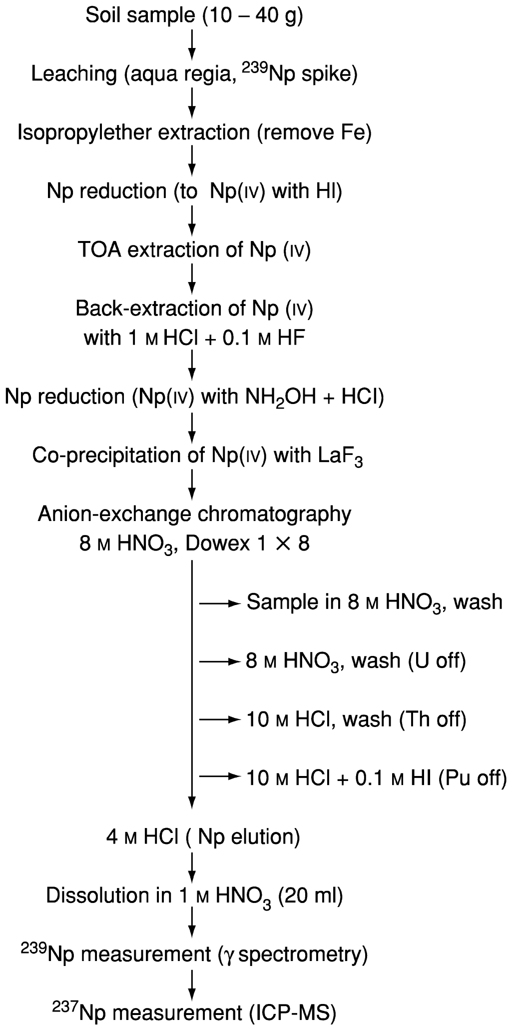

Fig. 6.12 *Chemical separation scheme for the determination of ^{237}Np by high-resolution ICP-MS.* (*Yamamoto* et al., 1994, *with permission from Elsevier Science*).

two steps of anion-exchange chromatography. ^{239}Np was used as a chemical yield monitor. The chemical yield of neptunium ranged from 50 to 84%. The detection limit for ^{237}Np was about 0.1 mBq per sample.

A method for the simultaneous determination of ^{237}Np and ^{239}Np in air, total deposition and sediment samples in ocean was developed (Rosner *et al.*, 1993). Alpha- and gamma-ray spectroscopies were used.

Alpha- and gamma-ray spectroscopies were applied to the determination of ^{237}Np in spent nuclear fuels (Shinohara *et al.*, 1989). After ion-exchange separation of the dissolved fuel solution, the content of ^{237}Np was determined from the activity of ^{237}Np or ^{233}Pa, which is in radioactive equilibrium with ^{237}Np. The chemical yield was determined using inherent ^{239}Np. The proposed method does not require quantitative separation of neptunium and can be applied to routine analyses of burnup for the nuclear spent fuel.

One of the few uses of gamma spectroscopy for Np radioanalysis was that of isotope dilution gamma-ray spectroscopy method using ^{239}Np as a spike for the determination of ^{237}Np in uranium, plutonium, and mixed oxide samples (Sus *et al.*, 1996). Extraction chromatography with trialaurylamine fixed on a SGX-C18 support was used for the isolation of neptunium. A pair of γ-rays of 86.53 keV (^{237}Np) and 106.13 keV (^{239}Np) was employed for the detection. The detection limit was evaluated to be 5×10^{-8} g ^{237}Np.

(b) Liquid scintillation counting method

Liquid scintillation counting method does not require extensive sample preparation and is very sensitive for alpha-decaying radionuclides such as ^{237}Np. The alpha liquid scintillation method with rejection of γ emitters (PERALS spectrometer) is useful because of its high sensitivity, selectivity, and rapid sample preparation. Aupiais *et al.* (1999) developed a method for the determination of ^{237}Np which consists of (1) oxidation of Np(v) to Np(vi) with Ag(ii), (2) extraction of Np(vi) from 0.5 to 0.75 M HNO_3 solution into the extractive scintillation cocktail of TOPO, and (3) gamma liquid scintillation counting with rejection of γ emitters. The method was applied to the biological samples.

The pulse shape discrimination (PSD) technique was introduced to liquid scintillation counting by Yang *et al.* (1994) for the determination of ^{237}Np coexisting with plutonium and americium. Np(iv) was separated from Pu(iii), Am(iii), and fission product elements by two steps of solvent extraction using TTA–xylene and triisooctylamine(TIOA)–xylene. The PDS technique enabled the alpha counting with an efficiency of higher than 99% and a beta discrimination factor of higher than 99.95%. The proposed method was applied to the determination of neptunium, plutonium, and americium in the HLW.

(c) Activation analysis

Neutron activation analysis based on ^{237}Np(n,γ)^{238}Np ($t_{1/2}$ of ^{238}Np = 2.117 days) reaction, for which the activation cross section is large and 170 barns, is one of the most sensitive methods for the determination of ^{237}Np. In general, neutron activation analysis is ca. 500 times more sensitive than the alpha-counting method. The procedure consists of (1) pretreatment of the sample, i.e. the leaching of ^{237}Np from the solid sample and the oxidation state adjustment at Np(iv), (2) the separation and preconcentration of Np(iv), (3) neutron irradiation, (4) separation of Np(iv) from the irradiated sample, and (5) the determination of ^{238}Np by gamma-ray spectroscopy. May *et al.* (1987) applied this method to irradiated nuclear fuels, radioactive waste solutions, and environmental samples such as seawater and submarine fauna and flora of disposal areas. Cation-exchange chromatography with Dowex 1 × 8 was employed to separate Np(IV) both before and after the irradiation. They determined the detection limit to be 5×10^{-13} g ^{237}Np. A similar procedure was applied to the sediment samples around Sellafield, Cumbria (Bryne, 1986) and the samples taken from the marine environment of coastal nuclear sites in India (Jha and Bhat, 1994). Depending on the nature of the sample, the removal of the bulk of the iron is required, and they employed solvent extraction with methylisobutylketone (MIBK) or isopropyl ether. After the irradiation, ^{238}Np purified by solvent extraction of Np(IV) with HTTA (cf. Fig. 6.12). If necessary, neptunium ions in a large volume of the sample solution such as seawater sample was preconcentrated by coprecipitation with iron(III) hydroxide precipitate, and Na^+ (^{24}Na) was removed from the irradiated sample using the flow-through column of the hydrated antimony pentoxide. The chemical yield was monitored, usually with ^{239}Np tracer. Bryne (1986) evaluated the detection limit by this method to be 0.1 to 0.5 mBq ^{237}Np.

Neutron activation analysis using epithermal neutron was applied to the determination of ^{237}Np for the purpose of an environmental monitoring of Yucca Mountain area (Riggle, 1992). The sensitivity obtained by the activation analysis using epithermal neutrons was found to be similar to that by using thermal neutrons. The neutron activation analysis method is also feasible for the determination of ^{235}Np and Zhao *et al.* (1991) applied this method to the determination of ^{235}Np in silicate samples.

Maslov *et al.* (1997) developed a highly sensitive method based on the (γ,f) reaction of ^{237}Np followed by the fission track counting. The proposed method was feasible for the determination of ultra-trace amount of ^{237}Np, e.g. in environmental water, and the detection limit was estimated to be 1×10^{-14} g ^{237}Np.

6.10.2 Spectrophotometric method

Several spectrophotometric methods are available: (1) absorption spectrophotometry of Np ions (direct absorption spectrophotometry); (2) absorption spectrometry of the colored complexes formed by Np ions and a chelating reagent; and (3) fluorescence spectrophotometry. A report by Burney and Harbour (1974) summarized and evaluated traditional spectrophotometric methods.

The direct absorption spectrophotometry is useful for the speciation of the Np ions in a solution by a simple procedure, though the sensitivity is not high. The most appropriate wavelengths for the determination of Np^{3+}, Np^{4+}, NpO_2^+, and NpO_2^{2+} in 2 M $HClO_4$ are 786 nm (molar extinction coefficient ε is approximately 45 $mol^{-1}\ dm^3\ cm^{-1}$), 960 nm ($\varepsilon = 160\ mol^{-1}\ dm^3\ cm^{-1}$), 980 nm

($\varepsilon = 395$ mol^{-1} dm^3 cm^{-1}), and 1223 nm ($\varepsilon = 45$ mol^{-1} dm^3 cm^{-1}), respectively (cf. Fig. 6.11). This method is useful for rapid and non-destructive speciation of the Np ions in acidic solution. The detection limits are approximately 5×10^{-4} M Np^{3+}, 1×10^{-4} M Np^{4+}, 5×10^{-5} M NpO_2^+, and 5×10^{-4} M NpO_2^{2+} simply assuming that the lowest detectable absorption is 0.02.

LIPAS enables the direct detection of the ions of relatively low concentration in the solution (Schrepp *et al.*, 1983; Klenze and Kim, 1988). An utilization of LIPAS leads to an enhancement of the sensitivity by a factor of ten or more compared with traditional absorption spectrophotometry. Pollard *et al.* (1988) realized the sensitivity in the measurement of Np(IV), Np(V), and Np(VI) of ca. 10^{-7} M in acidic solution using a dual beam LIPAS system equipped in Harwell. The LIPAS was applied to the monitoring of Np(V) in the nitric acid solution of the Purex process condition (Kihara *et al.*, 1996).

Colored complexes of neptunium with high absorption ability have been utilized for the sensitive determination of neptunium (Burney and Harbour, 1974). A method using the complex of Np(IV) and 1,8-dihydroxy–3,6-disulfonicnaphthalene–2,7diazo, commonly referred to as arsenazo-III, is one of the most sensitive with a molar extinction coefficient of 10^5 mol^{-1} dm^3 cm^{-1} at 665 nm, when the complex is formed in 4–6 M HNO_3. Uranium, thorium, plutonium, and other ions also form complexes with arsenazo-III, and therefore these ions should be removed from the sample solution before the color formation reaction. Solvent extraction with HDEHP acid or TIOA was used to separate neptunium from these interfering ions. The detection limit obtained by arsenazo-III method is approximately 4×10^{-8} g ml^{-1} of neptunium. Thorin, xylenol orange, and chlorophosphonazo III are other common color-forming reagents for use in the determination of neptunium.

6.10.3 Luminescence methods

Measurement of the luminescence intensity from a phosphor such as CaF_2- or $PbMpO_4$-based crystal that is doped with neptunium makes the sensitive determination of neptunium possible. Aleksandruk *et al.* (1990, 1991a) developed a method that consisted of the leaching of neptunium from solid samples such as soil, the isolation of the neptunium by solvent extraction and extraction chromatography, and counting the luminescence intensity at 651 or 663 nm from a CaF_2(Np) crystal at 77 K using a nitrogen pulsed laser (337 nm) as the excitation source. Neptunium was concentrated on the surface layer of a CaF_2 pellet, which resulted as a remarkable improvement of the sensitivity (Aleksandruk *et al.*, 1990). The detection limit of the absolute amount of neptunium was approximately 10^{-12} to 5×10^{-13} g. The proposed method was applied to the determination of Np in soil samples taken from the 30 km zone of the Chernobyl area.

Several attempts have been made to improve the reliability or the sensitivity of the luminescence method. Stepanov *et al.* (1997) proposed a method using uranium as an internal standard to enhance the reliability of determination of neptunium with CaF_2 phosphor. The procedure was applied to the neptunium analysis of nuclear materials. Ivanova *et al.* (1994) utilized a novel method for the preconcentration of neptunium with high concentrating efficiency by the use of a solid-supported liquid membrane containing trioctylmethylammonium nitrate, which was directly subjected to the preparation of the CaF_2 or $PbMoO_4$ phosphor. The detection limit was 1×10^{-13} g ml^{-1} in pure water and 5×10^{-13} g g^{-1} in soil sample. An alternative membrane technique, which is chemically compatible with the preparation of $PbMoO_4$ phosphor, was utilized by Novikov *et al.* (1997) for the preconcentration of neptunium and plutonium. The elaborate procedure for the determination of neptunium and plutonium consists of the HDEHP solvent extraction of Np(IV) and Pu(IV) from the soil leach and accumulation of these ions on the solid-supported aqueous membrane with $K_{10}P_2W_{17}O_{61}$.

Time-resolved laser-induced fluorescence spectroscopy (TRLFS) was applied for the analysis of Np in plutonium samples (Aleksandruk *et al.*, 1991b) to attain a detection limit of 2×10^{-12} g Np.

6.10.4 X-ray fluorescence spectroscopy (XRF)

The XRF technique, which is essentially a non-destructive method, does not require the removal of uranium, plutonium, and other elements, and can be applied to solid and liquid samples. This technique was utilized to monitor the neptunium content in the products of nuclear spent fuel reprocessing (Akopov *et al.*, 1988). It was found that neptunium of more than 4 mg L^{-1} could be determined by XRF using a high intensity X-ray source and Si:Li detector, when the Np/U and Np/Pu ratios were higher than 1/80 and 1/40, respectively. If the sample contained higher concentration of U or Pu, extraction chromatography was employed to remove these elements from neptunium and the detection limit was lowered to 0.1 mg L^{-1}.

A gamma-ray induced energy-dispersive K-line XRF was applied to the determination of heavy metals such as neptunium, uranium, and plutonium in the Purex process solution using a gamma-ray excitation source of ^{57}Co ($t_{1/2}$ = 27.1 days, 10 mCi), ^{133}Ba ($t_{1/2}$ = 10.7 years, 10 mCi), or ^{192}Ir ($t_{1/2}$ = 74 days, 10 Ci) (Pilz *et al.*, 1989). One of the most distinct advantages of this method is the wide dynamic concentration range from ppm level to 400 g L^{-1}.

6.10.5 Mass spectrometry

(a) Surface ionization mass spectrometry (SIMS)

Isotope dilution mass spectrometry using ^{235}Np or ^{239}Np as a spike is a useful method for the sensitive and precise determination of ^{237}Np. An ion source of surface ionization diffusion (SID)-type, which is prepared by electroplating neptunium and overplating the sample with rhenium or platinum metal film, was applied to the detection of neptunium (Efurd *et al.*, 1986). This technique was applicable to ^{237}Np amounts ranging from 10^{-17} to 10^{-8} g.

(b) ICP-MS

ICP-MS has become one of the most powerful methods for the determination of ultra-trace levels of ^{237}Np in many kinds of samples such as environmental and biological samples, uranium fuels, and Purex process solutions. Distinct advantages of this method are a capability of a simultaneous multi-element analysis providing information on the isotopic composition for a large number of elements with high precision and accuracy, as well as a rapid analysis compared with traditional alpha spectrometry and neutron activation analysis, which require tedious pretreatment and measurement procedures. Interfering elements such as uranium and other heavy elements must be removed from the sample solution using optimum chemical separation methods. The separation of uranium, in particular, is important to avoid the interference from the downmass tailing of ^{238}U.

Kim *et al.* (1989) recommended a separation scheme for the ICP-MS analysis of ^{237}Np in a soil:solvent extraction with isopropyl ether to remove iron, solvent extraction with TOA to recover neptunium, and three-step anion-exchange chromatography. They obtained a detection limit of 0.02 mBq ml^{-1} (ca. 8×10^{-13} g ml^{-1}) of ^{237}Np. Yamamoto *et al.* (1994) conducted ICP-MS analysis of ^{237}Np in paddy field soil samples in Japan using high-resolution ICP-MS equipped with a double-focusing mass spectrometer in order to elucidate the temporal feature of global fallout of ^{237}Np deposition.

Riglet *et al.* (1992) applied ICP-MS to the determination of ^{237}Np in enriched uranium solutions. After extracting neptunium as Np(IV) from 1 M HNO_3 solution into 0.5 M HTTA xylene solution and back-extracting in 10 M HNO_3, the ICP-MS signal of ^{237}Np was recorded. Concentrations of ^{237}Np of more than 5 ng in a 1 g uranium sample could be determined. Fig. 6.13 shows a typical ICP-MS spectrum for ^{237}Np in uranium samples.

Barrero Moreno *et al.* (1997) developed a method for the online separation of neptunium, plutonium, and uranium by ion chromatography using a high-capacity cation-exchange column followed by the direct injection of the effluent to the ICP-MS system to determine neptunium and plutonium in the presence of a high concentration of uranium. The method was applied to various kinds of irradiated UO_2 and MOX fuels.

(c) Other methods based on mass spectrometry

Resonance-ionization mass spectroscopy (RIMS) is expected to be powerful for the ultra-trace analysis of long-lived radioactive elements such as neptunium because of its extremely high sensitivity and selectivity. Riegel *et al.* (1993)
